Realization of Maxwell’s Hypothesis

A Heat-Electric Conversion in Contradiction to the Kelvin Statement

Maxwell’s demon    entropy decreasing    energy regeneration    energy circulation

Abstract
In a vacuum tube, two identical and parallel Ag-O-Cs surfaces, with a work function of approximately 0.8eV, ceaselessly emit thermal electrons at room temperature. The thermal electrons are so controlled by a static uniform magnetic field that they can fly only from one Ag-O-Cs surface to the other, resulting in a potential difference and an electric current, and transferring a power to a resistance outside the tube. The ambient air is a single-temperature heat reservoir in the experiment, and all the heat extracted by the tube from the air is converted into electric energy without producing other effects. The authors maintain that the experiment is in contradiction to the Kelvin statement of the second law of thermodynamics.

We have a video on you tube showing the main measuring process of the experiment: https://www.youtube.com/watch?v=PyrtC2nQ_UU.

1. Fundamental Concept

In a vacuum tube there is a quartz plate whose upper surface is coated with two identical and parallel thermal electron emitters, A and B, as shown in Fig.1. A gap between A and B insulates them from each other. The whole tube is immersed in a single-temperature heat reservoir whose temperature is such that A and B ceaselessly emit thermal electrons.

![Fig.1](image1)

Fig.1  Two identical thermal electron emitters, A and B, are set parallel in a vacuum tube.

Fig.2 (a) illustrates the motion of the thermal electrons emitted from two points located symmetrically on A and B while no magnetic field is applied to the tube. Some electrons emitted by A can travel across the gap and fall on B, and simultaneously an
approximately equal number of electrons emitted by B can also travel across the gap and fall on A. The two tendencies cancel, resulting in no charge distribution (whether positive or negative) on A or B.

Now, if a static uniform magnetic field is applied to the tube in the direction parallel to the gap, the paths of electrons will change into circles with different radii, swifter electrons flying along larger circles and slower ones along smaller circles. As shown in Fig.2 (b), now a certain part of the electrons emitted by A can travel across the gap and fall on B, but it is now difficult for the electrons emitted by B to travel across the gap and fall on A. Such a net migration of electrons from A to B will rapidly result in a charge distribution, with A charged positively and B charged negatively. A potential difference between A and B is established, resulting in a direct current and an electric power both transferred to a resistor or a reversible battery outside the tube.

(The above discussion neglects the effect of thermal electrons’ collisions with the glass tube wall, otherwise, due to the collisions, some of the electrons emitted by B may also fly across the gap to fall on A. Nevertheless, mostly, the flow of electrons from A to B prevails over the opposite flow.) [1] [2]

Reverse the direction of the magnetic field, as shown in Fig.2 (c), the direction of the electrons’ migration (from A to B), as well as the direction of the output current in the resistor, reverse, too.

There is a problem here: where does the electric power originate?

It is the heat extracted by the electron tube from the heat reservoir (in which the tube
is immersed) that provides the power. We explain this heat-electric conversion process as follows.

In Fig. 2(b), as A is charged positively and B charged negatively, a static electric field between them (especially in the region above the gap) emerges immediately. The direction of the static electric field is to resist the succeeding thermal electrons’ flight from A to B.

Let’s investigate the flight process of the electrons from A to B. As an example, at the middle of the upper part of Fig. 3, we see an electron with a velocity $v$ is flying rightward, and the force exerted on it by the static electric field $F$ is leftward, so the electron will be decelerated by the force. Nevertheless, a certain part of the electrons emitted by A (chiefly the faster ones), relying on their kinetic energy, can overcome the resistance of the static electric field and travel across the gap to fall on B. On arriving at B, each electron obtains an amount of electric potential energy in exchange for an equal amount of the electron’s kinetic energy. Thus these electrons “cool down”. Consequently the two emitters and then the whole electron tube cool down (may be slightly.) It is also explicit that as electric energy is continuously transferred to the outside resistance, the tube is losing its internal energy, so it should cool down, which is compensated by the heat the tube extracts from the surrounding heat reservoir.

In the above process, the electron tube extracts heat from a single-temperature heat reservoir and all the heat is converted into electric energy without producing other effect. We maintain that the process is in contradiction to the Kelvin statement of the second law of thermodynamics.

As is well known, in 1871, to challenge the absoluteness of the second law of thermodynamics, James Clerk Maxwell came up with a famous hypothesis — Maxwell’s demon[^1][^4]. According to Maxwell, Ehrenburg and some others, a demon may work in either of the two following modes[^8].

[^1]: Preprints (www.preprints.org) | NOT PEER-REVIEWED | Posted: 14 March 2017  doi:10.20944/preprints201607.0028.v4

In the first mode, as shown in Fig. 4 (a), the demon allows only the swifter molecules to pass through a small doorway and move from A to B, and the slower ones to pass through the doorway from B to A, causing eventually a difference in temperature between A and B.

In the second mode, as shown in Fig. 4 (b), the demon only allows the molecules to pass through the doorway from A to B, never from B to A, causing eventually a difference in pressure between A and B.

In our present design, the magnetic field functions as a demon, working in the second mode: It allows thermal electrons only to flight from A to B, causing a difference in electric potential between A and B and an output current.

Applying a static magnetic field in such a way does not need expenditure of work.

The following is an actual experiment we performed recently, showing how thermal electrons in a vacuum tube move in a magnetic field, causing an electric potential difference, a current, and an output power.

2. THE ELECTRON TUBE USED

A. Choice of thermal electron emitters and working temperature

In principle, any of the thermal electron cathode materials known today may be used for such an experiment. However, in order to accomplish an original and straightforward experiment, we chose Ag-O-Cs cathode material. Ag-O-Cs has the lowest work function among all the known thermal electron materials, about 0.8 eV, and is currently optimum in maximizing thermal electron emission at room temperature \[^6\]. We adopted this material and let the tube and the whole closed circuit shown in Fig.1 to operate under a uniform room temperature, so as to avoid disturbances arising from the Seebeck effect, etc.

Ag-O-Cs cathodes are in nowadays widely used in photoelectric tubes and photomultipliers, and their emission of thermal electrons is commonly referred to as
dark current. Users certainly prefer weak-dark-current Ag-O-Cs cathodes. Manufacturers adjust their technology and craft to produce cathodes with a low dark current, usually in the range $10^{-11}$ to $10^{-14}$ A/cm$^2$. In our experiment, on the contrary, we desired to use emitters of strong-dark-current. The authors adjusted the manufacturing technology and craft repeatedly over the past 18 years and succeeded in producing tubes with Ag-O-Cs emitters with a dark current in the range of $10^{-7}$ to $10^{-10}$ A/cm$^2$.\[7\]

In this experiment, the tube plays the role of an electric power source, and the load of the power source may be a resistor or a reversible battery. In our present tests, we used the input resistor of an electrometer, Keithley 6514, together with (in series) a resistor of $150\,\Omega$ as the load. In such an arrangement, the electrometer might simultaneously be used to measure the output current produced by the electron tube. A similar circuit may also be used to measure the output voltage. Working at room temperature, the whole closed circuit was readily kept at a rather uniform temperature.

**B. The structure of the electron tube**

The electron tube used in the present experiment was an FX12 type tube (actually the tube FX12-51, or, FX51(12)), whose structure is shown in Fig.5. The envelope was of glass. A and B, see Fig. 5 (a), were two identical Ag-O-Cs thermal electron emitters mounted on the tops of two parallel copper bars. Between the two copper bars there was a mica sheet (the gap), keeping A and B mutually insulated. The upper side of the
A mica sheet was in the same level with the two emitters A and B. Under the two copper bars, the mica sheet (in the gap) stretched out about 7mm, so as to prevent electrons cycling back from B to A in the space of the lower part of the tube. M, N and P were three molybdenum supporting rods. M and N were simultaneously used as electrical leads separately connecting A and B to the load outside the tube. P was 6mm above the gap, and was used as a temporary anode in the tube manufacture process to oxidize the silver films of A and B by oxygen-discharge. After the manufacture of the tube, P was again used as a temporary anode to measure the dark current of the two emitters to check the quality of the tube. The typical dark current of each emitter of the FX12 type tubes was $500 \sim 500,000$ pA.

Finally, the leakage resistance between A and B should be at least greater than 100MΩ. The value of this leakage resistance depends chiefly on the amount of cesium input during the manufacture.

3. MEASUREMENT OF THE MAGNETIC FIELD AND OUTPUT CURRENT

a) The magnetic field

The magnetic field used to deflect the orbits of the thermal electrons was produced by a 150 mm × 100 mm × 25 mm magnet (Ceramic 8, MMPA Standard). Fig. 6 shows the magnetic induction intensity $B$ at point O on the axis of the magnet, a distance $d$ apart. The $B \sim d$ relation was measured in advance with a tesla-meter, and the results are listed in Table 1. In our experiment of thermo-electric conversion, the electron tube was placed at point O, within a shielding box, with the tube axis parallel to the magnetic field.

b) The output current and voltage

The output current of the electron tube was measured using a Keithley 6514 electrometer with a highest current sensitivity of $1 \times 10^{-16} \text{A} = 0.1 \text{fA}$. A simple diagram of the measuring circuit is shown in Fig. 7.

![Diagram of Current Measuring Circuit](image)

Fig. 7 Current measuring circuit (with or without a resistor 150M$\Omega$ in series.)

In addition to the output current, the electrometer with the circuit was also used to measure the output voltage of the electron tube. The highest voltage sensitivity of Keithley 6514 is $1 \times 10^{-5} \text{V} = 0.01 \text{mV}$.

4. THE EXPERIMENT

Fig. 8 (a) is a photograph of the set up of the experiment, from left to right: a Keithley 6514 electrometer, a copper shielding box (containing electron tube FX12-51), and the magnet. Fig. 8 (b) shows how the electron tube lay within the copper shielding box. The anticipated output current or output voltage caused by a static magnetic field was transferred to the electrometer through a special accessory cable.

![Experiment Set Up](image)

(a) A Keithley 6514 electrometer, a copper shielding box (containing FX12-51), and a magnet. (b) Position and orientation of electron tube FX12-51 in the copper shielding box.

Fig. 8 Set up of the experiment
First, we chose a room temperature, which should be rather uniform and stable. Switch on the electrometer. Since the magnet was yet far from the tube, \( d \approx \infty, B \approx 0 \), the tube should produce no output current, \( I \approx 0 \). However, actually, \( I \) was not exactly zero at that time. There was a background current caused chiefly by the very small differences in temperature distributed along the closed measuring circuit, may be, 0.1 °C, 0.2 °C, 0.3 °C, etc. The background current changed from day to day, even from hour to hour. Fortunately, in most cases, it was much smaller than the output current produced by the magnetic field. Of course, the weaker the background current, the better it was for our experiment. The influence of the earth magnetic field to this experiment was small, we neglected it.

We then applied a weak positive magnetic field to the tube, and denoted it by \( B_+ \). For example, \( d = 60 \text{cm}, \) and \( B_+ = 0.6 \text{ gauss} \). The compass placed on the top of the copper box demonstrated the direction of the magnetic field, (which should be adjusted to be parallel to the axis of the tube in all the steps of the whole measuring process.) We observed that the tube now put out a weak but stable current.

The magnetic induction intensity of the field was then increased in steps by reducing the distance \( d \) between the tube and the magnet. During each step, we let the magnet remain stationary for a period of several minutes (so as to exclude disturbance of Faraday’s electromagnetic induction), and we found that the output current firstly changed quickly, and soon after that, it reached a stable value and then kept the stable value unchanged as long as the magnet kept stationary. From the beginning when \( B_+ \approx 0 \) and \( I \approx 0 \), as \( B_+ \) increased in steps, the output current \( I \) (i.e., the stable value of each step) also increased, until \( I \) reached a maximum value. After that, \( I \) decreased as the magnetic field increased further. This drop down of the output current accorded with our expectation: as the magnetic field became stronger and stronger, the radii of thermal electrons became smaller and smaller, resulting in an increasing proportion of electrons that were no longer able to cross the gap to fly from A to B, causing the output current to progressively reduce.

The magnet was then returned to the position of \( d = 60 \text{cm}, \) and rotated through 180°. The direction of the magnetic field in the copper shielding box consequently reversed. The magnetic field was now negative and denoted by \( B_- \). As we expected, the direction of the output current also reversed. We then again reduced the distance \( d \) in steps to...
increase the intensity of the magnetic field $B$. The output current first increased, then
decreased after reaching a maximum value. The situation was similar in pattern to that
with a positive magnetic field.

Further experiment showed that, in each step, provided the magnetic field remained
stable (i.e., the magnet kept stationary), the output current $I$ would remain stable, with
periods of stability possible for as long as several minutes, several hours, and even
several days.

We call the output current of the electron tube Maxwell’s current and denote it by $I$.
In general, the Maxwell’s current for a given FX tube depends on two factors, the
temperature $T$ and the magnetic induction intensity $B$.

$$I = I(B, T).$$

Tables 2, 3 and 4 list the data from three tests at three different temperatures, 10°C,
22°C and 32°C. The corresponding $I \sim B$ graphs are shown in Figs. 9 (a), (b) and (c).

From $t = 10^\circ C$ to $t = 33^\circ C$, the temperature rose only 23°C, nevertheless, the output current rose
from 40fA to 1600fA, 40 times! This can be finely explained by Richardson’s formula: thermal
electron emission rises very rapidly as the temperature rises,

$$J = A T^2 e^{\frac{W}{kT}}.$$
Fig 9 The $I \sim B$ curves of electron tube FX12-51 at three different temperatures.
Keithley 6514 electrometer may also be used to measure the output voltage produced by the electron tube when a magnetic field is applied. The voltage here is actually the open-circuit voltage of the tube, or the electric motive force of the tube. This output voltage chiefly depends on the average kinetic energy of the thermal electrons of the emitters, i.e., depends on the temperature. Nevertheless, we noted that the leakage current between the two emitters might also affect the value of the output voltage.

The following were the output voltages we measured from electron tube FX12-51 in a test at room temperature of $T = 25^\circ C$ (298K):

- Background voltage $B \approx 0$, $V_o = -5.6 \text{ mV}$.

The maxima of the output voltages when a magnetic field was applied to the tube were also stable provided the magnet kept stationary, each measured for four times

$$
B \uparrow \approx 3.5 \text{ gauss } V = -20 \hspace{1em} -21 \hspace{1em} -20 \hspace{1em} -21 \text{ mV},
$$

$$
B \downarrow \approx 3.5 \text{ gauss } V = 16 \hspace{1em} 18 \hspace{1em} 16 \hspace{1em} 17 \text{ mV}.
$$

According to Boltzmann’s law of equi-partition of energy, the average kinetic energy of thermal electrons at $25^\circ C$ (298K) is

$$
\bar{\varepsilon} = \frac{3}{2} kT = \frac{3}{2} \times 1.38 \times 10^{-23} \times 298 \text{ J} = 0.0385 \text{ eV} = 38.5 \text{ mV}
$$

In $38.5 \text{ mV}$, the factor $38.5 \text{ mV}$ is of the same magnitude order with the output voltage we measured in our experiment (about $20 \text{ mV}$). Therefore, we saw, the output voltages were surely resulted from the conversion of part of the kinetic energy of the thermal electrons.

Both the output current and output voltage from our experiment were very weak, nevertheless, they were no doubt DC current and DC voltage, both being macroscopic ones. A large number of such Ag-O-Cs pairs could be connected in parallel to increase the output current, in series to increase the output voltage, so as to build up a considerably greater electric power output.

### 5. CONCLUSIONS

In the above experiment, the heat extracted by electron tube FX12-51 from the ambient air converted completely into electric energy without producing any other effect. The process proves that the second law of thermodynamics is not universally valid, just as Maxwell and Planck had predicted many years ago.\[^{[3]}[^{[4]}\]
The authors maintain: in ordinary thermodynamic processes, just as Clausius and Kelvin correctly pointed out, entropy always increases, never decreases. Nevertheless, in some specific or extraordinary thermodynamic processes, such as the process in our present experiment, entropy does decrease.
