1 Machine Learning flow rules

This notebook represents supplementary material to the publication “Data-Oriented Constitutive Modeling of Plasticity in Metals” by Alexander Hartmaier in Materials (2020). It demonstrates the training and application of ML flow rules in FEA in form of simple examples with data synthetically produced from standard flow rules, like isotropic J2 (von Mises) or Hill-type anisotropic plasticity and also with Tresca yield functions. FEA is performed with the pyLabFEA package, which - together with further tutorials and examples - is freely available on GitHub (<https://github.com/AHartmaier/pyLabFEA.git>). This notebook uses the matplotlib (<https://matplotlib.org/>) library for the visualization of results, and NumPy (<http://www.numpy.org>) for mathematical operations with arrays. Machine learning algorithms have been adopted from the scikit-learn platform (<https://scikit-learn.org/stable/>).

1.1 Introduction

Machine Learning (ML) algorithms provide a great flexibility to describe arbitrary mathematical functions. At the same time they offer the possibility to handle large data sets and multi-dimensional features as input. Hence, using ML algorithms as constitutive rules for plastic material behavior offers the possibility to explicitly take into account microstructural information of the material in the constitutive modeling. Furthermore, data resulting from experiment and micromechanical simulations can be hybridized to generate training data sets. The present example is using Support Vector Classification (SVC) as yield function. The SVC algorithm is trained by using deviatoric stresses as input data and the information whether a given stress state leads to purely elastic or rather to elastic-plastic deformation of the material as result data. In this way, a ML yield function is obtained, which can determine whether a given stress state lies inside or outside of the elastic regime of the material. Furthermore, the yield locus, i.e., the hyperplane in stress space on which plastic deformation occurs, can be reconstructed from the SVC, and the gradient on this yield locus can be conveniently calculated. Therefore, the standard formulations of continuum plasticity, as the return mapping algorithm, can be applied in Finite Element Analysis (FEA) in the usual way. Thus, it is demonstrated that the new ML yield function can replace conventional FEA yield functions.

1.2 Theoretical background

The yield function of a material is defined as

$$f = \sigma_{eq} - \sigma_y, \quad (1)$$

where plastic deformation sets in at $f = 0$, i.e. when the equivalent stress σ_{eq} equals the yield strength σ_y of the material. The equivalent stress used here is based on the principal stresses σ_i with $(i = 1, 2, 3)$, as

$$\sigma_{eq}^2 = \sqrt{\frac{1}{2} \left[H_1 (\sigma_1 - \sigma_2)^2 + H_2 (\sigma_2 - \sigma_3)^2 + H_3 (\sigma_3 - \sigma_1)^2 \right]}. \quad (2)$$

In this yield function, the anisotropy of the material's flow behavior is described in a Hill-like approach for orthotropic materials. If the axes of the principal stresses do not match the symmetry axes of the material, the material axes and with it the parameters H_1, H_2 and H_3 must be rotated into the coordinate system of the eigenvectors of the stress tensor.

The gradient of the yield function with respect to the principal stresses is needed for calculating the plastic strain increments in the return mapping algorithm of continuum plasticity, and can be evaluated analytically as

$$\frac{\partial f}{\partial \sigma_1} = \frac{\partial \sigma_{eq}}{\partial \sigma_1} = \frac{(H_1 + H_3) \sigma_1 - H_1 \sigma_2 - H_3 \sigma_3}{\sigma_{eq}} \quad (3)$$

$$\frac{\partial f}{\partial \sigma_2} = \frac{\partial \sigma_{eq}}{\partial \sigma_2} = \frac{(H_2 + H_1) \sigma_2 - H_1 \sigma_1 - H_2 \sigma_3}{\sigma_{eq}} \quad (4)$$

$$\frac{\partial f}{\partial \sigma_3} = \frac{\partial \sigma_{eq}}{\partial \sigma_3} = \frac{(H_3 + H_2) \sigma_3 - H_3 \sigma_1 - H_2 \sigma_2}{\sigma_{eq}} \quad (5)$$

Note that in the case of isotropic plasticity, i.e. $H_1 = H_2 = H_3 = 1$, the gradient takes the simple form

$$\frac{\partial f}{\partial \sigma_i} = 3 \frac{\sigma_i - p}{\sigma_{eq}} \quad (i = 1, 2, 3), \quad (6)$$

where $p = 1/3 \text{Tr}(\sigma)$.

1.3 Deviatoric stress space

Since plastic deformation in most metals does not depend on hydrostatic stress components, it is useful to transform the principal stresses from the representation as Cartesian (3D) vector $\sigma = (\sigma_1, \sigma_2, \sigma_3)$ in the principal stress space into a vector $s = (\sigma_{eq}, \theta, p)$ in the cylindrical coordinate system, with the equivalent stress σ_{eq} representing the norm of the deviator of σ and the polar angle θ lying in the deviatoric stress plane normal to the hydrostatic axis p . This coordinate transformation improves the efficiency of the training, because only 2D data for the equivalent stress and the polar angle θ need to be used as training features, whereas the hydrostatic component is disregarded. The coordinate transformation is performed by introducing a complex-valued deviatoric stress

$$\sigma'_c = \sigma \cdot \mathbf{a} + i \sigma \cdot \mathbf{b} = \sqrt{2/3} \sigma_{eq} e^{i\theta}, \quad (7)$$

where i is the imaginary unit, such that the polar angle is obtained as

$$\theta = \arg \sigma'_c = -i \ln \frac{\boldsymbol{\sigma} \cdot \mathbf{a} + i \boldsymbol{\sigma} \cdot \mathbf{b}}{\sqrt{2/3} \sigma_{eq}}, \quad (8)$$

where $\mathbf{a} = (2, -1, -1)/\sqrt{6}$ (real axis) and $\mathbf{b} = (0, 1, -1)/\sqrt{2}$ (imaginary axis) are the unit vectors that span the deviatoric stress plane normal to the hydrostatic axis $\mathbf{c} = (1, 1, 1)/\sqrt{3}$.

An advantage of this coordinate transformation is that the gradient of the yield function w.r.t. the cylindrical coordinates has only one non-constant component. The complete gradient w.r.t. the cylindrical coordinates reads

$$\begin{aligned} \frac{\partial f}{\partial \sigma_{eq}} &= 1 \\ \frac{\partial f}{\partial \theta} &= \frac{\partial \sigma_y}{\partial \theta} \\ \frac{\partial f}{\partial p} &= 0. \end{aligned}$$

To transform the gradient of the flow rule from this cylindrical coordinate system back to the principle stress space, in which form it is used later on to calculate the direction of the plastic strain increments in the return mapping algorithm of the plasticity model, we introduce the Jacobian matrix for this coordinate transformation as

$$J = \frac{\partial s}{\partial \sigma} = \begin{pmatrix} \frac{\partial \sigma_{eq}}{\partial \sigma_1} & \frac{\partial \theta}{\partial \sigma_1} & \frac{\partial p}{\partial \sigma_1} \\ \frac{\partial \sigma_{eq}}{\partial \sigma_2} & \frac{\partial \theta}{\partial \sigma_2} & \frac{\partial p}{\partial \sigma_2} \\ \frac{\partial \sigma_{eq}}{\partial \sigma_3} & \frac{\partial \theta}{\partial \sigma_3} & \frac{\partial p}{\partial \sigma_3} \end{pmatrix} \quad (9)$$

with $\partial \sigma_{eq}/\partial \sigma_i$ as given above, $\partial p/\partial \sigma_i = 1/3$, and

$$\frac{\partial \theta}{\partial \sigma_j} = -i \left(\frac{\mathbf{a} + i \mathbf{b}}{\boldsymbol{\sigma} \cdot \mathbf{a} + i \boldsymbol{\sigma} \cdot \mathbf{b}} - \frac{3 \sigma'}{\sigma_{eq}^2} \right) \quad (j = 1, 2, 3). \quad (10)$$

Finally, the gradient in the 3D principle stress space is obtained as

$$\frac{\partial f}{\partial \sigma_j} = \sum_{k=1}^3 J_{jk} \frac{\partial f}{\partial s_k} \quad (j = 1, 2, 3). \quad (11)$$

1.4 Material definition

In the following, the Python class **Material** is invoked to be used as a material card in FEA, demonstrating the application of standard flow rules and machine learning (ML) flow rules. This class **Material** contains the attributes and methods to defining the elastic and plastic material behavior and to evaluate the materials constitutive behavior. Furthermore, all necessary subroutines for plotting the results are defined. Two identical materials are defined, **mat_h** will be used to apply the standard Hill-like flow rules in FEA and to generate synthetical data that is used to train a ML flow rule in **mat_ml**. Consequently, **mat_h** and **mat_ml** should reveal identical properties, which is verified in simple FEA demonstrations for 2D plane stress cases. As reference, a further material with the same yield strength, but isotropic J2 plasticity is defined as **mat_iso**. Here, we consider ideal plasticity, i.e. no work hardening, and no dependence on the hydrostatic stress.

```

Yield loci of anisotropic reference material and isotropic material

1.4.1 Create reference stress strain curves

The mechanical behavior of the reference material is characterized by FEA, invoking the pyLabFEM module. Four load cases are simulated: (i) uniaxial stress in x-direction, (ii) uniaxial stress in y-direction, (iii) equibiaxial tensile strain under plane stress, and (iv) pure x-y-shear strain.

```

Hill yield stress under uniax-x loading: 150.0 MPa

Hill yield stress under uniax-y loading: 150.0 MPa

Hill yield stress under equibiax loading: 150.0 MPa

Hill yield stress under shear loading: 150.0 MPa

1.5 Setup ML constitutive models

Here, the reference material `mat_h` with Hill-type anisotropy is used to produce training and test data for the machine learning algorithm. The yield function is represented as a step function such that Support Vector Classification (SVC) is used. In the FEA all stresses are considered in form of principal stress vectors, such that a coordinate transformation into the cylindrical coordinate system with equivalent stress and polar angle θ takes place within the training and evaluation procedure. Furthermore, to make the training process efficient, stress data for training and testing are already produced as purely deviatoric stress components, following the cylindrical stress vector definition given above.

As one cannot assume the Hill-coefficients as known for the ML material, the standard J2 equivalent stresses for isotropic materials must be used in the analysis. In consequence, the yield stress must depend on the angle θ in order to describe the anisotropy on the flow behavior. Thus, the yield function takes the form

$$f = \sigma_{eq} - \sigma_y(\theta), \quad (12)$$

in which the dependencies on isotropic J2 equivalent stress σ_{eq} and angle θ are separated.

1.5.1 Train ML yield function

In the following code segment, training and test data are generated and applied for training of the SVC, and the quality test of the result. For the data and the trained ML yield function are plotted in the cylindrical stress space.

```

[3]: 'Create training data in deviatoric stress space for components seq and theta'

1.5.2 Apply trained ML flow rule in FEA

After the successful training of the ML yield function, it can be applied directly in FEA. Its gradients can be calculated directly from the coefficients and the support vectors resulting from the training process. The following code segment demonstrates the application of the ML yield function in the pyLabFEA module. First, a model with two sections is generated, where section 1 is assigned to the reference material `mat_h` and section 2 is assigned to `mat_ml` with the ML yield function.

```
[4]: fem=FE.Model(dim=2,planestress=True)
fem.geom([2, 2], LY=2.) # define sections in absolute lengths
print('=====')
print('=== FEA with reference and ML material ===')
print('=====')
fem.assign([mat_h, mat_ml]) # create a model with trained ML-flow rule (mat_h)
                             ↪ and reference material (mat3)
fem.bclleft(0.)
fem.bcbot(0.)

```

Note: Different definitions of SEQ for Hill and J2.

Note that the element stresses in both materials are very similar (top figure). However, the different definitions of the Hill equivalent stress and the J2 equivalent stress produce a numerical difference in the plot of the equivalent stresses (middle figure). The resulting plastic strains in both sections are quite similar (bottom figure).

The second example applies the same four load cases under which the reference material has been characterized and compares the results.

[5]: <matplotlib.collections.PathCollection at 0x1a24d32a50>

1.6 Train ML yield function with results of 4 load cases

In the following, the training data is created only from the four load cases of the reference material. For all load cases $\sigma_3 = 0$, yet due to the data-oriented formulation of the yield function on the deviatoric plane, a full yield function can be achieved. A new material `mat3` is created on which the ML training is performed.

```

1.8 Tresca yield function

In the next example a ML flow rule will be trained to a reference material with Tresca yield function

$$f = \sigma_{eq}^{\text{Tresca}} - \sigma_y, \quad (13)$$

with the Tresca equivalent stress

$$\sigma_{eq}^{\text{Tresca}} = \frac{\sigma_I - \sigma_{III}}{2}. \quad (14)$$

based on the principal stresses in the sequence $\sigma_I \geq \sigma_{II} \geq \sigma_{III}$. In the following cell, the material definitions are performed.

```
[9]: 'define two elastic-plastic materials with identical yield strength and elastic_
      ↪properties'
E=200.e3
nu=0.3
sy = 150.
'Tresca-material as training model'
