Abstract: In this review dedicated to the great protistologist Edouard Chatton (1883-1947), I wanted to highlight the originality and remarkable diversity of some dinoflagellate protists through the lens of cell biology. Their fossilized traces date back to more than 538 million years (Phanerozoic eon). However, they may be much older, because acritarchs from the (Meso) Proterozoic era (1,500 million years ago) could be their most primitive ancestors. Here, I described several representative examples of the various lifestyles of free-living (the autotrophic thecate *Prorocentrum micans* Ehrenberg and the heterotrophic athecate *Noctiluca scintillans* McCartney and other "pseudo-noctilucidae", as well as the thecate *Crypthecodinium cohnii* Biecheler) and of parasitic dinoflagellates (the mixotroph *Syndinium* Chatton). Then, I compared the different dinoflagellate mitotic systems and reported observations on the eyespot (ocelloid), an organelle that is present in the binucleated *Glenodinium foliaceum* Stein and in some Warnowiidae dinoflagellates and can be considered an evolutionary marker. The diversity and innovations observed in mitosis, meiosis, reproduction, sexuality, cell cycle, locomotion and nutrition, allow us to affirm that Dinoflagellates are among the most innovative unicells in the Kingdom Protista.

Keywords: dinoflagellates; cell biology; innovative features; evolution

1. Preamble

This review is dedicated to the great protistologist Edouard Chatton (1883-1947), a pioneer in the study of the cytology of many (free-living and mixotrophic) dinoflagellates who revealed the complexity and originality of these protists at the beginning of the 20th century. E. Chatton (1883-1947) was the first scientist to take a detailed interest in the description of the external morphology of many dinoflagellates and especially in their life cycle, cytology and mitosis (dinomitosis and syndinian mitosis). He masterfully described his findings in his PhD thesis, published more than one hundred years ago [1]. Chatton reported all his observations in his monumental Titres et Travaux Scientifiques (in English, Titles and Scientific Works) [2], a publication enriched by splendid course boards (160/110cm), genuine artistic works he drew for his students, starting in 1920. A selection of the finest drawings by Chatton have been recently published in a book [3]. Chatton was also the first to distinguish between prokaryotic and eukaryotic microorganisms [4].

2. Introduction

Opening the chapter on the Phylum Dinoflagellates written by FJR Taylor in the 1990s [5] is enough to appreciate the immense diversity of these protists. The current classification recognizes ~550 genera and a total of 6,000 described species that play a prominent role in water ecology. Molecular clock and biogeochemical indices indicate that the dinoflagellate lineage diverged ~650 Ma, and fossil traces of thecate cells and of cysts/zygotes appeared during the Triassic [6]. Evidences

 doi:10.20944/preprints202503.1826.v1

of dinoflagellate existence come from the biogeochemical analysis of early Cambrian sediments (~520 million years ago), in which dinoflagellate-specific sterols (i.e., dinosterols) were detected in rock extracts and petroleum. However, some scholars think that they may have an older, earlier Precambrian origin, forming part of the Acritarchs [6,7]. According to B. Dale (2023) [8], the first dinoflagellates would have been naked and therefore, without fossil traces except for biogeochemical residues. Only later, they would have acquired a protective theca to escape various predators. According to the phylogeny analyses by Bachvaroff et al. [9] and by Delwiche [10], they belong to the alveolates and can be autotrophic (about half are photosynthetic), heterotrophic, parasitic and/or mixotrophic, symbiotic, plasmodial, or organized as "bi-nucleated" or "pseudo-multinucleated" cells. They all live in aquatic environments (seawater, brackish or freshwater), and they have hemolymph, gut or coelomic cavity for mixotrophic dinoflagellates [11]. The composition of their chromatin and the organization of their nucleus (dinokaryon) also are unique as well as their "dinomitosis" [6,12,13]. In the nucleus of many dinoflagellate species, chromosomes are maintained in a quasi-permanent compacted state. Molecular studies to estimate their diversity and to attempt their classification were carried out, especially to locate dinoflagellates among other Protists and to classify dinoflagellate taxa [14]. Phylogenetic trees were built using protein sequences (e.g., dimeric iron-containing superoxide dismutases) [15], or the sequence of specific genes (e.g., 18S rRNA, 5.8S rRNA, 24S rRNA or SS rRNA). All genomic data have been regrouped in the recent and very complete review by Serjie Lin [16].

In this review, I chose to present several examples of different categories of these original protists, from a non-exhaustive list of representatives of their different lifestyles, in order to highlight their remarkable diversity and adaptability, but without classifying them from the simplest to the highest evolutive complexity. I then focused on some innovative features, several of which were previously but partially described [6] using cell biology tools. I particularly highlight the acquisition of an eyespot (ocelloid) in several species belonging to the Warnowiidae family.

3. Materials and Methods

A review of the literature was carried out by searching the PubMed and Google Scholar databases from 2000 to 2024 following the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) guidelines, except for pioneering references (from 1920 to 2000). Studies were identified using the following keywords: Dinoflagellates, Eyespot, Mitotic apparatus, *Prorocentrum*, *Noctiluca*, *Crypthecodinium*, *Syndinium.* Many illustrations in this review were taken from the selected publications, after having obtained permission by the publishers. For unpublished microphotographs taken by the author, the preparation/analysis methods were described in [17–19].

4. Results

This review summarizes the amazing and innovative diversity of dinoflagellates (autotrophic, heterotrophic or mixotrophic) and their adaptations.

4.1. An Autotrophic Free-Living Dinoflagellate: Prorocentrum micans Ehrenberg

4.1.1. General Features

The cell cycle of *P. micans* Ehrenberg vegetative cells (Figure 1a') was deciphered by Bhaud and Soyer-Gobillard [20], and lasts 6 days, that is relatively long cell cycle. This protist is characterized by an original flagellar system: an undulating membrane attached to the polysaccharidic epitheca that ends in a short transverse flagellum and a longitudinal flagellum (**Figure 1a-c**).

 doi:10.20944/preprints202503.1826.v1

4.1.2. Original Features

Nucleus

 doi:10.20944/preprints202503.1826.v1

The nucleus is filled with hundred large chromosomes (10 µm long and 1 µm wide) (**Figure 2a)** and surrounded by large plastids. As these chromosomes are quite large, Haapala & Soyer-(Gobillard) could observe them using transmission electron microscopy (TEM) for the first time after spreading them on water (**Figure 2b**). This allowed describing their organization, particularly the superhelical twisted structure of their nucleofilaments [22]. The twisted and regular unwinding of these chromosomes led to the hypothesis that they are organized in multiple circular chromatids (**Figure 3c**) [22,23]. This hypothesis was later confirmed and thoroughly described by Oakley and Dodge [24]. The isolation of chromatids from purified DNA molecules, spread and shadowed with platinum carbon, was particularly difficult to achieve [25] (**Figure 2c**).

P. micans has two types of reproduction: a vegetative reproduction, carried out by binary fission, and a sexual reproduction. In vegetative cells, dividing chromosomes must be attached to the internal part of the nuclear envelope (**Figure 3a, b**) and are not directly in contact with the microtubular spindle located in cytoplasmic channels that pass through the mitotic nucleus. This observation is supported by the absence of centromeric heterochromatin in *P. micans* [26]. As centromeres are localized at the chromosome ends in this species, they can be considered to be telomeres. However, heterochromatin is lacking in these telomeres, making of *P. micans* a kind of "immortal cell" incapable of apoptosis.

P. micans chromosomes are devoid of histones and nucleosomes, but are rich in 5-hydroxymethyluracil [27]. However, nucleosomal structures could be easily reconstructed in vitro using *P. micans* DNA and purified corn histones, showing that the presence of this abnormal base is not an impediment to their reconstruction [28]. *P. micans* also allowed us to carry out some of the first phylogenetic molecular analyses using ribonucleoprotein subunit (SSU, LSU) sequencing data [29,30].

in the chromosomes of a primitive Eukaryote Dinoflagellate. *J. Cell Biol.*, **1990,** *111*, 293-308**,** [19]. Courtesy of The Rockefeller University Press.

Interestingly, using immunogold electron microscopy after sample preparation by vitrification [18], a technique developed by Professor Jacques Dubochet (Nobel Prize in Chemistry) that preserves the antigenic sites particularly well, we could detect two DNA types in *P. micans* chromosomes: B-DNA (right-handed DNA) and the so-called "mirror" Z-DNA (left-handed DNA). B-DNA represents the usual DNA conformation (right-handed double helix). It is the most represented in the living world **(Figure 3, d**), unlike Z-DNA (which turns left). Thanks to work in collaboration with Etienne Delain's group at the Gustave Roussy Cancer Research Institute in Villejuif (France), who produced an anti-Z-DNA antibody from urine samples of people with cancer [19], we could detect the presence of Z-DNA as clusters of gold particles at the chromosome periphery (**Figure 3, f**) and in the chromosomal fission zones (**Figure 3, e**). Conversely, B-DNA was localized in the chromosome body (**Figure 3, d, f**). We hypothesized that in these always compacted chromosomes, transcription takes place at the chromosome periphery and DNA opening occurs through loop opening process dependent on the mirror Z-DNA [19].

Sexual reproduction

P. micans sexual reproduction was observed in our laboratory by chance, after a glass bottle with some cultured cells was placed in a refrigerator at 4° in the dark for 12 hours. The next morning, many cells had paired up, clinging one to the other through their apical spine and emitting a connecting tube (i.e., fertilization tube) (**Figure 4A, b, c**) through which one cell injects its genetic material surrounded with nuclear membrane into the other [31,32]. Shortly after the fusion of the two nuclei, their chromatin undergoes a very impressive movement (i.e., chromatic cyclosis) for several minutes, during which the male and female genetic materials mingle and chromosomes lose completely their regular helical structure (**Figure 4, f'**). By quantifying DNA in single cells, we showed that in *P. micans*, early planozygotes (2q DNA content) double their DNA to 4q before the first of the two zygotic divisions (meiosis), which leads to 1q vegetative cells [31]. Later [32], we observed that nuclear chromatic cyclosis occurred directly before the first meiotic division and that the chromosome nucleofilament organization was altered. Nuclear chromatic cyclosis was discovered in two *Ceratium* species by Pouchet in 1885 [33] and thoroughly described in six *Peridinium* species by Biecheler in 1935 [34]. Many other dinoflagellates present both vegetative (binary reproduction) and sexual reproduction, the last occurring often when the physicochemical conditions are unfavorable.

Intriguing intranuclear supercoiled micro-cables during meiosis [35].

During meiosis, TEM observations showed a total disorganization of the chromosomal nucleofilaments. Specifically, the chromosomes are very uncoiled, but still well individualized (**Figure 4f'**) [32] to allow inter-genomic exchanges. During this period, chromatic cyclosis occurs and micro-cables are visible in the nucleoplasm from TEM observations (**Figure 5a**) [35]. They are

 doi:10.20944/preprints202503.1826.v1

composed of twisted filaments organized in a helix in which the unitary microfilaments have a diameter of 60 Å. They are organized in a right tetrahelix with a diameter that varies from 35 to 45 nm (**Figure 5 a', b**). The microfilament diameter corresponds to that of actin that we detected and described for the first time in a dinoflagellate [36]. The presence of actin was confirmed by Berdieva *et al.* (2018) [37] who demonstrated F-actin in the cytoplasm and G-actin in the nucleus at the nucleolar level in the dinoflagellate *Prorocentrum minimum* (Pavillard) Schiller. These evidences allowed us to hypothesize that micro-cables could be the driving element of chromatid mixing during chromatic cyclosis as well as of chromosome transport during dinomitosis.

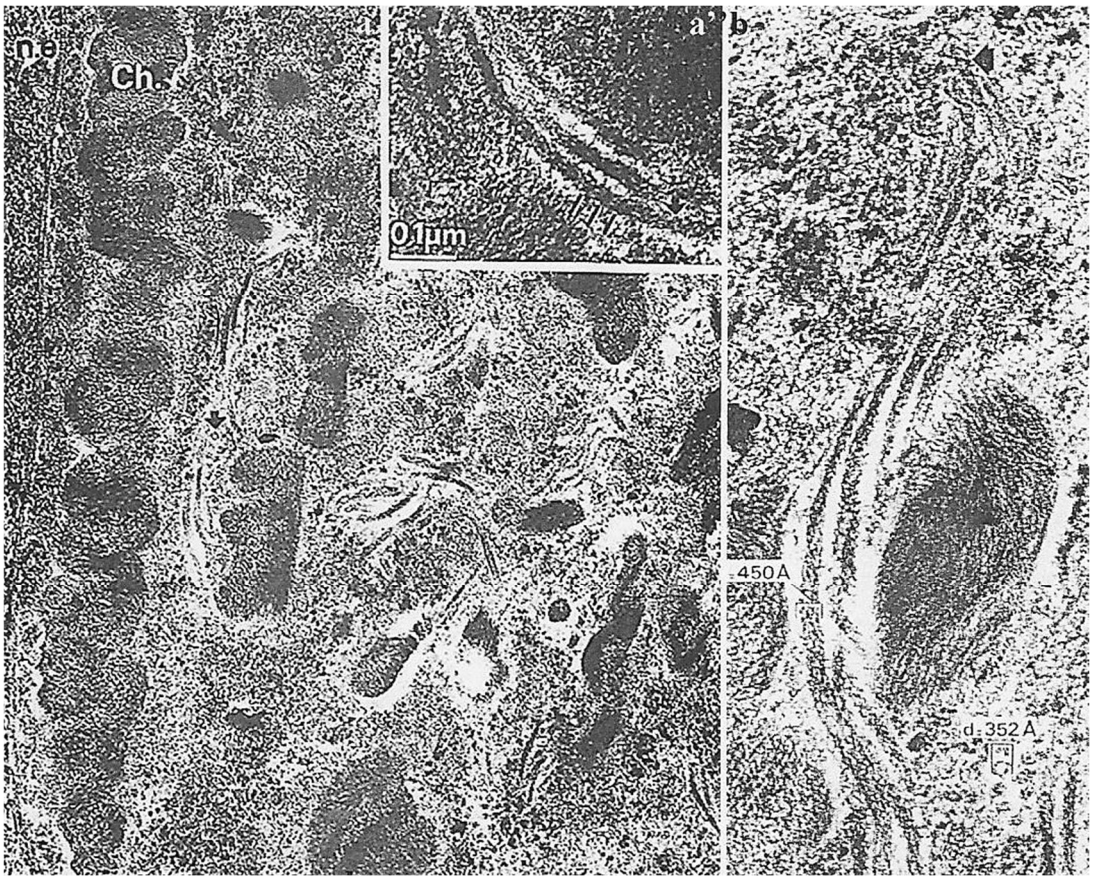

Figure 5. Intranuclear micro-cables in the nucleoplasm observed after *P. micans* cell vitrification (-269°C) followed by cryosubstitution according to the methods described in [18,19]. **(a)** At this meiosis stage, during the chromatic cyclosis, chromosomes (Ch.) are unwound. (**a'** and **b),** organization of nucleoplasmic microfilaments is supercoiled (black arrowhead). From Soyer-(Gobillard), M.-O. 4.2. Two Heterotrophic Free-Living Dinoflagellates: Noctiluca scintillans Mc Cartney and Crypthecodinium cohnii Biecheler

4.2.1. *Noctiluca scintillans* McCartney

4.2.1.1. General Features

Commonly called "Fire of the Sea", *N. scintillans* McCartney is a non-parasitic athecate free-living spherical protist (**Figure 6a-c**) without plastids that lives in marine environments. It exhibits bio-luminescence when agitated, through a luciferin-luciferase system in its cytoplasm [38,39], like some other dinoflagellate species (see **Figure 13).** These planktonic dinoflagellates, which have not been recorded to produce toxins, can bloom into non-toxic "red tides" that spread as a several centimeter thick layer on the sea surface. *N. scintillans* McCartney does not have cellulose

 doi:10.20944/preprints202503.1826.v1

thecal plates, but is not completely "naked". Indeed, its amphiesma presents an outer membrane that surrounds the cell, amphiesmal vesicles and a thin pellicular layer, as described by Melkonian and Höhfeld (1988) [40]. *N. scintillans* McCartney can divide by binary fission after loss of the tentacle or by sporulation after sexual reproduction [41] to form sporocytes (**Figure 6a-c)** and then uniflagellate spores (**Figure 6b**) [42–44]. During sporogenesis, their chromatin progressively condenses as the divisions progress [45]. Chromosomes are well individualized only in mature spores where there are at least 120 chromosomes per nucleus.

4.2.1.2. Original Features

In trophozoites and at the start of divisions, the nuclear membrane is lined with nuclear ampullae that bear nuclear pores and actively participate in sporogenesis **(Figure 7a-d).** In a trophozoite, the surface area of ampullae is twice the surface area of the total nuclear envelope [43]. Trophozoites can undergo a binary division or form spores. In a very short time, nuclear ampullae constitute nuclear membrane reserves available during sporulation, accelerating the divisions during a bloom (red tide). Indeed, during sporulation, nuclear ampullae fuse to leave a smooth nuclear envelope devoid of ampullae into the spores (**Figure 7d**) [43,44].

Cytochemical investigations did not detect histone-like proteins in the trophocyte nucleus. At the molecular level, the unusual 5-hydroxymethyluracil base has been found in the nuclear DNA of *N. scintillans* [28]. In the investigated dinoflagellate species, this unusual base replaces 12%–68% of all thymine residues, a relatively important replacement amount.

Cytoskeletal elements that participate in *N. scintillans* trophozoite motility are also involved in nutritional functions. They are located in the tentacle (**Figure 10, a, b)** and at the level of the cytostome where filaments are organized into myonemes and where cytoplasmic fibrils are organized in striated and contractile strips (**Figure 11a, b, b'**). We were the first to observe these striated fibrillar structures in *N. scintillans*, that are similar to the striated myonemes in its contractile tentacle [42,46]. Myonems are inserted on the epiplasmic membrane (E), equipped with a large number of microtubule rows (**Figure 11d**, arrowheads) that are crosslinked with each other (**Figure 11d,** arrows) [42]. Striated myonemes are distributed along the tentacle or linked to one another by a knot (**Figure 11b, c)**. Tentacle contraction involves ectosarc deformation, myoneme contractility, and microtubule modifications [46].

The cytostome opening and closing **(Figure 12a-c**) during prey capture is ensured by a complex system of curtains of striated (contractile) fibers (**Figure 12d**) that run between the cytostome and are anchored at a reinforced furrow or sulcus (schematized in **Figure 12a, e**) [42]. Preys include pollen grains, other protists, sometimes even congeners. It is amusing to note that this is one of the first recorded cases of cannibalism in the Kingdom Protista.

Scale bar = 1µm. **(e)** Schematic representation of the connection between the anchoring sulcus (S) and the cytostome (Cy) by long ribbons of myonemes (My). **a-e**: Reproduced from Soyer-(Gobillard), M.O., Les ultrastructures liées aux fonctions de relation chez *Noctiluca miliaris* S. (Dinoflagellata). *Z. Zellforsch. (Cell and Tissue Research*), **1970**, *104*, 29- 55, [42]. Courtesy of Springer Nature.

Phylogenetic analyses of this complex cell, using the gene sequences of beta-tubulin, HSP90 [47] or nuclear 28S rDNA [48], support its placement among dinoflagellates, not far from *Oxyrrhis marina* Dujardin. These species do not have a theca and probably appeared very early in the Precambrian era, according to Dale [8].

4.2.2. Other Free-Living Bioluminescent Dinoflagellates: An Homage to Edouard Chatton's Scientific and Artistic Talents [3]

 doi:10.20944/preprints202503.1826.v1

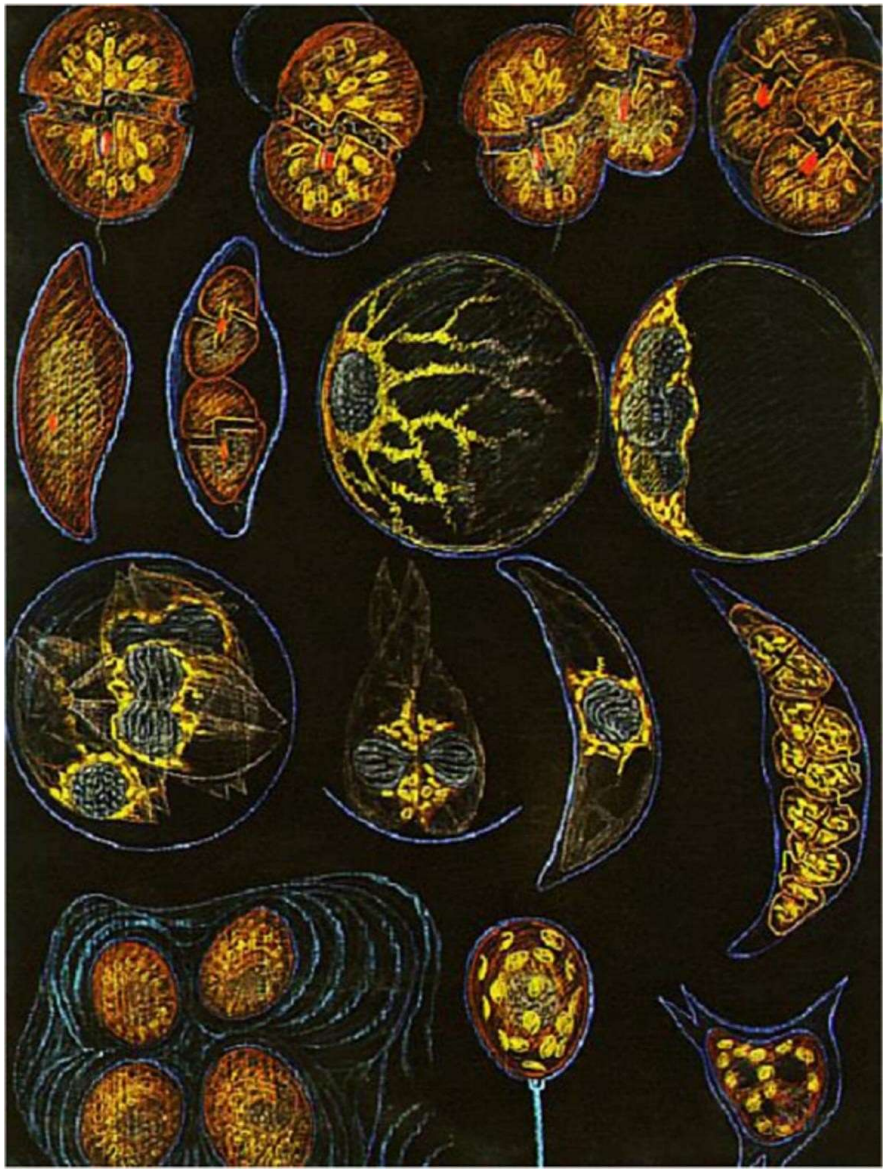

Figure 13. Several free-living bioluminescent (athecate) dinoflagellates and the life cycle of the genus *Pyrocystis* Murray ex Haeckel, 1890. E. Chatton (1930) represented these species on a magnificent course board (160/110cm) drawn with colored pastels on black paper, for his students [3]. The species *Pyrocystis pseudonoctiluca* Wyville-Thomson, 1876, is in the second row on the right; *Pyrocystis lunula* Schütt 1896 is in the third row, on the right. The blue color of the amphiesma simulates their bioluminescence in the night. In these species, this phenomenon has been described as well as its chemistry and molecular control [38,39]. 4.2.3. *Crypthecodinium cohnii* Biecheler

4.2.3.1. General Features

The heterotrophic dinoflagellate *C. cohnii* Biecheler is a particularly fascinating protist, despite its classical biflagellate morphology (**Figure 12a**). Kubai & Ris described for the first time its mitosis [49].

4.2.3.2. Innovative Features

C. cohnii presents a complex cell cycle [50]. In the example in **Figure 14b**, one vegetative cell performs two successive complete cell cycles (16 h) and releases four daughter cells. One of these new

 doi:10.20944/preprints202503.1826.v1

swimming cells releases two daughter cells 10 h later (external circle of the diagram). During this time, other swimming cells could produce two or four daughter cells. Different diagrams could be possible with different cycle lengths and numbers of daughter cells. Immunocytochemistry and confocal microscopy analyses of the microtubular cortex and mitotic apparatus [52,53] showed a well-developed microtubular cytoskeleton (**Figure 12c**). Interestingly, we have shown that a HSP70-related protein is associated with the centrosome and is conserved from *C. cohnii* to human cells [54]. *C. cohnii* is rich in lipids [55], and among the heterotrophic marine dinoflagellates, is a prolific producer of docosahexaenoic acid (DHA), an important fatty acid [56]. Amusingly, after the publication of the study on the complex *C. cohnii* cell cycle by our laboratory [50], we were contacted on several occasions to give advice concerning the specific culture of this species by industrial groups in the USA working on the elaboration of artificial "maternal" milk or of DHA production.

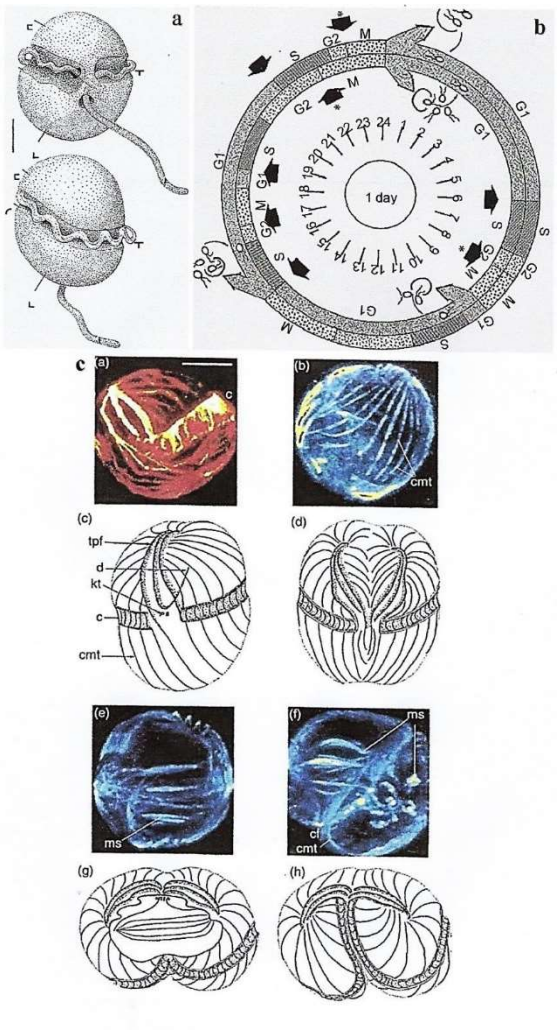

Figure 14. (a) Schematic representation of a *C. cohnii* Biecheler cell. The diagram is drawn from our previously published scanning electron microscopy images. 4.3. A Mixotrophic Dinoflagellate: Syndinium spp Chatton

4.3.1. General Features

According to the first descriptions by Chatton (1910), the main hosts of this parasitic plasmodial dinoflagellate are the pelagic copepods of the Mediterranean Sea close to Banyuls-sur-Mer, France [1,2]. The plasmodium, which has numerous nuclei with five V-shaped chromosomes and is constantly in mitosis, grows in the general cavity (coelomic cavity) of copepods and other crustaceans, rapidly destroying all their vital organs. The mature biflagellate dinospores, totally devoid of plastids, are released into the sea water and very rapidly swim to quickly parasitize another prey.

4.3.2. Innovative Features

Like *Hematodinium perezi* (Syndiniales) that was discovered by Chatton and Poisson [57] on the French coasts and parasitizes the blood of crabs, *Syndinium* sp. also can parasitize the general cavity of many crustaceans, especially copepods. Currently these Syndiniales are widespread throughout the world, and many scientists have been working to refine their molecular characterization [58,59] in connection with important economic issues because they often infest edible crustaceans. Their destructive action due to their rapid multiplication can cause the death of many crustacean species in a short time, and their power of contamination by dinospores (totally devoid of plastids) is infinite.

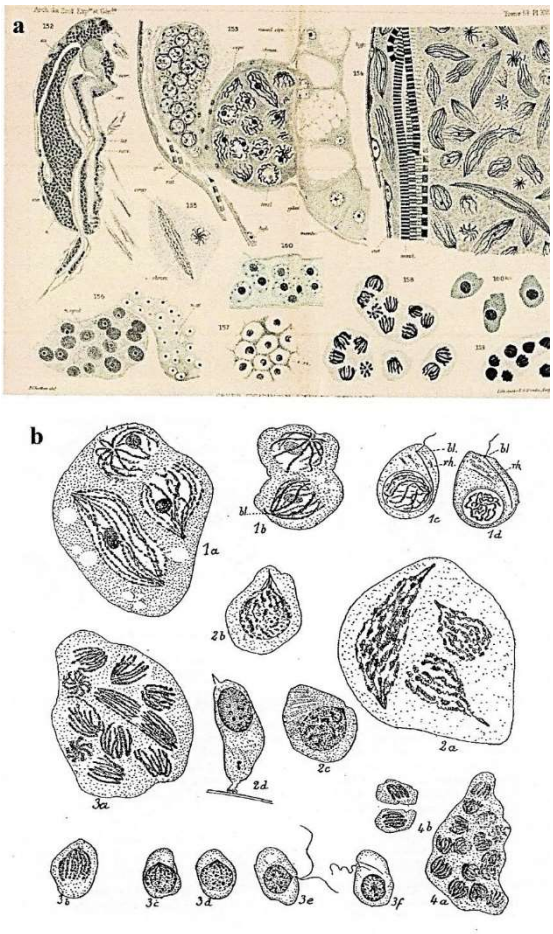

Figure 15. (a) *Syndinium turbo* Chatton, coelomic parasite of copepods. At the top, a plasmodium with nuclei containing five chromosomes. At the bottom, on the right, sporocytes with five chromosomes. *In*: *Thèse de*

 doi:10.20944/preprints202503.1826.v1

CHATTON, E. Plate XIV*: Les Péridiniens parasites. Morphologie, reproduction, éthologie. Arch. Zool. Exp. Gen.*, **1919**, *59,*1– 475. *E. Chatton del*. [1]. **(b)** Plasmodia with dividing nuclei and dinospores (bottom). 1. *Syndinium rostratum*; 2. *S. corycoei*; 3. *S. turbo*; 4. *S. microsporum*. *E. Chatton del.* From Titres et Travaux Scientifiques by Chatton [2]. *E. Chatton del*.

Chatton considered syndinian mitosis as a particular mitosis in dinoflagellates [60] and described it in detail (Figure 17a, b) [1,2] in several different species that parasitize various copepod crustaceans or radiolarians. Subsequently, TEM observations by Ris and Kubai (1974) showed the originality of this mitotic system [61]. The compacted chromosomes are attached to the extranuclear microtubular mitotic spindle through the nuclear membrane by means of kinetochores via a large cytoplasmic channel [61,62]. They are connected to the centrosome region that contains two centrioles (Figure 16a) and to microtubules of the mitotic spindle. It is important to note that kinetochores appeared for the first time within dinoflagellates in the kingdom Protista.

Figure 16. TEM images of *Syndinium sp.* **(a)** One dividing cell showing one of the five V-shaped chromosomes linked by microtubules of the mitotic spindle to one of the two centrioles that compose the centrosome (white arrows). Scale bar = 0.5µm From Ris, H. and Kubai, D.F. An unusual mitotic mechanism in the parasitic protozoan *Syndinium* sp. *Journal of Cell Biology*, **1974**, *60*, 702–720, [61]. Courtesy of The Rockefeller University Press. **(b)** Sporocyte of *Syndinium sp.* just before its emission from the coelomic cavity. No plastid is visible. The chromosomes are fragmented in the nucleus and an external flagellum is visible (arrow). Scale bar = 0.5µm. From Soyer-(Gobillard) M.-O. Etude ultrastructurale de *Syndinium sp.* Chatton, parasite coelomique de Copépodes pélagiques. *Vie Milieu Life & Environment*, **1974**, *XXIV*, 191-212, [62]. Courtesy of *Vie Millieu Life & Environment*.

In his different descriptions of *Syndinium* sp., Chatton observed three different spore types, with different sizes **(Figure 15b)** [2], that parasitize two different copepod species (*Clausocalanus arcuicornis* and *Paracalanus parvus*) and wondered about their roles. Later, Skovgaard et al. (2005) [58] using full-length SSU rDNA sequences of *Syndinium turbo* from these two copepod hosts concluded that the three spore morphotypes are 100% identical and belong to a single species, *Syndinium turbo* Chatton. Moreover, phylogenetic analyses place *Syndinium* as a sister taxon of *Hematodinium* sp., a blue crab parasite according to Chatton and Poisson. The main innovations in *Syndinium* sp. essentially concern motility, nutrition and reproduction (sexual or not) and also the appearance of histone-like basic nuclear proteins linked to their DNA [61,62] as well as the presence of kinetochores during mitosis [61].

 doi:10.20944/preprints202503.1826.v1

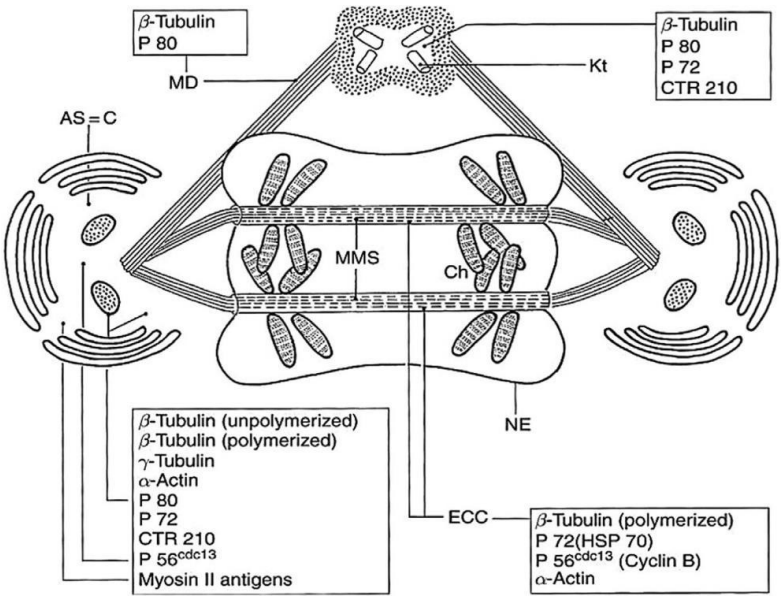

Figure 17. Schematic representation of a dinoflagellate (except *Syndinium* and *Oxyrrhis*) mitotic apparatus in anaphase with the list of remarkable centrosome - associated proteins. Microtubular mitotic spindles lie throughout the nucleus, pass into the archoplasmic spheres (Golgi apparatus), and are linked to the two pairs of kinetosomes or flagellar bases. AS, archoplasmic sphere (containing Golgi bodies); C, centrosome (without centrioles); ECC, extranuclear cytoplasmic channel; MMS, microtubular mitotic spindle; MD, microtubular desmose; Kt, kinetosomes; N, nucleus; NE, nuclear envelope (permanent); Ch, chromosomes. Courtesy of Elsevier.

5. Dinoflagellate Mitotic Apparatus as an Evolutionary Marker

Despite the great dinoflagellate diversity in terms of innovations, physiology, lifestyle and cell cycle, they have a remarkably homogeneous mitosis mechanism, except for *Syndinium* spp., *Oxyrrhis marina* and some *Amoebophrya* species. The system of cytoplasmic channels passing through the intact nucleus indicates that microtubules are never in direct contact with the chromosomes, but are always separated from them by the persistent nuclear envelope, as shown in the "models" *C. cohnii* Biecheler and *P. micans* Ehrenberg (**Figure 17**) [63,64].

It should be noted that the kinetochores (contact between chromosomes and mitotic spindle) and the polarized centrosomes, which contain two centrioles that govern mitosis, were first observed in Syndinidae. This kind of mitosis has been particularly well studied by Ris and Kubai (**Figure 18a-f**). [61]

 doi:10.20944/preprints202503.1826.v1

Figure 18. Schematic representation of nuclear division in *Syndinium* sp. (**a**) Interphase. (**b**) Early division: centrosome (two centrioles), kinetochores and chromosomes have duplicated. (**c**) Early stage of chromosome segregation. Central spindle between separating centrioles. (**d**) Late stage of chromosome segregation. Central spindle in cytoplasmic channel throughout the nucleus. (**e**) Division of nucleus. (**f**) Early daughter nucleus with persisting channel and microtubules. Reproduced from Ris, H. and Kubai, D.F., An unusual mitotic mechanism in the parasitic protozoan *Syndinium* sp. *Journal of Cell Biology*, **1974**, *60*, 702–720, [61]. Courtesy of The Rockefeller University Press.

From all the precedent data and from their own findings in *Amoebophrya* spp., Moon et al. (2015) observed that not all species classified as dinoflagellates have an extranuclear spindle [64]. For instance, in some *Amoebophrya* spp. species, an extranuclear microtubule cylinder, located in a depression of the nuclear surface during interphase, moves into the nucleoplasm via sequential membrane fusion events and develops into an entirely intranuclear spindle [64]. Their results suggest that the intranuclear spindle of *Amoebophrya* spp. may have evolved from an ancestral extranuclear spindle, as shown on the phylogenetic tree of different mitotic apparatuses in **Figure 19**.

6. A Rather Perfected System: The Eyespot (Ocelloid) of Dinoflagellates

Surprisingly, the eyespot (ocelloid) is one of the most evolved photosensitive organelles in protists [5] and is considered an important phylogenetic marker in dinoflagellates. The ocelloid is present in several heterotrophic athecate dinoflagellates from the *Warnowiaceae* family, such as *Nematodinium, Warnowia, Erythropsis,* in several *Woloszynskioids*, and in the autotrophic *Glenodinium* (*Peridinium*) *foliaceum* Stein, a binucleate dinoflagellate, with both a dinokaryon and another nucleus probably of endosymbiotic (diatom) origin. Greuet (1965) published the first description of an eyespot in the dinoflagellate *Erythropsis pavillardi* Hertwig [65], as reported by Gehring (2001) [66], and then Francis (1967) in *Nematodinium spp.* [67]. By TEM, Greuet showed that this most sophisticated structure is ~25 µm long and 15 µm wide [68–70]. Its main characteristics is the presence of a transparent and domed hyalosome, which plays the role of the lens, and of a pigment layer, which plays the role of the retina **(Figure 20A, B**). This complex photosystem was observed in many species of the family of heterotrophic *Warnowiidae* [71,72], and also in the binucleated dinoflagellate *Glenodinium foliaceum* Stein, now *Kryptoperidinium triquetrum* (Ehrenberg) U. Tillmann, M. Gottschling, M. Elbrächter, W.-H. Kusber & M. Hoppenrath, 2019. Its light transmission mechanism was elucidated by Kreimer [73].

 doi:10.20944/preprints202503.1826.v1

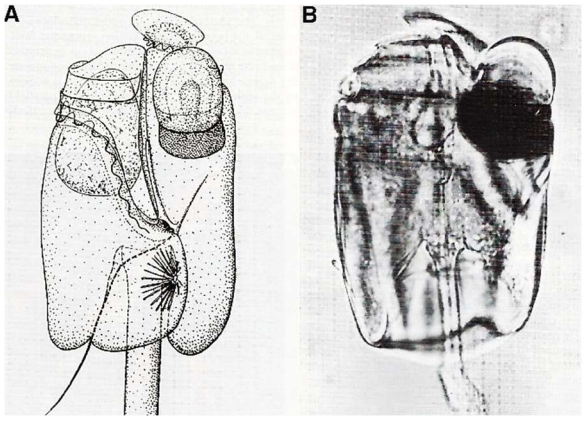

Figure 20. Ocelloid of the dinoflagellate *E. pavillardi* Hertwig. **(a)** Schematic drawing of *E. pavillardi* in which the eyespot is represented on the right of the cell. **(b)** Light microscopy image showing the hyalosome, which plays the role of the lens (upper part) and the pigment, which plays the role of the retina. From Greuet C. Structure fine de l'ocelle d'*Erythropsis pavillardi* Hertwig, Péridinien Warnowiidae Lindemann. *C. R. Acad. Sci*. (Paris), **1965**, *261*, 1904-1907, [65].

In 1999, Kreimer (1999) [73] described the eyespot of the binucleated *G. foliaceum* in which two DNA types from two nuclei (a dinokaryon and a nucleus of endosymbiotic origin of diatom type) and two chloroplast types of the same origin have been detected in this protist [74]. In this dinoflagellate, eyespot is located in the posterior part of the cell close to the sulcus. It is composed of a pigment cup, retinoid, and lens and functions as a photoreceptor **(Figure 21a, b)** through which light can pass and be reflected outside, or can pass through the protist body before being reflected back out **(Figure 21A, B).**

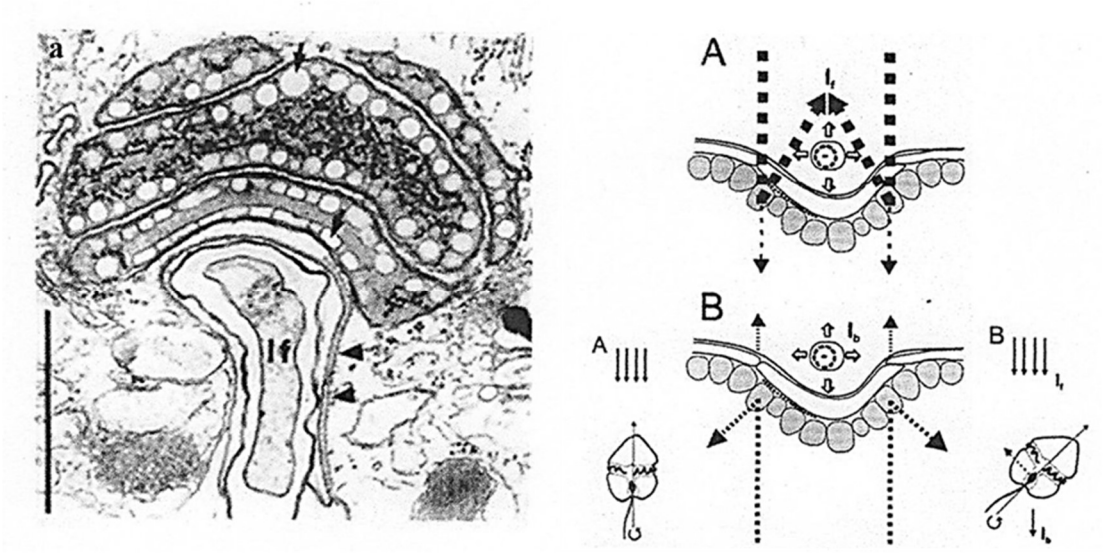

Figure 21. TEM image of the eyespot of the binucleated dinoflagellate *G. foliaceum* in transverse section **(a)** localized in the posterior part of the cell. The images show the layers of refracting globules that form the pigment cup, composed of carotenoid-rich lipids through which light passes **(A)** and/or is reflected **(B)**, which determines the cell orientation, according to Kreimer's hypothesis. The longitudinal flagellum (lf) is visible in the hollow of the posterior sulcus. Reproduced from Kreimer G. (with permission). Reflective properties of different eyespot types in Dinoflagellates. Protist, **1999,** *150*, 311-323, [73]. Courtesy of Elsevier.

The eyespot of Warnowiidae is located in the anterior part of the cell. In *Erythropsidinium spp*., a heterotrophic dinoflagellate with a posterior appendage called piston that plays a role in its

 doi:10.20944/preprints202503.1826.v1

locomotion, the eyespot occupies a significant volume of the cell (**Figure 22a**). Walter Gehring† (1939-2014), to whom I would like to pay special tribute here, worked on the genetic control of eye development and the evolution of eyes and photoreceptors in animal kingdom [66,75]. From the work of Greuet [65,68–70], he thought that the dinoflagellate ocelloid represents an evolutionary enigma because it looks like a multicellular camera-type eye, but is found in a unicellular protist. Then, in 2015, , Hayakawa et al., with Walter Gehring [76] used TEM to determine whether the dinoflagellate ocelloid is functionally photoreceptive. They found that this sophisticated structure is composed of a retina and lens-like structures called retinal body and of a transparent hyalosome (the lens) (**Figure 22b**). Moreover, they observed that the retinal body changes its morphology depending on the illumination conditions and that the hyalosome displays a refractile nature. Lastly, they identified a rhodopsin gene fragment by in situ hybridization in *Erythropsidinium* expressed sequence tags (ESTs) that is expressed in the retinal body [76] and is most closely related to bacterial rhodopsin. Therefore, with Gavelis et al. (2015), they could strongly affirm [77] that "Eye-like ocelloids of dinoflagellates are built from different endosymbiotically acquired components".

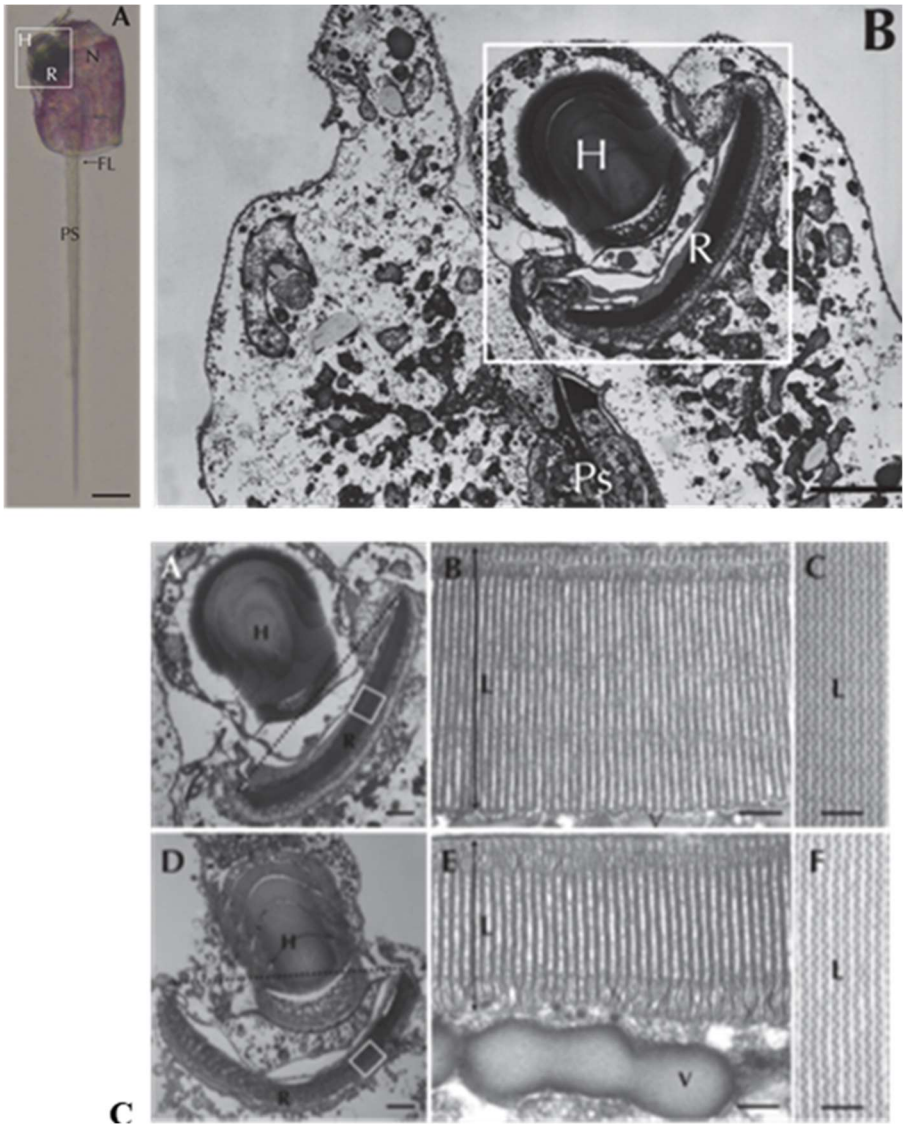

Figure 22. *Erythropsidinium spp***.** dinoflagellate equipped with a piston (PS) involved in locomotion in water. **(a)** General view of the cell with the ocelloid in the left anterior part of the cell (square). Scale bar = 20µm. **(b)** Fine structure of the ocelloid: hyalosome (H), which plays the role of the lens, and lamellated retina-like body (R). Scale bar = 10µm. **(c)** In the ocelloid of *Erythropsidinium* spp., the retinal body (R) can change its morphology when the light conditions change (from light, A-C, to dark, D-F).  doi:10.20944/preprints202503.1826.v1

7. Conclusions

As reported by Hayakawa et al. (2014) [76], Darwin wrote in his work "On the Origin of Species" [78] that the eyes are an example of organs of extreme perfection and complication. Darwin was convinced that they had only appeared thanks to natural selection. In the case of the *Erythropsidinium* ocelloid, a highly elaborate camera-type eye that resembles part of the metazoan eye [76,77] has evolved in a single cell, a protist dinoflagellate, and is probably the vestige of endosymbiosis. Despite the great diversity of these protists in terms of taxomony and innovations, and the fact that some specific proteins associated with the centrosome are conserved up to human cells (e.g., HSP70-related protein) [54], right (B-) and left (Z-) handed DNA in their chromosomes [19], we observe the result of their evolution as it appears today, after more than 1,500 million years since the beginning, probably dating back to the Proterozoic era according to Brian Dale [8]. Much research is still be necessary to try to solve these enigmas.

Funding: All the scientific career of M.-O. Soyer-Gobillard and her research on Dinoflagellates were supported by the French National Center of Scientific Research. Pages charge coast are partially covered by MDPI Vouchers after the realization of several reviews of articles by the author.

Acknowledgments: The author would like to thank Prof. Linda Medlin, The Marine Biological Association of the UK, and Prof. Mona Hoppenrath, Institut für Biologie und Umweltwissenschaften (IBU), Germany, who encouraged me to write this review. Mrs Marie Albert†, Françoise de Billy, Marie-Line Géraud-Escande and Danièle Saint Hilaire† are warmly acknowledged for their technical support. The author warmly acknowledges Dr Elisabetta Andermarcher for critical review of the manuscript.

Conflicts of Interest: The author declares no conflict of interest.
