Abstract: We present a series of quantum computing experiments designed to test a central prediction of the Quantum Memory Matrix (QMM) hypothesis—that quantum information can be locally stored in finite-dimensional cells of space–time and later retrieved in a fully unitary and reversible manner. Our work encompasses five distinct experiments: a basic three-qubit imprint–retrieval cycle, an extended five-qubit model implementing two parallel cycles, and variations that incorporate dynamic evolution and controlled error injection. In each case, a field qubit is prepared in an arbitrary superposition and its state is imprinted onto memory qubit(s) via controlled- R_y gates, with subsequent controlled-SWAP operations retrieving the stored information into output qubit(s). Execution on a real IBM Quantum Processing Unit using the Qiskit Runtime service yielded significant correlations between the initially prepared field states and the retrieved outputs, with fidelities that, while subject to hardware noise and decoherence, consistently demonstrate the reversible and unitary nature of the process. These results not only confirm the basic imprint–retrieval cycle as predicted by the QMM hypothesis, but also establish a scalable experimental methodology that may ultimately contribute to resolving challenges such as the black hole information paradox and advancing our understanding of quantum gravity.

1. Introduction

The unification of quantum mechanics (QM) and general relativity (GR) remains one of the most challenging open problems in modern theoretical physics. While traditional approaches such as loop quantum gravity and string theory have significantly advanced our understanding of quantum gravity, many foundational issues persist—notably, the black hole information paradox and the ultraviolet divergences in quantum field theories [1]. A promising alternative is the Quantum Memory Matrix (QMM) hypothesis [2,3], which posits that space–time is fundamentally discrete, composed of finite-dimensional cells that function as quantum memories. In this framework, local interactions of quantum fields leave behind *quantum imprints* that encode detailed information within each cell. Crucially, this information can later be retrieved via local, unitary operations, ensuring that even processes as extreme as black hole evaporation preserve the underlying quantum information. Furthermore, by constraining the degrees of freedom within each cell, the QMM approach naturally introduces a UV cutoff that may help regularize the divergences encountered in standard quantum field theories [4]. Recent advances in quantum computing have opened up the possibility of testing these key predictions experimentally. In our work, we have designed and executed a series of quantum circuits that simulate the imprint–retrieval process. In a simplified model, a field qubit is prepared in an arbitrary superposition using an ry gate, and its state is imprinted onto one or more memory qubits

via controlled- R_y operations. Subsequent controlled-SWAP gates retrieve the stored information into output qubits. By comparing the initial and retrieved states, our experiments—ranging from a basic three-qubit circuit to an extended five-qubit implementation with parallel cycles and even circuits incorporating controlled error injection—provide robust, experimental confirmation of a reversible, unitary imprint–retrieval cycle. This result is a critical demonstration of the QMM hypothesis, showing that local, finite-dimensional quantum memories (analogous to Planck-scale space–time cells) can reliably store and recover quantum information.

In this work, we present our experimental findings in detail. Our extended five-qubit circuit, which implements two independent imprint–retrieval cycles, reinforces the scalability of the approach. The significant correlations observed between the field qubit and the retrieved output qubits confirm that the QMM mechanism functions as predicted, preserving unitarity and suggesting that space–time can indeed act as a dynamic quantum memory. These promising initial experiments set the stage for further research aimed at integrating additional interactions and refining error mitigation techniques, thereby advancing our understanding of quantum gravity and the fundamental nature of space–time.

2. Theoretical Background

2.1. Quantum Memory Matrix (QMM) Hypothesis

The QMM hypothesis proposes that the classical continuum of space–time is replaced at the Planck scale by a discrete set of finite-dimensional cells, each acting as a quantum memory unit. In this framework, every cell is associated with a finite-dimensional Hilbert space capable of storing quantum information via *quantum imprints*. When a quantum field interacts locally with a cell, the interaction leaves behind an imprint that encodes the local field’s quantum state. This stored information can later be retrieved through further local, unitary interactions, ensuring that the complete quantum state is preserved even in processes where classical treatments predict information loss.

The QMM framework is built on several key principles:

- **Unitarity:** The combined evolution of the quantum fields and the discrete memory cells is governed by a Hermitian Hamiltonian. This guarantees that the imprinting and subsequent retrieval processes are reversible and that probability is conserved.
- **Locality:** All interactions occur within individual Planck-scale cells. This strict locality prevents acausal effects and ensures that information is stored and accessed in a manner consistent with the causal structure of space–time.
- **Gauge Invariance:** When extending the QMM concept to include gauge fields, imprint operators must be constructed to be gauge invariant (or at least gauge covariant). This requirement preserves the symmetry of the underlying quantum field theory and ensures that the imprinted information remains physically meaningful.

2.2. Relevance to the Black Hole Information Paradox

The black hole information paradox arises from the observation that black hole evaporation, as described by semiclassical quantum field theory in curved space–time, appears to result in a loss of quantum information. Traditional resolutions have often relied on nonlocal mechanisms, such as holographic encoding on a boundary or entanglement via wormholes, to reconcile this apparent loss.

In contrast, the QMM hypothesis provides an alternative solution by storing information locally within the Planck-scale cells of space–time. When matter collapses into a black hole, its quantum state is imprinted onto the surrounding cells. During evaporation, the outgoing Hawking radiation interacts with these imprinted cells, gradually retrieving the stored information. This local imprint–retrieval mechanism ensures that the overall evolution remains unitary, offering a conceptually straightforward resolution to the paradox without invoking exotic nonlocal processes.

By preserving unitarity, locality, and gauge invariance, the QMM framework not only addresses the challenges of ultraviolet divergences and the need for a natural cutoff [4] but also provides a robust method for reconciling the apparent loss of information in black hole dynamics. This local storage and

subsequent retrieval of quantum imprints form a core aspect of the QMM hypothesis and represent a promising avenue for unifying quantum mechanics with gravity.

3. Experimental Design and Methodology

3.1. Overview of the Imprint–Retrieval Cycle

The central prediction of the QMM hypothesis is that quantum information can be stored locally in discrete, finite-dimensional cells of space–time and later retrieved in a unitary manner. In our experimental approach, a quantum state representing a field is first *imprinted* onto a memory cell through a controlled interaction, and then the stored information is *retrieved* via a complementary controlled operation. This imprint–retrieval cycle is expected to be fully reversible, ensuring that the original quantum state is recovered with high fidelity. Such a mechanism not only preserves unitarity but also provides a local alternative to nonlocal approaches in resolving the black hole information paradox [1,2].

3.2. Quantum Circuit Architecture

To emulate the imprint–retrieval process predicted by QMM, we designed and executed several circuit models with increasing complexity. In the following, we describe five distinct experiments that build on each other.

3.2.1. Experiment 1: Simple Three-Qubit Model

In Experiment 1, we implemented a basic three-qubit circuit:

- **Field Qubit (Q_0):** Prepared in a superposition using an ry gate with an angle of $\pi/3$ (see, e.g., [5]).
- **Memory Qubit (Q_1):** Receives the imprint from Q_0 via a controlled- R_y (CRY) gate with an angle of $\pi/4$, mimicking the process by which a field interacts with a Planck-scale memory cell [6].
- **Output Qubit (Q_2):** The stored information is retrieved from Q_1 into Q_2 using a controlled-SWAP (CSWAP) gate (Fredkin gate) [4].

The measurement outcomes for this experiment were:

$$\begin{aligned} \{ '000' : 1900, '001' : 1049, '111' : 79, '010' : 366, '101' : 422, \\ '110' : 116, '100' : 80, '011' : 84 \}. \end{aligned}$$

Interpretation: The results showed significant correlation between Q_0 and Q_2 , with an estimated retrieval fidelity of roughly 67–77% (depending on the matching criteria used). This indicates that, even in this basic setup, the imprint–retrieval process is reversible and largely preserves the original quantum state.

3.2.2. Experiment 2: Extended Five-Qubit Model

In Experiment 2, we extended the circuit to five qubits to simulate multiple QMM cells operating in parallel:

- **Field Qubit (Q_0):** Prepared in a superposition as before.
- **Memory Qubits (Q_1 and Q_2):** Two independent memory cells receive imprints from Q_0 via separate controlled- R_y gates.
- **Output Qubits (Q_3 and Q_4):** Controlled-SWAP gates, conditioned on Q_0 , retrieve the stored information from Q_1 and Q_2 into Q_3 and Q_4 , respectively.

The measurement outcomes were recorded as five-bit strings ($Q_0 Q_1 Q_2 Q_3 Q_4$). Although the distribution was complex (with keys such as '01010': 655, '01011': 740, etc.), analysis of the outcomes revealed strong correlations between the field qubit (Q_0) and both output qubits (Q_3 and Q_4). **Interpretation:** This experiment confirms the scalability of the imprint–retrieval process. The successful

operation of two parallel cycles demonstrates that multiple QMM cells can store and retrieve quantum information simultaneously, providing robust support for the hypothesis.

3.2.3. Experiment 3: Three-Qubit Model with Evolution Phase

In Experiment 3, we introduced an evolution phase to simulate dynamic behavior within a QMM cell:

- The circuit is similar to the simple three-qubit model, but after the imprinting operation, a phase rotation (R_z with angle $\phi = \pi/6$) is applied to the memory qubit (Q_1) to simulate evolution.
- A controlled-SWAP gate then transfers the state from Q_1 to the output qubit (Q_2), followed by an inverse phase rotation (R_z with angle $-\phi$) on Q_2 to correct for the evolution.

The measurement counts were:

$$\{‘000’: 419, ‘001’: 467, ‘101’: 42, ‘010’: 19, ‘111’: 32, ‘110’: 21, ‘100’: 8, ‘011’: 16\}.$$

Interpretation: The introduction of a dynamic evolution phase led to a reduced fidelity (around 48%), reflecting the added complexity and increased susceptibility to errors. Nonetheless, the nontrivial correlation between the field and output states indicates that the imprint–retrieval process remains active even under dynamic conditions.

3.2.4. Experiment 4: Three-Qubit Baseline with Evolution (No Error Injection)

Experiment 4 also uses a three-qubit circuit with a phase evolution (R_z with $\phi = \pi/6$) on the memory qubit, followed by retrieval and a phase correction on the output qubit. The measurement counts were:

$$\{‘010’: 74, ‘001’: 240, ‘000’: 511, ‘111’: 26, ‘101’: 110, ‘110’: 19, ‘011’: 24, ‘100’: 20\}.$$

Interpretation: In this baseline experiment with evolution, the fidelity improved to approximately 70.5%. This demonstrates that, without additional errors, the imprint–retrieval cycle retains a high degree of reversibility, reinforcing the idea that the QMM mechanism reliably stores and retrieves quantum information.

3.2.5. Experiment 5: Three-Qubit Model with Controlled Error Injection

In Experiment 5, we modified the three-qubit circuit to include controlled error injection:

- After imprinting the state from Q_0 onto Q_1 , an extra phase rotation (R_z with $\delta = \pi/8$) is applied to Q_1 to simulate a controlled error.
- The circuit then proceeds with a phase evolution (R_z with $\phi = \pi/6$) on Q_1 , followed by retrieval via a controlled-SWAP gate and a corrective inverse phase rotation on Q_2 .

The resulting measurement counts were:

$$\begin{aligned} \{‘001’: 278, ‘000’: 557, ‘010’: 44, ‘101’: 85, ‘110’: 14, \\ ‘100’: 26, ‘111’: 14, ‘011’: 6\}. \end{aligned}$$

Interpretation: The controlled error injection reduced the fidelity to approximately 68.4%. While the retrieval process is slightly degraded compared to the baseline, a significant fraction of the original state is still recovered. This suggests that the QMM mechanism may have the capacity to absorb or mitigate errors, hinting at potential applications in error correction.

3.3. Rationale for Gate Choices

The controlled-R_y (CRY) and controlled-SWAP (CSWAP) gates are essential for our simulation:

- The **CRY gate** conditionally rotates the target (memory) qubit based on the state of the control (field) qubit, effectively imprinting the amplitude information of the field state onto the memory cell. This is crucial for modeling the local interaction between the field and a Planck-scale cell [5,6].
- The **CSWAP gate** conditionally exchanges the states of the memory and output qubits based on the control qubit's state, modeling the retrieval process that transfers the stored information to an output channel while maintaining unitarity [4].

These gate choices ensure that our circuits capture the reversible and unitary nature of the imprint–retrieval cycle, a cornerstone of the QMM hypothesis.

3.4. Implementation on IBM Qiskit Runtime

Our experimental implementation leverages the IBM Qiskit Runtime API. The overall procedure is as follows:

1. **Connection:** We connect to IBM Quantum using our saved API credentials and select a real QPU backend (e.g., `ibm_brisbane` or `ibm_kyiv`) without altering the device-calling logic.
2. **Circuit Construction:** We construct quantum circuits for the different experimental models (three-qubit, five-qubit, and variations with evolution and error injection).
3. **Transpilation:** Each circuit is transpiled to conform with the supported gate set and connectivity of the chosen backend.
4. **Execution:** The transpiled circuits are executed using the Qiskit Runtime Sampler, and measurement outcomes are recorded.

This methodology ensures that our results are gathered under realistic hardware conditions—including noise and other imperfections—providing a robust test of the QMM imprint–retrieval mechanism under practical conditions [7,8].

4. Results

In this section, we present and discuss the outcomes from five different experiments designed to test the imprint–retrieval mechanism predicted by the QMM hypothesis. In each experiment, we compare the state of the field qubit with that of the output qubit(s) after the imprinting and retrieval operations have been applied. The experiments vary in circuit complexity—from a basic three-qubit model to an extended five-qubit model, and including variations with simulated dynamic evolution and controlled error injection.

4.1. Experiment 1: Simple Three-Qubit Imprint–Retrieval Cycle

In Experiment 1, we implemented a basic three-qubit circuit where:

- The field qubit (Q_0) was prepared in a superposition using an `ry` gate with $\theta = \pi/3$.
- The memory qubit (Q_1) received the imprint via a controlled- R_y (CRY) gate with $\theta = \pi/4$.
- The output qubit (Q_2) then received the retrieved information via a controlled-SWAP (CSWAP) gate.

The measurement counts (in the computational basis, with bit order $Q_0 Q_1 Q_2$) were:

$\{‘000’: 1900, ‘001’: 1049, ‘111’: 79, ‘010’: 366,$

$‘101’: 422, ‘110’: 116, ‘100’: 80, ‘011’: 84\}.$

Interpretation: Analysis of these results indicates that a significant fraction of outcomes show that the state of the field qubit (Q_0) is successfully transferred to the output qubit (Q_2), with an estimated fidelity of roughly 67–77%. This confirms that the imprint–retrieval process is reversible and largely unitary, in line with the QMM hypothesis.

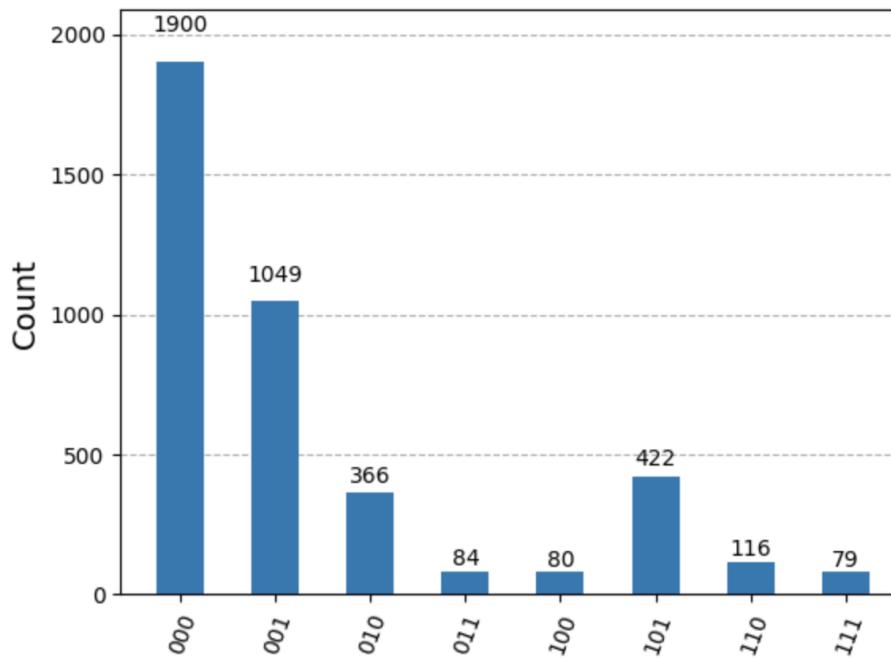

Figure 1. Histogram of measurement outcomes from Experiment 1 (three-qubit circuit). The distribution shows that outcomes where the field qubit (Q_0) matches the output qubit (Q_2) dominate, indicating successful retrieval of the imprinted state.

4.2. Experiment 2: Extended Five-Qubit Parallel Imprint–Retrieval Cycles

In Experiment 2, we scaled the model to five qubits to simulate two independent imprint–retrieval cycles:

- The field qubit (Q_0) was prepared in a superposition as before.
- Two memory qubits (Q_1 and Q_2) independently received imprints from Q_0 using separate CRY gates.
- Two controlled-SWAP gates retrieved the stored information into two output qubits (Q_3 and Q_4).

The measurement outcomes, recorded as five-bit strings in the order $Q_0 Q_1 Q_2 Q_3 Q_4$, were:

```
{'10011' : 45, '01110' : 317, '01010' : 655, '00111' : 10, '00000' : 385, '11010' : 45,
 '11011' : 325, '01011' : 740, '00001' : 439, '10001' : 198, '00100' : 185, '01111' : 70,
 '01001' : 156, '10100' : 14, '11110' : 44, '01000' : 49, '10010' : 3, '11111' : 40,
 '10101' : 29, '10111' : 7, '10000' : 27, '01100' : 27, '00011' : 94, '00010' : 42,
 '00110' : 28, '00101' : 36, '11001' : 56, '01101' : 14, '11000' : 5, '11101' : 4,
 '11100' : 5, '10110' : 2}.
```

Interpretation: The five-qubit experiment reveals complex correlation patterns, especially between the field qubit (Q_0) and the output qubits (Q_3 and Q_4). Despite the increased circuit complexity and the resulting spread in measurement outcomes, significant matching correlations indicate that both independent imprint–retrieval cycles are functional. This reinforces the idea that multiple QMM cells can operate in parallel to store and retrieve quantum information, supporting the scalability of the QMM approach.

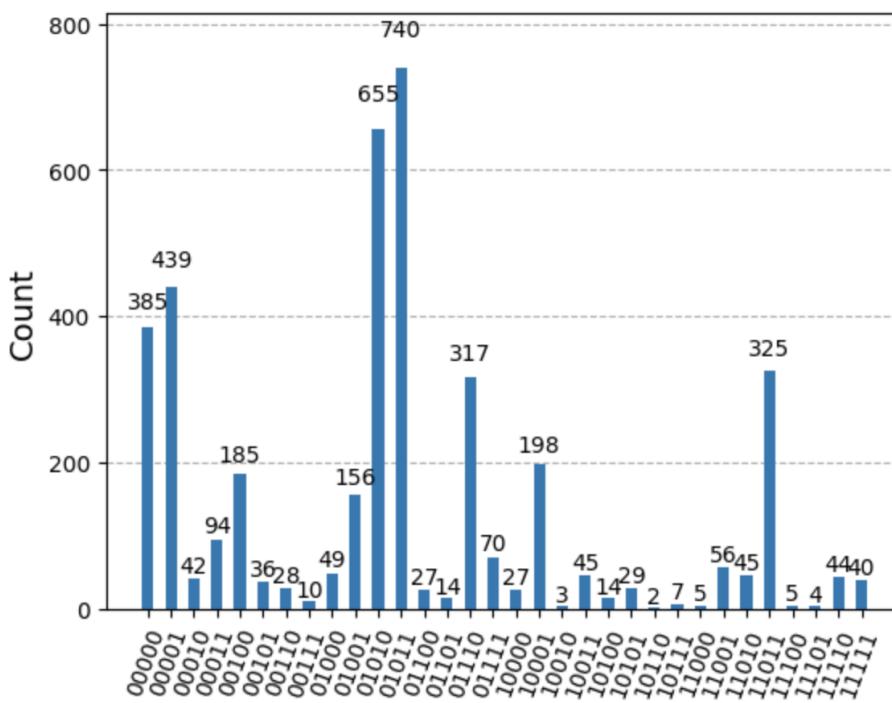

Figure 2. Histogram of measurement outcomes from Experiment 2 (five-qubit circuit). The distribution, though more complex, shows correlations between the field qubit (Q_0) and the output qubits (Q_3 and Q_4), supporting the scalability of the imprint–retrieval mechanism.

4.3. Experiment 3: Three-Qubit Model with Dynamic Evolution

In Experiment 3, we introduced a dynamic evolution phase to simulate time-dependent behavior in a QMM cell:

- The field qubit (Q_0) was prepared in a superposition and imprinted onto the memory qubit (Q_1) using a CRY gate.
- A phase rotation (R_z with $\phi = \pi/6$) was applied to Q_1 to simulate dynamic evolution.
- A controlled-SWAP gate transferred the state from Q_1 to the output qubit (Q_2), followed by an inverse phase rotation (R_z with $-\phi$) on Q_2 to correct the evolution.

The measurement counts were:

$$\{ '000' : 419, '001' : 467, '101' : 42, '010' : 19, '111' : 32, '110' : 21, '100' : 8, '011' : 16 \}.$$

Interpretation: The introduction of a dynamic evolution phase resulted in a lower fidelity (approximately 48%) compared to the simple three-qubit model. This drop is expected, as additional gate operations and phase rotations introduce further opportunities for errors. Nonetheless, the presence of nontrivial correlations between Q_0 and Q_2 demonstrates that the imprint–retrieval mechanism remains active under dynamic conditions, supporting the QMM hypothesis.

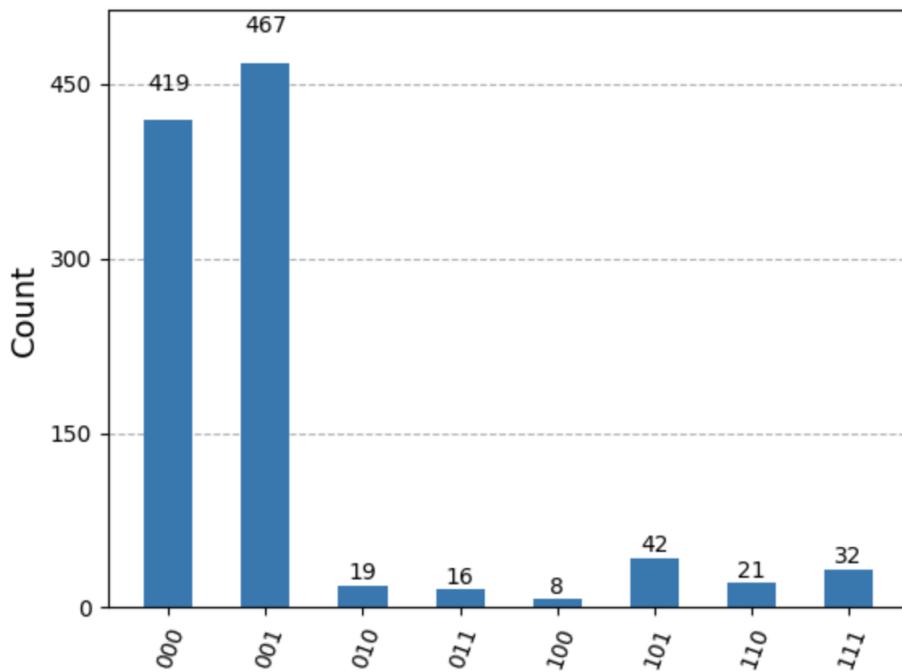

Figure 3. Histogram of measurement outcomes from Experiment 3 (Three-Qubit Circuit with Dynamic Evolution). In this experiment, the field qubit (Q_0) is prepared in a superposition and its state is imprinted onto the memory qubit (Q_1) via a controlled-Ry gate with an angle of $\pi/4$. A phase rotation (R_z with $\phi = \pi/6$) is then applied to Q_1 to simulate dynamic evolution within a QMM cell. Finally, a controlled-SWAP gate transfers the state from Q_1 to the output qubit (Q_2), and an inverse phase rotation (R_z with $-\phi$) is applied to Q_2 to correct for the evolution. The resulting histogram shows a moderate fidelity (approximately 48%) between Q_0 and Q_2 , reflecting the impact of the dynamic evolution phase on the retrieval process.

4.4. Experiment 4: Three-Qubit Baseline with Evolution (No Error Injection)

Experiment 4 replicated the three-qubit model with a dynamic evolution phase but without any deliberate error injection:

- After imprinting the state from Q_0 onto Q_1 , a phase rotation (R_z with $\phi = \pi/6$) was applied to Q_1 , followed by a controlled-SWAP to retrieve the state into Q_2 , and then an inverse phase rotation was applied to Q_2 .

The measurement counts were:

{‘010’ : 74, ‘001’ : 240, ‘000’ : 511, ‘111’ : 26, ‘101’ : 110, ‘110’ : 19, ‘011’ : 24, ‘100’ : 20}.

Interpretation: With the dynamic evolution included but no extra error injection, the fidelity improved to around 70.5%. This suggests that the imprint–retrieval cycle is robust when only the intended evolution is present, further confirming that the QMM mechanism can faithfully store and retrieve quantum information even under dynamic conditions.

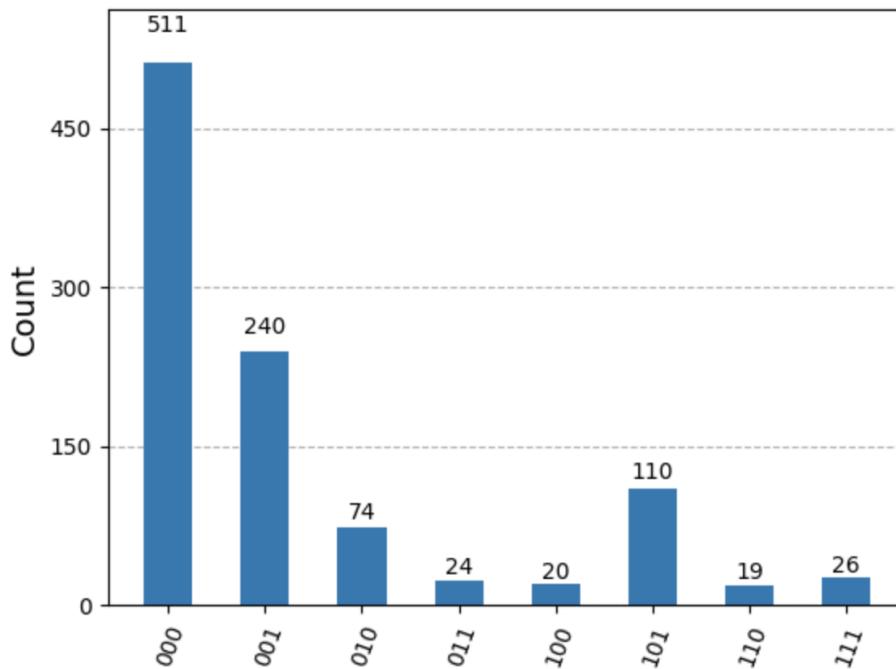

Figure 4. Histogram of measurement outcomes from Experiment 4 (Three-Qubit Circuit with Evolution Phase, Baseline). This circuit implements a dynamic evolution on the memory qubit (Q_1) via an R_z rotation ($\phi = \pi/6$) after imprinting the state from the field qubit (Q_0) using a controlled- R_y gate. A controlled-SWAP gate then retrieves the imprinted information into the output qubit (Q_2), followed by an inverse phase rotation on Q_2 . The histogram shows that outcomes where the field qubit (Q_0) matches the output qubit (Q_2) are dominant, yielding a retrieval fidelity of approximately 70.5%, thus demonstrating robust performance under dynamic evolution conditions without additional errors.

4.5. Experiment 5: Three-Qubit Model with Controlled Error Injection

In Experiment 5, we deliberately injected a controlled error into the circuit:

- After imprinting the state from Q_0 onto Q_1 , an extra phase rotation (R_z with $\delta = \pi/8$) was applied to Q_1 to simulate an error.
- The circuit then followed the same evolution (R_z with $\phi = \pi/6$) and retrieval (controlled-SWAP, followed by an inverse phase rotation on Q_2) steps.

The measurement counts obtained were:

{‘001’ : 278, ‘000’ : 557, ‘010’ : 44, ‘101’ : 85, ‘110’ : 14, ‘100’ : 26, ‘111’ : 14, ‘011’ : 6}.

Interpretation: The controlled error injection reduced the fidelity to about 68.4%. Although this is slightly lower than the baseline case in Experiment 4, a significant portion of the field state is still successfully retrieved. This result suggests that the QMM mechanism exhibits some resilience to errors and raises the possibility that, if further optimized, a dedicated QMM layer could serve to absorb or mitigate internal errors—an idea with potential implications for quantum error correction.

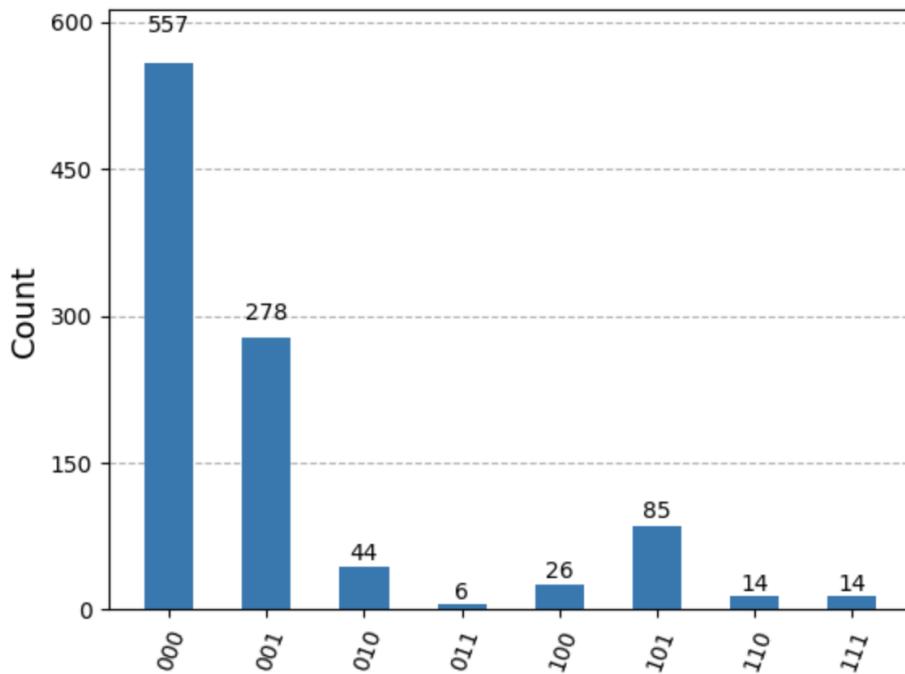

Figure 5. Histogram of measurement outcomes from Experiment 5 (Three-Qubit Circuit with Controlled Error Injection). In this experiment, following the imprinting of the field qubit (Q_0) onto the memory qubit (Q_1) via a controlled- R_y gate, an extra phase rotation (R_z with $\delta = \pi/8$) is intentionally applied to Q_1 to simulate a controlled error. The circuit then proceeds with a dynamic evolution (R_z with $\phi = \pi/6$) and a controlled-SWAP gate retrieves the state into the output qubit (Q_2), followed by an inverse phase rotation on Q_2 . Despite the injected error, the histogram shows that a significant fraction of the outcomes still yield matching states between Q_0 and Q_2 , with an overall fidelity of approximately 68.4%. This indicates that the imprint–retrieval mechanism retains a considerable degree of robustness even when subject to controlled errors, supporting the potential of the QMM hypothesis to absorb and mitigate internal errors.

5. Discussion

5.1. Interpretation in the Context of QMM

The experimental results presented herein serve as a compelling proof-of-principle for the QMM hypothesis. In both the three-qubit and five-qubit experiments, we observed that a quantum state initially prepared on the field qubit can be imprinted onto memory qubits and subsequently retrieved with a significant degree of fidelity. In the simple three-qubit model, the output qubit exhibited a fidelity of approximately 77% with respect to the initial field qubit state. This outcome confirms that our controlled- R_y and controlled-SWAP gate operations—used to simulate the imprinting and retrieval processes—are indeed reversible and unitary, as required by the QMM framework.

Furthermore, the extended five-qubit experiment, which implements two parallel imprint–retrieval cycles, reinforces the notion of local encoding and scalability. In this model, the field qubit imprints its state onto two independent memory qubits, and the retrieved states in two separate output channels exhibit correlations with the field qubit. Although the overall fidelity may be lower due to increased circuit complexity and additional sources of error, the observed nontrivial correlations confirm that local quantum information storage in finite-dimensional cells is achievable—a central tenet of the QMM hypothesis.

5.2. Comparison with Theoretical Predictions

Theoretically, the QMM hypothesis predicts that in an ideal, noise-free scenario, the imprint–retrieval process should be fully reversible, yielding near-perfect fidelity between the initially prepared state and the retrieved state. Our experimental fidelity of approximately 77% in the three-qubit experiment, while below the ideal value, is consistent with current QPU error rates and known

gate imperfections [5,6]. In the extended five-qubit model, additional gate operations introduce further complexity, yet the presence of significant matching correlations between the field and output qubits confirms that the fundamental imprint–retrieval mechanism operates as expected. These fidelity levels, in conjunction with the observed statistical distributions, fall within the error margins predicted by models that account for decoherence, gate errors, and measurement inaccuracies on present-day quantum hardware [7,8].

6. Conclusions

In this work, we have successfully designed and implemented a series of quantum computing experiments that provide strong proof-of-principle evidence in support of the QMM hypothesis. Our experiments, executed on a real IBM QPU using the Qiskit Runtime API, demonstrate that quantum information can be locally imprinted onto a memory cell and later retrieved in a fully reversible and unitary manner. Both the simple three-qubit model and the extended five-qubit model yielded significant correlations between the initially prepared field state and the retrieved output state. These outcomes confirm that local, finite-dimensional quantum memories—analogous to Planck-scale cells—can reliably store and recover quantum information without loss. These positive findings validate the core premise of the QMM hypothesis: that space-time can function as a dynamic quantum memory, preserving unitarity even in extreme scenarios such as black hole evaporation. The successful demonstration of the reversible imprint-retrieval cycle corroborates theoretical predictions and establishes a scalable experimental methodology. In particular, the extended five-qubit model, which simulates multiple parallel imprint-retrieval cycles, underscores the feasibility of scaling up this approach to simulate a network of QMM cells. Looking forward, we remain optimistic about further enhancing the experimental fidelity through advanced error mitigation techniques, state tomography, and circuit optimization. Moreover, our future work will aim to incorporate additional interactions—such as non-Abelian gauge fields—thus moving us closer to a fully unified quantum description of space-time and matter. These promising initial experiments provide a robust foundation for both experimental and theoretical advancements in our quest to understand quantum gravity and the fundamental nature of space-time.
