Simple Summary: The territories of Crimea and the Black Sea coast of the Caucasus are considered high risk areas for the resurgence of malaria transmission. Cases of imported malaria are reported annually in these regions. Mosquito species of the genus *Anopheles* (Diptera, Culicidae) inhabit the Black Sea coast, and they can be effective vectors of malaria. The malaria mosquito habitat in this region has been affected by the development of tourist resorts over the last 20 years. To understand the current species abundance and distribution, we studied malaria mosquito breeding sites, measured ecological parameters of water bodies, determined larval density and species composition of mosquitoes. Seven species of malaria mosquitoes were found in the study areas: *An. atroparous*, *An. claviger*, *An. daciae*, *An. hyrcanus*, *An. maculipennis*, *An. plumbeus* and *An. melanoon*. Although, the dominant species was *An. maculipennis*, *Anopheles plumbeus* has recently spread to urbanized areas. The level of chromosomal polymorphism in *An. daciae* was significantly higher in the Caucasian populations than in the Crimean population. Data on the species composition and distribution of malaria mosquitoes will help to develop appropriate measures to prevent and control of imported malaria and other mosquito-borne diseases..

Abstract: Ecological and genetic studies of malaria mosquitoes of the Black Sea coast have not been recently conducted despite increasing human-caused environmental changes in the area. In this study, we investigated the species composition, geographical distribution, ecological preferences, and chromosomal polymorphism of malaria mosquitoes of the Crimean Peninsula and the Black Sea

coast of the Caucasus. Species were diagnosed using a combination of morphological, cytogenetic, and molecular markers. The ecological conditions of the larval habitats, such as dissolved oxygen content in the water, acidity, salinity, and temperature, were measured. Seven species of malaria mosquitoes were identified in the pool of 2229 individual mosquitoes collected at 56 breeding sites including *An. atroparvus*, *An. claviger*, *An. daciae* (formerly identified as *An. messeae* s. l.), *An. hyrcanus*, *An. maculipennis* s. s., *An. plumbeus* and *An. melanoon*. The previously recorded species of *An. algeriensis*, *An. messeae* s. s., *An. sacharovi*, *An. superpictus* were not found in this study. *Anopheles maculipennis* was dominant in typical anophylogenic water bodies. *Anopheles plumbeus*, which used to breed mainly in tree holes in coastal forests, has spread to urban settlements along the Black Sea coast and breeds in artificial containers. Chromosomal polymorphism was studied and found in *An. atroparvus* and *An. daciae* populations. Differences in the chromosomal composition of *An. daciae* populations in Crimea and on the Black Sea coast of the Caucasus were revealed. The Crimean population had a low level of polymorphism in autosomal inversions. The data obtained in this study can be used to inform a better control of potential malaria vectors in the Black Sea coastal region.

Keywords: *Anopheles*; the Crimean Peninsula; Black Sea coast of Caucasus; distribution; breeding sites; chromosomal polymorphism

1. Introduction

The environmental and ecological conditions of the Crimean Peninsula and the Black Sea coast of the Caucasus have changed dramatically over the last 20 years [1,2]. Human population growth, expansion of economic activities and increased anthropogenic pressure from resort development, have led to the destruction and further degradation of natural ecosystems and landscapes, and massive environmental pollution. In addition, global warming has an increasingly strong impact on ecosystems, thus constantly changing the epidemiologic situation in the world, including those at the Black Sea coast [3,4]. Although the implementation of antimalarial interventions led to the elimination of autochthonous malaria in Europe [5,6], the territories of Crimea and the Black Sea coast of the Caucasus are currently classified as high-risk areas for resurgence of malaria transmission [7]. Cases of imported malaria are reported annually in the Crimea and Krasnodar Krai [8–10]. Therefore, understanding the current state of epidemiologically important groups of insects, such as malaria mosquitoes of the genus *Anopheles* (Diptera, Culicidae), has become urgent.

Most of the data on species composition and geographical distribution of malaria mosquito in the southern European part of Russia were collected between 1920 and 1960 [11] and are largely out of date. Moreover, the taxonomic status of mosquitoes in the *Maculipennis* complex has changed. Originally, the sibling species of this complex were considered as subspecies of the broadly polytypic species *An. maculipennis* s. l. [12]. Hybridization experiments and numerous data on morphology, ecology, and cytogenetics supported the taxonomic status of the following species of the *Maculipennis* group: *An. atroparvus* Van Theil, 1927; *An. maculipennis* Meigen, 1818; *An. messeae* Falleroni, 1926; *An. melanoon* Hackett, 1934; *An. sacharovi* Favre, 1903; *An. subalpinus* Hackett & Lewis, 1937 [13–18]. Later, several sibling species of the *Maculipennis* group were diagnosed using cytogenetic analysis [13,19–23]. Two new species of Palearctic malaria mosquitoes have been distinguished by differences in banding patterns of polytene chromosomes: *An. beklemishevi* Stegny & Kabanova, 1976 [24] and *An. martinius* Shingarev, 1926 [25]. The reproductive isolation of new species has been demonstrated by studying experimental interspecific hybrids [26] obtained by the method of forced mating [27].

Molecular genetic methods provided additional opportunities to discover new malaria mosquito species and became an important approach in determining their taxonomic status [28–30]. The most valuable data for *Anopheles* systematics have been obtained by studying the nucleotide composition of the second internal transcribed spacer (*ITS2*) of the ribosomal gene cluster that separates the 5.8S and 28S genes of ribosomal RNA [31]. Three new species have been identified in

the *Maculipennis* complex based on *ITS2* sequence: *An. persiensis* Linton, Sedaghat & Harbach, 2003 [32,33]; *An. daciae* Linton, Nicolescu & Harbach, 2004 [34]; *An. artemievi* Gordeev, Zvantsov, Goryacheva, Shaikevich & Yezhov, 2005 [35]. *Anopheles subalpinus* has been synonymized with *An. melanoon* because the *ITS2* sequences were identical in both species [36]. In addition, the *ITS2* region of ribosomal DNA served as a tool for reconstructing phylogenetic relationships in malaria mosquitoes [37–42]. Further advances in species recognition and phylogeny reconstruction in the *Maculipennis* group of the malaria mosquitoes have been achieved through whole-genome sequencing [43,44].

According to 2003 and 2008 studies, the list of malaria mosquitoes of the North Caucasus and the Southern Russian Plain included 10 species [45–47]. Nine of which belong to the subgenus *Anopheles*: *An. algeriensis* Theobald, 1903; *An. atroparvus* Van Theil, 1927; *An. claviger* Meigen, 1804; *An. hyrcanus* Pallas, 1771; *An. maculipennis* Meigen, 1818; *An. melanoon (subalpinus)* Hackett, 1934; *An. messeae* Falleroni, 1926; *An. plumbeus* Stephens, 1828; *An. sacharovi* Favre, 1903. One species was a member of the subgenus *Cellia* – *An. superpictus* Grassi, 1899. However, the present geographical distribution of malaria mosquitoes on the Black Sea Coast of the Caucasus and in Crimea is poorly understood.

The aim of this work was to revisit and describe in detail the species composition, geographic distribution, breeding sites and chromosomal polymorphism of the malaria mosquitoes of the Crimean Peninsula and the Black Sea coast of the Caucasus focusing on the sibling species of the *Maculipennis* group. The dynamics of the epidemic situation under the conditions of global warming and urbanization in the study area was discussed.

2. Materials and Methods

2.1. Field Collection and Material Preservation

Malaria mosquito larvae were collected from 2009 to 2024 at 56 locations along the Black Sea coast of the Caucasus and the Crimean Peninsula. A total of 2229 individual mosquitoes were included in this study. The coordinates of the collection sites and the number of mosquitoes collected are shown in Table 1. Fourth instar *Anopheles* larvae were collected from the surface of water by dipping method [48] and then were placed in Clark's solution (glacial acetic acid and 95% ethanol in a 1:3 ratio). Each larva was removed from Clark's solution and was divided into two parts. The head and thorax were placed back into Clark's solution for inversion polymorphism analysis. The abdomen was fixed in 70% ethanol for molecular identification. All samples were placed in a 1.5 ml Eppendorf tube and stored at -20°C . The obtained samples were used for preliminary species identification based on morphological characters [49,50]. Morphologically identical species were identified by cytogenetic and molecular genetic markers.

Ecological characteristics of malaria mosquito breeding sites were determined in local habitats. Water temperature (T), potential of hydrogen (pH), and total salinity (ppt) were measured using a Hanna Combo HI 98129 (Hanna Instruments, Woonsocket, Rhode Island, USA) conductometer. Dissolved oxygen content in water was measured using an ExStik DO600 oximeter (Extech Instruments, Waltham, Massachusetts, USA). The density of larvae of 1-4 stages (number of individuals per m²) was estimated in natural habitats (ponds, lakes, river outfalls).

2.2. Karyotyping

Polytene chromosome preparations were obtained from the salivary glands of fourth instar larvae according to the standard technique [23; 51]. Salivary glands were extracted from larval thorax with dissecting needles in Clark's solution. The glands were stained with lacto-aceto-orcein (2% orcein in 80% lactic acid and 100% acetic acid in a 1:1 ratio). The time for lacto-aceto-orcein staining was increased from 40 to 80-90 minutes. The stained glands were squashed under a coverslip in 50% acetic acid for 15-20 min.. Mosquito karyotypes were analyzed using an Eclipse E200 light microscope (Nikon, BioVitrum, Moscow, Russia). Karyotypes were used to identify sibling species of malaria mosquitoes. Chromosomal inversions were determined by comparing banding patterns with cytogenetic maps of the studied species [52,53]. Differences in inversion frequencies between mosquito populations were assessed using the Chi-square (χ^2) test [54]. A total of 2229 individual mosquitoes were karyotyped, of which 75 *An. atroparvus*, 158 *An. claviger*, 27 *An. hyrcanus*, 908 *An. maculipennis*, 750 *An. daciae*, 309 *An. plumbeus* and 2 *An. melanoon* larvae.

2.3. Genotyping by RLFP-PCR

Karyotyped mosquitoes were used for molecular identification of the sibling species *An. daciae*/*An. messeae*. All samples were analyzed individually. Total DNA was extracted from alcohol-fixed larval fragments (abdomen) using the phenol-chloroform method [55]. DNA concentration was determined spectrophotometrically using Implen NanoPhotometer NP80 (Implen, Munich, Germany). The concentration was adjusted to 30–60 ng/ μ l. Polymerase chain reaction (PCR) was performed in a final volume of 20 μ l using EncycloPlus PCR kit (Eurogen, Moscow, Russia) according to the manufacturer's instructions.

Species *An. daciae* and *An. messeae* were distinguished by the *ITS2* fragment of the rDNA. The *ITS2* fragment was amplified with the forward primer *its2_vdir*: 5'-TGTGAACTGCAGGACACATG-3', and reverse primer *its2_nrev*: 5'-ATGCTTAAATTTAGGGGGTA-3', as described previously [53]. *RsaI* endonuclease (SibEnzyme, Novosibirsk, Russia) was used for PCR-restriction fragment length polymorphism (RFLP) analysis [53]. PCR product *ITS2* in *An. daciae* has 3 restriction sites for *RsaI*, the length of restriction fragments is 10, 47, 71 and 307 bp. PCR product *ITS2* in *An. messeae* has 4 restriction sites, the length of restriction fragments is 10, 47, 71, 72 and 235 bp. The obtained PCR products were stained with ethidium bromide and analyzed by electrophoresis in 1.5% agarose gel and TBE buffer.

2.4. Genotyping by Sequencing

The rDNA-*ITS2* of mosquitoes from two Crimean and two Caucasian populations were sequenced. Each larval abdomen was homogenized separately in liquid nitrogen. Genomic DNA was extracted using a standard protocol from the Qiagen DNeasy Blood and Tissue Kit (Qiagen, Germantown, MD, USA). DNA elution was performed in 100 μ l of water. *ITS2* from *An. maculipennis* s. l. which do not differ significantly in electrophoretic mobility of PCR products (*An. messeae*, *An. daciae*, *An. atroparvus*, and *An. maculipennis*) was amplified with the forward universal primers: *its2_ndir* 5'-ATCACTCGGCTCGTGGATCG-3', or *its2_vdir* 5'-TGTGAACTGCAGGACACATG-3' and the reverse primer *its2_nrev* 5'-ATGCTTAAATTTAGGGGGTA-3', or *its2_rev* 5'-ATGCTTAAATTTAGGGGGTAGTC-3', with modifications [56,57]. The HotStarTaq Plus Master Mix Kit (Qiagen, Germantown, MD, USA) was used for PCR amplification. The PCR mix consisted of a

total volume of 20 μ l of ~40 ng DNA, 0.5 μ M of each forward and reverse primer, and 10 μ l of 2 \times HotStarTaq Plus reaction mix. PCR was performed on thermocycler Applied Biosystems GeneAmp PCR system 2700 (Applied Biosystems, Waltham, Massachusetts, USA) under the following conditions: initial denaturation at 95°C for 5 min, followed by 25–35 cycles of 95°C for 15 s, 58°C for 30 s and 72°C for 30 s and a final elongation step at 72°C for 5 min. The resulting reaction mix was placed in a stand-by mode at 4°C. The amplicons were visualized by gel electrophoresis in a 2% agarose gel. The DNA amplicons were purified using the Wizard™ PCR Clean Up Kit (Promega, Fitchburg, WI, USA). PCR products were sequenced by Sanger using the BigDye Terminator v3.1 Cycle Sequencing Kit (Thermo Fisher Scientific, USA) from suitable forward or reverse primers. The DNA products of the sequencing reactions have been purified by ethanol precipitation and analyzed at the Genomics Core Facility of the Siberian Branch of the Russian Academy of Sciences (<http://sequest.niboch.nsc.ru>). Nucleotide positions in *ITS2* sequences of *An. daciae* and *An. messeae* were compared with the reference sequence AY648982 in *An. messeae* [43]. Only nucleotides AC in positions 412 and 432 were considered as species-specific for *An. daciae*, respectively [43].

Anopheles melanoon / *An. maculipennis* s. s. mosquitoes were identified by the BOLD fragment of the mitochondrial *COI* gene, using the following Folmer primers: 5'-TTTCAACAAACCATAAGGATATTGG-3' and 5'-TATACTTCAGGATGACCAAAAATCA-3', which were adapted using the "Primer3" program [58]. Total DNA was extracted individually from alcohol-fixed larval fragments (abdomen) using the phenol-chloroform method [55]. PCR amplification was performed at an annealing temperature of 59°C. PCR was performed in a final volume of 20 μ l using EncycloPlus PCR kit (Eurogen, Moscow, Russia). Elution of fragments from the gel was performed using Zymoclean™ Gel DNA Recovery Kit (Zymo Research, Los Angeles, California, USA). The obtained fragments were sequenced by Sanger sequencing. The nucleotide sequence of PCR fragments was determined from forward and reverse primers on a 3500 Genetic Analyzer using BigDye® Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, Waltham, Massachusetts, USA).

3. Results

3.1. Species Composition, Geographical Distribution and Ecological Preferences

Our study found 7 species of malaria mosquito in the Crimea and the Black Sea coast of the Caucasus: *An. atroparvus* Van Thiel, 1923; *An. claviger* Meigan, 1904; *An. daciae* Linton, Nicolescu & Harbach, 2004; *An. hyrcanus* Pallas, 1771; *An. maculipennis* Meigan, 1818; *An. melanoon* Hackett 1934; *An. plumbeus* Stephens, 1828 (Table 1). Four of them were sibling species of the *Maculipennis* group: *An. atroparvus*, *An. daciae*, *An. maculipennis* s. s., and *An. melanoon*. The geographical distribution of the species is shown in Figure 1. Six of them were present in both regions, one species *An. melanoon* was found only in the Imereti Valley on the Black Sea coast of the Caucasus (Table 1, location number 51 in the vicinity of Sochi). The previously reported in this area species *An. algeriensis*, *An. messeae* s. s., *An. sacharovi*, *An. superpictus* were not found [47].

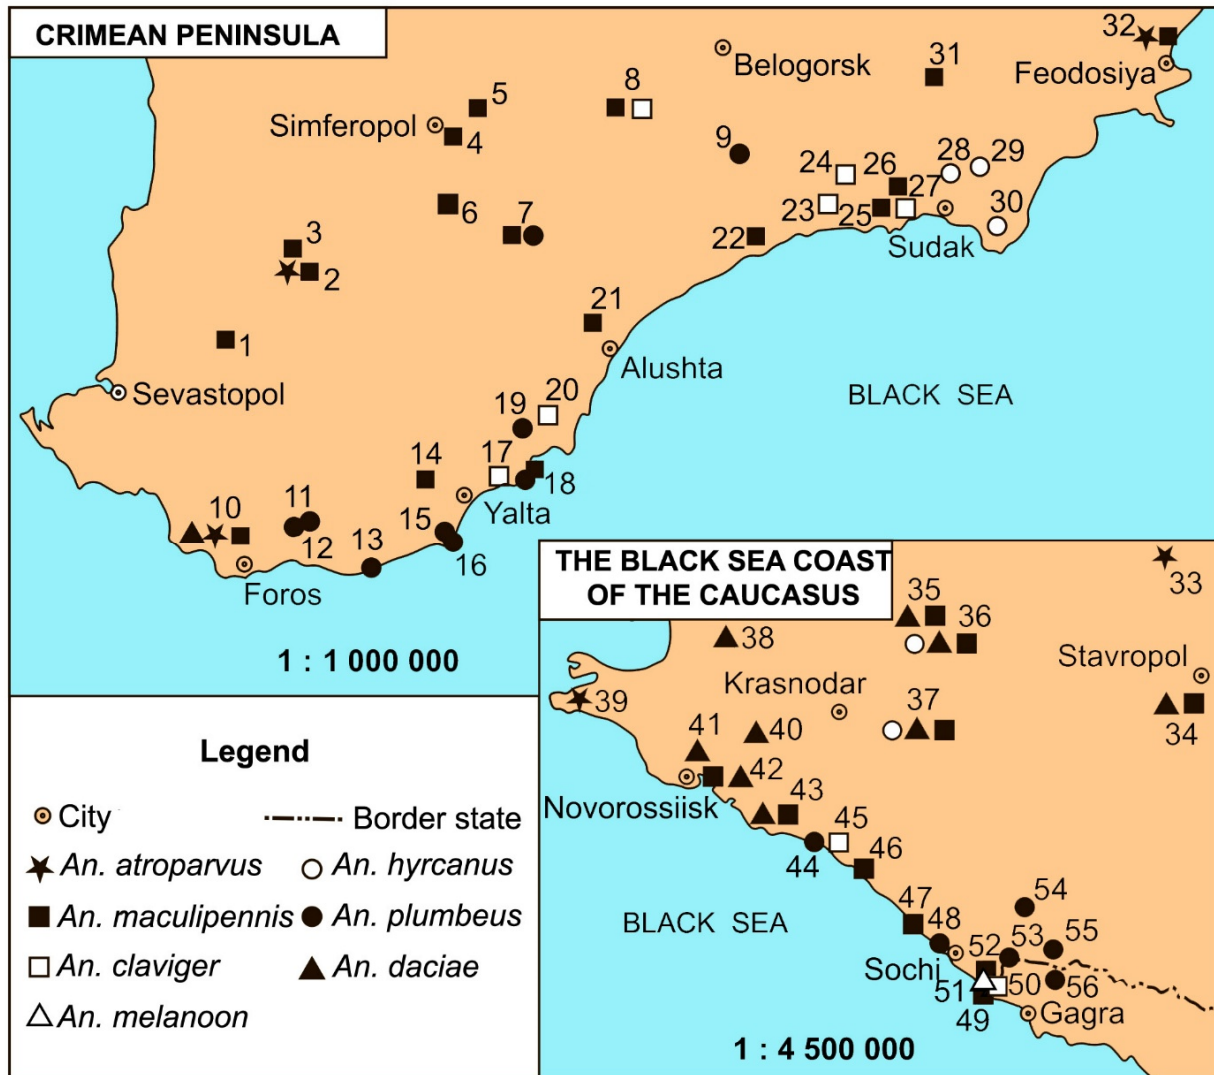

Figure 1. Geographical distribution of malaria mosquitoes on the Crimean Peninsula and the Black Sea coast of the Caucasus. Numbers indicate locations as in Table 1.

Anopheles maculipennis s. s. mosquitoes dominated everywhere along the Black Sea coast and in the mountainous forest zone of the Crimean Peninsula, as well as in the foothills of the northern Caucasus. This species was found in 28 out of 56 locations (50%). *Anopheles maculipennis* s. s. larvae were found in most typical *Anopheles* breeding sites, and mosquitoes of this species alone were found in 14 locations (Table 1). Immature stages developed in ponds, water reservoirs, drainage, and irrigation canals, as well as in temporary pools of water. Mass larval development occurred in habitats with pH 6.48-8.85, but predominantly in the pH range of 7.0-8.4 (Table 2). Total dissolved solids (TDS) of water in larval habitats ranged from 0.15 to 2.56 ppt, rarely exceeding 1.5. Larvae are sensitive to dissolved oxygen in the water. The oxygen content varied in the range of 4.4-10.2 mg/l in most breeding sites. The density of *An. maculipennis* s. s. larvae was low at oxygen levels of 0.5-2.3 mg/l. Larval development occurred over a wide range of daytime temperatures from 16.5 to 33°C, but the highest density of 160 larvae per square meter was observed at a water temperature of 20.7°C and an oxygen level of 4.5 mg/l (Table 2; location 3).

Table 2. Ecological characteristics of breeding places of malaria mosquitoes of the Crimean Peninsula and the Black Sea coast of the Caucasus.

No.	Location / breeding place	Latitude	Longitude	Date of sampling	Density of larvae (1-4 instars/sq. m)	Ecological characteristics of habitats

No., location number; h (m), altitude above sea level in meters; pH, hydrogen index; T (°C), water temperature in Celsius degrees; ppt, total dissolved solids in grams per liter (parts per thousand); O₂ (mg/L), quantity of dissolved oxygen in water.

Anopheles daciae was the most abundant species in the plains located north of the Greater Caucasus Range. *Anopheles daciae* mosquitoes were recorded on the Black Sea coast of the Caucasus near Novorossiysk and Gelendzhik (Figure 1; locations 41-43). A single population of *An. daciae* in Crimea was found near Sevastopol (Figure 1; location 10). The larvae of *An. daciae* developed separately (Table 1; locations 40, 41) or together with *An. maculipennis* s. s. (Table 1; locations 10, 34-37, 42, 43). In some breeding sites shared with *An. maculipennis* s. s., *An. daciae* larvae dominated. At *An. daciae* breeding sites, water pH ranged from 7.0 to 8.4; TDS varied between 0.20 and 1.58 ppt; dissolved oxygen content varied between 0.5 and 8.1 mg/L; and water temperature ranged from 20.5 to 33.3°C (Table 2).

Anopheles atroparvus mosquitoes were found in steppe biotopes in the Crimea and the North Caucasus. Only this species larvae were able to develop in a highly saline water reservoirs with a TDS of 5.99 ppt (Table 2; location 33). *Anopheles atroparvus* larvae were found together with *An. maculipennis* s. s. and *An. daciae* mosquitoes in ponds and lakes with less saline water with TDS range of 0.59-1.46 ppt (Table 2; locations 10, 32). pH value at *An. atroparvus* breeding sites ranged from 7.14 to 9.1; daytime water temperature ranged from 18.0 to 28.0°C; and dissolved oxygen content ranged from 7.7 to 16.5 mg/L.

We found a single breeding site of *An. melanoon* mosquitoes in the Imereti Valley near Sochi (Figure 1; location 51). Two larvae were caught in a temporary water reservoir such as a stream overflow. *Anopheles melanoon* larvae were identified by the BOLD fragment of the mitochondrial *COI* gene. *Anopheles melanoon* larvae developed together with *An. maculipennis* s. s. in permanent water reservoirs with abundant aquatic vegetation in the floodplain of the Psou River. Many natural breeding sites in the Psou River estuary are now lost due to large-scale construction. *Anopheles maculipennis* s. s. and *An. plumbeus* mosquitoes numerically outnumber *An. melanoon* in the Imereti Valley and neighboring in Abkhazia (locations 47-49, 52-56).

Anopheles hyrcanus breeding sites were found in lakes along the eastern zone of the southern Crimean coast. Larvae developed in dense sedge and reed thickets, perennial grasses of the Cyperaceae and Poaceae families, where other malaria mosquito species were absent (Figure 1; locations 28-30). *An. hyrcanus* mosquitoes were found together with *An. maculipennis* s. s. and *An. daciae* larvae in two biotopes in the south of the Azov-Kuban Plain (Figure 1; locations 36-37). Water pH ranged from 7.00 to 8.24 *An. hyrcanus* breeding places; daytime temperature varies between 22.4 and 33.3°C; TDS changed from 0.81 to 3.02 ppt; the dissolved oxygen content in the water reached 10.0 mg/L (Table 2).

Because *Anopheles claviger* is a highly specialized malaria mosquito species, its larvae were found in springs, ditches with running water or in water reservoirs fed by groundwater. Water temperatures ranged from 16.5-23.7°C at most of the breeding sites (Table 2). Higher water temperatures of up to 27.5°C were only recorded in one biotope, with flowing water and a low density of *An. claviger* larvae (Table 2; location 50). Water pH varied within a narrow range of 7.14-7.72, but was 9.26 in one biotope (Table 2; location 50). TDS in all locations varied between 0.24 and 2.08 ppt. The amount of dissolved oxygen in water was 2.5 and 7.6 mg/L (Table 2; locations 45 and 50).

Anopheles plumbeus mosquitoes were found in the mountainous forested part of the southern Crimean coast. Larvae developed in shallow forest lakes, overflow of small rivers, in temporary micro-habitats such as tree holes, condensation puddles between piles of stones (Table 1; locations 7, 9, 11-13, 15, 16, 18, 19). Breeding sites of this species were found in tree holes on the Black Sea coast of the Caucasus (locations 48, 53) and in mountains at altitudes up to 1700 m (Table 1; locations 54, 55). Breeding sites of *An. plumbeus* mosquitoes were found in old car tires in Caucasian resorts (Table 1; locations 44, 53, 56). Water composition in larval habitats was highly variable (Table 2). Water acidity correlated with organic matter content, and pH varied from 5.20 to 8.32 (in open biotopes mainly in the range from 7.14 to 7.62). TDS varied between 0.03 and 2.78 ppt. Daytime water temperatures at breeding sites ranged from 14.9 to 32.3°C. Dissolved oxygen content was measured in a number of micro-watersheds and ranged from 2.5 to 7.5 mg/L. Larval densities did not exceed 9 per square meter at most breeding sites, but in habitats with high saprobic conditions larval densities

reached 32-90 mosquitoes of all instars per square meter. *Anopheles plumbeus* larvae developed together with *An. maculipennis* s. s. in the two largest of the listed breeding sites - in a forest lake and in an ornamental pond of the Nikitsky Botanical Gardens (Table 1; locations 7, 18).

3.2. Chromosomal Inversion Polymorphism

The mitotic chromosome set in malaria mosquitoes includes three pairs of chromosomes [59]. Salivary gland cells of the larvae contain polytene chromosomes. Homologous chromosomes are paired during polytenization. The karyotype of polytene chromosomes consists of 5 arms (short arm of sex chromosome XL and arms of autosomes 2R, 2L, 3R, 3L). All 5 arms are connected by a common chromocenter. The long arm of the XR sex chromosome and both arms of the Y chromosome consist of heterochromatin and are not polytenized. Male karyotypes have only one polytene X chromosome that is thinner than the X chromosome of females.

Chromosomal inversions were studied in populations of *An. atroparvus* and *An. daciae*. We identified chromosomal inversions in accordance with the previously published photo maps of polytene chromosomes in *An. atroparvus* and *An. daciae*/*An. messeae* [52,53].

Anopheles daciae differed from other species by a high degree of chromosomal polymorphism (Table 3).

Table 3. The frequencies of chromosomal variants in populations of *An. daciae* in the Crimean Peninsula and the Black Sea coast of the Caucasus.

Inversion homo- and heterozygotes	Frequencies of chromosomal variants, $f \pm Sf, \%$			
	Crimean Peninsula	Black Sea coast of the Caucasus		
	Location 10	Location 36	Location 40	Location 42
Males, n	30	16	49	46
XL ₀	73,3±8,1	56,2±12,4	61,2±7,0	37,0±7,1
XL ₁	26,7±8,1	43,8±12,4	38,8±7,0	63,0±7,1
Females, n	36	14	59	61
XL ₀₀	41,7±8,2	35,7±12,8	32,2±6,1	23,0±5,4
XL ₀₁	50,0±8,3	42,9±13,2	45,8±6,5	36,0±6,1
XL ₁₁	8,3±4,6	21,4±11,0	22,0±5,4	41,0±6,3
Both sexes, n	66	30	108	107
2R ₀₀	100	100	100	99,1±0,9
2R ₀₅	0	0	0	0,9±0,9
2L ₀₀	100	100	100	100
3R ₀₀	100	90,0±5,5	92,6±2,5	91,6±2,7
3R ₀₁	0	10,0±5,5	7,4±2,5	7,5±2,5
3R ₁₁	0	0	0	0,9±0,9
3L ₀₀	98,5±1,5	83,3±6,8	89,8±2,9	81,3±3,8
3L ₀₁	1,5±1,5	13,3±6,2	10,2±2,9	15,9±3,5
3L ₁₁	0	3,3±3,3	0	2,8±1,6

Homo- and heterozygotes for three paracentric inversions were common in populations of this species: XL₁ (2a-5b); 3R₁ (23c/24a-26c/27a); 3L₁ (34b/c-37a/b-38c/39a-39c/d), whereas the 3L₁ inversion consists of two overlapping inversions. Only one heterozygote for new inversion 2R₅ (11c-14a) was found in the Novorossiysk population (Figure 2; location 42). There were no inversions in the 2L arm.

Figure 2. A chromosomal complement of a squashed preparation of salivary gland cells in an *An. daciae* female, stained by lacto-aceto-orcein. Panel (a) shows the standard karyotype XL₁₁, 2R₀₀, 2L₀₀, 3R₀₀, and 3L₀₀, where XL, 2R, 2L, 3R, and 3L represent chromosome arms and the numbers ₁₁ and ₀₀ are chromosomal variants (objective lens – Nikon Plan Fluor 60x/0,85). Chromosome arms XL, 2R, 2L, 3R, 3L are indicated. Panel (b) shows the inversion heterozygote 2R₀₅ (11c-14a) in *An. daciae* (objective lens – Nikon Plan 100x/1,25). The arrows indicate the points of breaks and homologues exchanges in the inversion loop. CC – stands for the chromocenter. Scale bar equals 50 μm.

We described, for the first time, the chromosomal polymorphism of marginal populations of *An. daciae* in the southern part of the species range. The only one population of *An. daciae* in the Crimean Peninsula (Figure 3; location 10) differed in chromosomal composition from three Caucasian populations (Figure 3; locations 36, 40, 42).

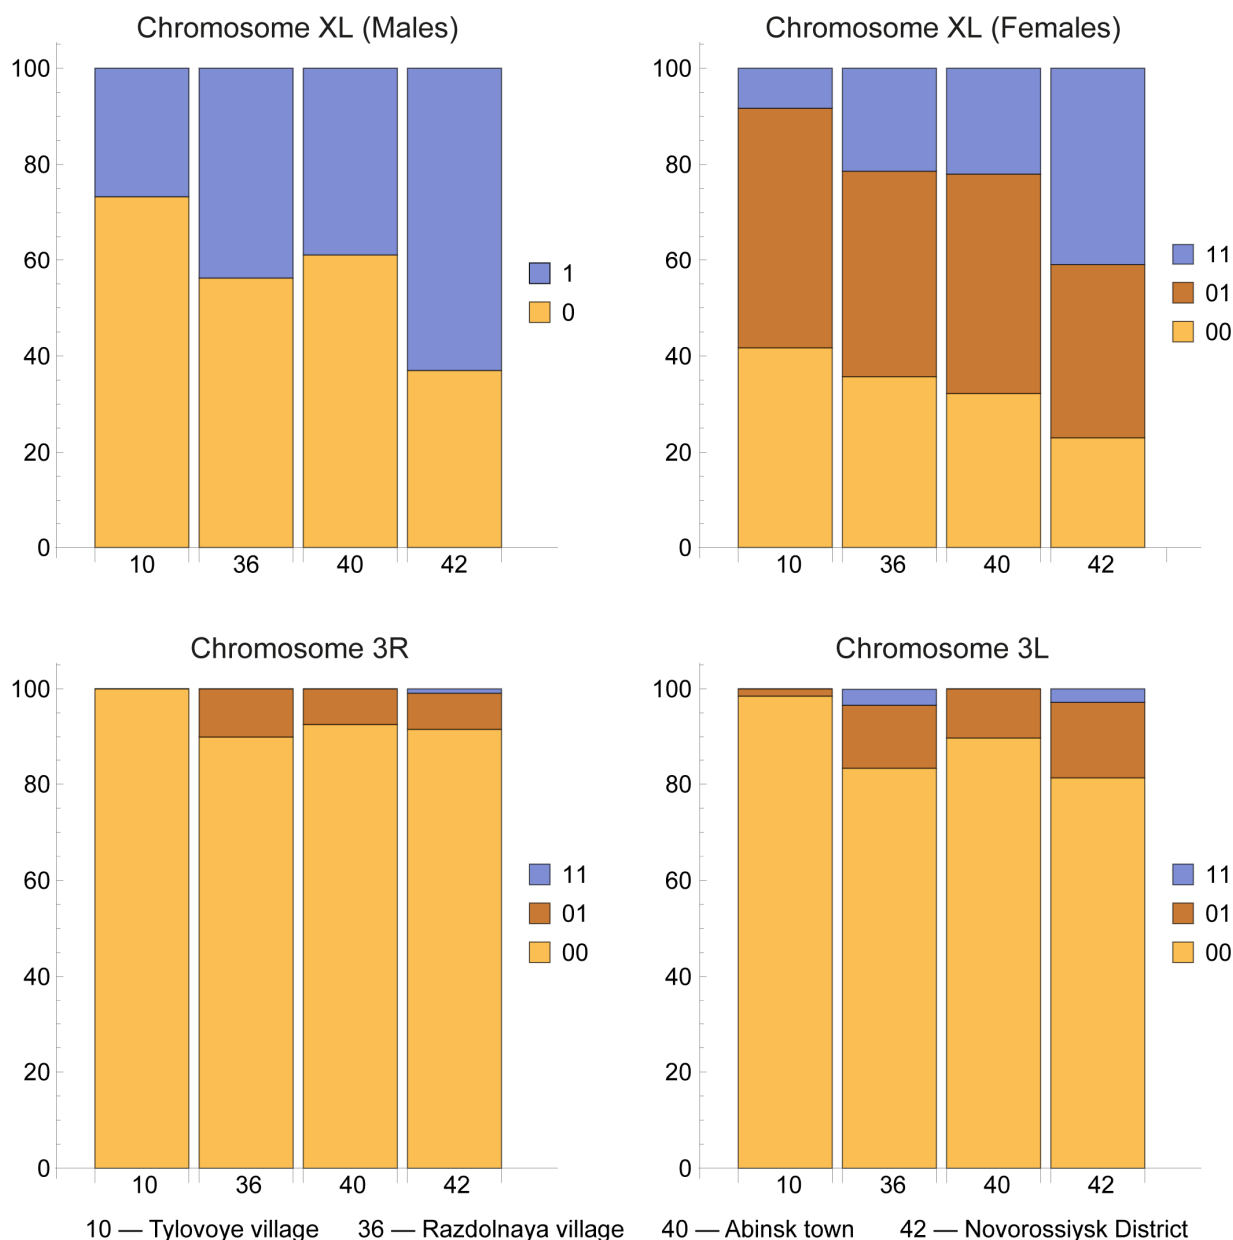

Figure 3. Frequencies of inversion homo- and heterozygotes in populations of *Anopheles daciae* in Crimea (location 10) and on the Black Sea coast of the Caucasus (locations 36, 40, 42). The frequencies of inversions of sex chromosome XL in males and females are given separately. The frequencies of inversions of 3R and 3L autosomes are shown for individuals of both sexes.

A high level of inversion polymorphism of sex chromosome XL is observed in all populations of *An. daciae* on the Black Sea coast (Figure 3), but the frequency of chromosomal variants with XL₀ inversion was significantly higher in the Crimean population in males ($\chi^2=4.47$; number of degrees of freedom $df=1$; $p<0.05$) and females ($\chi^2=6.16$; $df=2$; $p<0.05$). XL₀ inversion serves as a species marker of *An. daciae*. The alternative inversion XL₁ is considered ancestral to the two cryptic species *An. daciae* and *An. messeae* [53]. According to molecular genetic analyses, the separation of *An. daciae* and *An. messeae* happened about 2 Ma during the glaciation in Eurasia [44]. It is assumed that *An. daciae* mosquitoes were isolated in a refugium in southern Europe. The XL₀ inversion, which occurs with high frequency in populations of the steppe zone and broad-leaved forest zone, probably arose during this period [60].

Autosomal inversions 3R₁ and 3L₁ are present with low frequency in coastal populations of *An. daciae* (Figure 3). These inversions were probably derived from the common ancestor of *An. daciae*

and *An. messeae*, since polymorphism on inversions 3R₁ and 3L₁ is present in populations of both species. Geographical gradients in longitude suggest the influence of climatic factors on the frequencies of these inversions [56]. The frequencies of homo- and heterozygotes with 3R₁ and 3L₁ inversions were significantly higher in Caucasian populations ($\chi^2=4.48$ and 7.40; $df=1$; $p<0.05$ and $p<0.01$, respectively). In general, the level of chromosomal polymorphism was significantly higher in the Caucasian populations than in the Crimean population.

The inversion polymorphism was observed in *An. atroparvus* populations. Heterozygotes for inversion 3L₁ (34b/c-38b) were found in two populations from Crimea and the Stavropol Region (Figure 4).

Figure 4. A chromosomal complement of a squashed preparation of salivary gland cells in an *Anopheles atroparvus* female, with karyotype XL₀₀, 2R₀₀, 2L₀₀, 3R₀₀, and 3L₀₁, stained by lacto-aceto-orcein, where XL, 2R, 2L, 3R, and 3L represent chromosome arms and the numbers 00 and 01 are chromosomal variants (objective lens – Nikon Plan 100x/1,25). The inversion heterozygous variant 3L₀₁ (34b/c-38b) in *An. atroparvus* appears as a loop in the chromosome. CC – stands for the chromocenter. Chromosome arms XL, 2R, 2L, 3R, 3L are indicated. Scale bar equals 20 μm .

Heterozygotes 3L₁ occurred with a frequency of 33.3% in both populations (Table 1; locations 2, 19). No homozygotes for this inversion were detected. Chromosome 3L has an identical disc pattern in *An. atroparvus* and *An. daciae*. Interestingly, the breakpoints of the 3L₁ inversion of *An. atroparvus* (34b/c and 38b) are close to two breakpoints of the overlapping 3L₁ inversion of *An. daciae* (34b/c-38c/39a). Perhaps this localization of inversions determines similar adaptive effects, so individuals of two species with these inversions are found in the same regions.

Discussion

In this study, we examined the malaria mosquito species composition, geographical distribution, and ecological preferences in the Crimean Peninsula and the Black Sea coast of the Caucasus. *Anopheles maculipennis* s. s. was the most abundant species in the foothills and coastal areas. *Anopheles daciae* dominated in freshwaters in the Kuban-Priazov lowland. *Anopheles atroparvus* larvae developed in saline lakes, but they may also be subdominant in freshwater pools. *Anopheles melanoon* mosquitoes were found only in the humid subtropical zone of the Black Sea coast of the Caucasus. *Anopheles claviger* mosquitoes preferred cool springs and groundwater outflows. *Anopheles hyrcanus* larvae developed in reed thickets along the shores of shallow lakes. *Anopheles plumbeus* larvae inhabited tree holes and shallow temporary water pools. The diversity of coastal landscapes allowed the above species with different ecological preferences to co-occur in the same area. The number of malaria mosquitoes was limited by the lack of suitable water pools during dry and hot summers, especially in the steppe zone.

Anopheles maculipennis s. s. appeared to out-compete mosquitoes of other *Maculipennis* species in water pools with standing fresh water on the southern coast of the Crimea and in the foothills of the Caucasus. This species was found together with *An. daciae* and *An. messeae* s. s. over a wide area of the Russian Plain [44]. *Anopheles maculipennis* s. s. larvae also occupied temporary water pools dominated by other closely related malaria mosquito species. It has been shown that climate warming is contributing to the expansion of the species range of *An. maculipennis* s. s. in the north and east of European Russia [61,62]. Chromosomal polymorphism in *An. maculipennis* populations has been noticed but it was not evaluated in the current study. Populations of this species are considered as chromosomally monomorphic throughout the territory of the Russian Plain. Only one single heterozygous inversion on the left arm of chromosome 2L, at the 5c-20c region, was observed in the population of Falesti [52,63].

Before the description of *An. daciae* in 2004 [34], both *An. daciae* and *An. messeae* were diagnosed as *An. messeae* Fall., 1926 [11,45–47]. We were unable to find any *An. messeae* s. s. mosquitoes in the studied regions. This result was verified by sequencing *ITS2* fragments of 166 larvae from three habitats (Table 1; locations 10, 40, 42) [56]. The ecological niches of *An. daciae* and *An. maculipennis* partially overlap in the Russian Plain; larvae of both species can develop in the same water reservoirs under similar temperate conditions. However, more suitable breeding sites for *An. maculipennis* were found in the subtropical zone, on the southern coast of the Crimea and on the southern part of the Black Sea coast of the Caucasus, where *Anopheles daciae* mosquitoes were not found. The southern range limit of *An. daciae* was in the Pshadsky district of Krasnodar Krai (Figure 1; location 43), where the transition from temperate to subtropical climate occurs. Winter temperatures are significantly higher in southern areas, in the Tuapse-Sochi coastal strip making over-wintering conditions as the main limiting factor for Palearctic species of malaria mosquitoes in the south [64]. It is likely that diapausing females of *An. daciae* cannot tolerate warm winters in the humid subtropical zone. In contrast, *An. maculipennis* s. s. females can blood feed repeatedly during the over-wintering period [7,64–66]. Feeding on blood during diapause helps species to survive in excessively warm winter shelters whereas fat reserves of diapausing females are rapidly depleted. So far, only *An. maculipennis* s. s. has been considered as the main potential vector of malaria throughout the southern Russian Plain, especially in the mountainous and foothill areas of the North Caucasus [7]. However, we believe that the epidemiologic role of *An. daciae* is currently underestimated and needs to be further evaluated.

Our study indicated that populations of *An. daciae* and *An. maculipennis* s. s. on the Crimean Peninsula were isolated from those of the Kuban-Priazov lowland and the Black Sea lowland. A natural barrier for these mosquitoes is the dry steppes with saline lakes in the northern Crimea and the Taman Peninsula. The isolation of populations likely occurred after the last glaciation in Europe because of the Black Sea natural disaster [67]. The Black Sea was a freshwater lake with the level of 120 m below the present-day level. The rupture of the Bosphorus, followed by the intrusion of saline water from the Mediterranean Sea, occurred around 9300 BC. Prior to this, a significant part of the

present underwater continental shelf of the Black Sea was a terrestrial area with a common flora and fauna. Flooding led to the breakage of a continuous coastal strip and the formation of the Crimean Peninsula. The subsequent climatic aridification in the northern part of Crimea led to the isolation of the mosquito fauna of the southern Crimean coast. The use of inversions as genetic markers allows reconstructing the genetic history of *An. daciae* populations on the Black Sea coast. Apparently, long-term isolation caused differences in the chromosomal composition of *An. daciae* populations in Crimea and on the Black Sea coast of the Caucasus. The Crimean population had a low level of polymorphism in autosomal inversions: 0% homo- and heterozygotes for inversion 3R₁ and only 1.5% heterozygotes for inversion 3L₁ (Tab. 3; location 10). In Caucasian populations, the frequencies of homo- and heterozygotes for 3R₁ and 3L₁ inversions were much higher and vary between 7.4-10.0% and between 10.2-18.7%, respectively (Tab. 3; location 36, 40, 42). We determined that the Crimean and the Black Sea coast populations of this species were more homogeneous than in the center of the Russian Plain. The long-term isolation of the Crimean populations has led to even more pronounced differences in the chromosomal polymorphism of the *An. daciae* populations there. Local populations within Crimea differ mainly in the frequency of inversions in the sex chromosome XL. The autosomal inversions 3R₁ and 3L₁ occur with lower frequency than in the center of the Russian Plain [43]. The level of chromosomal polymorphism in *An. daciae*/*An. messeae* mosquitoes was shown to be associated with specific landscape-climatic zones [60]. We believe that the high level of inversion polymorphism is associated with optimal landscape-climatic zones for this species. The sub-taiga and forest-steppe zones are probably more favorable for the development of *An. daciae* mosquitoes than the steppes of the Kuban-Priazov lowland.

In contrast to *An. daciae* and *An. maculipennis* s. s., *An. atroparvus* mosquitoes develop en masse in the steppe salt lakes in the northern Crimea [68]. The steppes and semi-deserts of the northern Crimea belong to the same natural zones of the Black Sea lowlands. The steppes of the Kerch Peninsula in Crimea are separated from the steppes of the Taman Peninsula by the relatively narrow Kerch Strait. Thus, the range of *An. atroparvus* covered the coastal areas as a continuous strip. Similar chromosomal variability occurred in geographically distant populations of this species. For example, the chromosomal inversion 3L₁ is present in the Crimea and on the Black Sea coast of the Caucasus in this mosquito species. The northern limit of the *An. atroparvus* range is the southern Russian Plain, approximately south of the 48th parallel [47] but is not well defined.

The malaria mosquito *An. melanoon* was one of the rarest species of the *Maculipennis* complex on the Black Sea coast of the Caucasus. This species lives in sympatry with *An. maculipennis* s. s. on the territory of Bulgaria, Moldova, Romania, Georgia and Turkey [34,69–73]. We assumed that the northern limit of the *An. melanoon* distribution was the subtropical zone of the Black Sea coast of the Caucasus and may have shifted southwards to the Imereti Valley under conditions of anthropogenic transformation of coastal landscapes. The species was chromosomally monomorphic [18]. The polytene chromosomes of *An. melanoon* and *An. maculipennis* s. s. in ovarian nurse cells have the same banding patterns except for pericentromeric regions [74] that attach to the nuclear periphery, which causes the differentiation of chromosomal morphology between these species [75–77].

The malaria mosquito *An. hyrcanus* inhabited steppe plains and was one of the most highly specialized species. The larvae of this exophilic mosquito developed mainly in the coastal zone of lakes and in wetlands covered with reeds, rushes, sedges, cattails, and other aquatic vegetation. In the Krasnodar Krai, rice fields created favorable breeding conditions for *An. hyrcanus* mosquitoes. *Anopheles hyrcanus* breeding sites have been found in the Tien Shan and Pamir-Alai valleys of Central Asia at altitudes of up to 1000 m [78]. Chromosomal polymorphism in *An. hyrcanus* populations has not been studied. A high level of chromosomal variability was found in populations of another species of the Oriental Hyrcanus group, *An. kleini* Rueda, 2005, which lives in the Far East [79,80].

Anopheles claviger mosquitoes were widespread in the foothills of the Caucasus and Crimea. We studied several *An. claviger* breeding sites on the southern coast of Crimea. The natural complexes of the southern coast of Crimea were formed under the conditions of a hot sub-Mediterranean climate [81]. The sub-Mediterranean climate zone consists of a western part (from Cape Aya to Alushta) and

a more arid eastern part (from Alushta to Feodosia). *Anopheles claviger* mosquitoes inhabited both parts of the sub-Mediterranean climate zone, especially in mountain forests at the northern limit of this zone. Two population peaks of *An. claviger* mosquitoes have been recorded during the summer season: in mid-late June and late October [82]. The summer decline in abundance was specific for *An. claviger* throughout the southern Russian Plain. *Anopheles claviger* can be found at altitudes up to of 2200 m in the Tien Shan Mountains and numerically outnumbers other *Anopheles* species in the foothills throughout the breeding season [83]. A sharp decline in *An. claviger* mosquito numbers was shown to occur during the summer months in the lowlands of Central Asia, as reservoirs of cold clear water are required for larval development of this species. Chromosomal variability in the wide distribution of *An. claviger* has not been studied.

Anopheles plumbeus mosquitoes were usually found in the mountainous forests. The larval stages of this species developed in the rotten tree holes filled with rainwater with a high organic content, as well as in small water pools of natural origin [82]. *Anopheles plumbeus* females laid eggs in water pools just above the waterline and the larvae hatch during the first floods of the rainy season [84]. *Anopheles plumbeus* was originally considered a dendrolimnetic species, but the ecological preferences of this species have now changed [85,86]. In several European countries, this species has begun to breed in water pools of artificial origin, such as rainwater barrels, lagoons, septic tanks, car tires, cemetery vases, liquid manure collection tanks, and manure puddles [85–89]. According to our observations, *An. plumbeus* has started to breed in the territory of Caucasian resorts since 2018. The anthropogenic transformation of coastal landscapes has created favorable conditions for the development of this species in artificial water containers with hard walls polluted with organic matter. An increase in the number of *An. plumbeus* in Crimea and the Black Sea coast of the Caucasus began in 2018. The expansion of the *An. plumbeus* range from the vicinity of Sochi city (Tab. 1; location 53) to Tuapse district (Tab. 1; location 44). occurred in several stages and was similar to the spread of the invasive Asian tiger mosquito *Aedes albopictus* Scuse, 1895 [90]. Unlike other Eurasian malaria mosquito species, *An. plumbeus* has been shown to be capable of transmitting malaria parasites *Plasmodium falciparum* and *Plasmodium vivax* [85,91,92]. This malaria mosquito was considered the probable cause of two autochthonous cases of *Pl. falciparum* malaria in Germany [66,93]. Moreover, *An. plumbeus* was shown to be susceptible to West Nile virus and, because of its double ornithophilic and anthropophilic behavior, was considered as one of the potential vectors of this virus from birds to humans [94,95]. Clearly, the epidemiological significance of this species as a secondary vector of vector-borne diseases in Crimea and the Black Sea coast of the Caucasus needs to be reconsidered. It remains unknown how changes in the ecological preferences of *An. plumbeus* are related to the genetic variability of natural populations. Chromosomal polymorphism in *An. plumbeus* populations has not been studied.

Although *An. algeriensis*, *An. sacharovi*, and *An. superpictus* were previously recorded in the Crimea and the Black Sea coast of the Caucasus [47], we have not found any breeding sites of these species. Previously, *An. algeriensis* was found in spring water in the foothills of the North Caucasus and in the Kuban-Priazov lowland [96]. *Anopheles algeriensis* larvae begin to emerge in spring waters in the Caucasus at a temperature of about 5°C [97]. The breeding sites of mosquitoes of this species have not been found less than 3-5 km from any settlement [98]. The most recent record of *An. algeriensis* mosquitoes was made in Kalmykia [99]. The northern limit of the range of *An. algeriensis* is south of the 48th parallel on the Russian Plain and is not well defined. *Anopheles algeriensis* has been shown to be a competent vector for *Plasmodium* parasites [100]. However, this species is rare, lives far from human settlements and may not play a role in the malaria transmission in the Caucasus. The karyotype composition and chromosomal polymorphism in *An. algeriensis* populations have not been studied.

The malaria mosquito *An. sacharovi* has not been recorded in Crimea and the Black Sea coast of the Caucasus, but it has been found the adjacent plains of Transcaucasia and Dagestan [101]. This species was the main vector of three-day malaria caused by *Pl. vivax* in the valleys of Transcaucasia (Georgia, Armenia, Azerbaijan) during the malaria outbreak in the late 20th and early 21st centuries

[7]. The malaria mosquitoes *An. sacharovi* and *An. superpictus* are among the most epidemiologically important species in the Palearctic [7]. Global warming may contribute to the expansion of the range of these species to the southern Russian Plain [102–104]. For example, the northern limit of the range of *An. sacharovi* has shifted from Dagestan to the territory of Kalmykia, where this species was not previously recorded [101]. Environmental changes can affect not only the geographical distribution but also the abundance and ecological preferences of malaria mosquitoes. Finally, *An. superpictus* was considered a mountain stream species in Central Asia (Tajikistan). Currently, mosquitoes of this species are found in lowland waters with increased eutrophication, including rice fields. The abundance of *An. superpictus* increased significantly as a result of changes in ecological preferences [78].

Our findings demonstrate that malaria mosquitoes of the Crimean Peninsula and the Black Sea coast of the Caucasus consists of ecologically specialized species. This study helped to better understand the dynamics of the malaria mosquito species distribution and their ecological preferences under the effects of global warming and increasing human activities. Further monitoring of the composition of malaria vector species and their geographic distribution represents an important component of entomological surveillance, which stimulates the development of appropriate mosquito control strategies aimed at preventing the re-emergence and spread of malaria in areas where it was previously eliminated.
