

Network Analysis: A Novel Approach to Understand Suicidal Behavior

Derek de Beurs

Netherlands Institute for Health Services Research, Otterstraat 118-124, Utrecht, The Netherlands;
d.debeurs@nivel.nl

Abstract: Although suicide is a major public health issue worldwide, we understand little of the onset and development of suicidal behavior. Suicidal behavior is argued to be the end result of the complex interaction between psychological, social and biological factors. A new approach called network analysis can help us better understand suicidal behavior as it allows to visualize and quantify complex association between many different symptoms or risk factors. Risk factors for suicidal behaviour such as intensity of suicidal thoughts and impulsivity are thought to cause each other. A network perspective can help us understand how these risk factors interact and how their interaction is related to future suicidal behaviour. A network perspective has been successfully applied to the field of depression and psychosis, but not yet to the field of suicidology. In this theoretical article, I will introduce the concept of network analysis to the field of suicide prevention, and offer directions for future applications and studies.

Keywords: suicide; network analysis; symptoms; personalized treatment

1. Introduction

1.1 the complexity of suicidal behavior

Suicide is a major public health issue worldwide[1]. It is the tenth leading cause of death, and in many countries, numbers have been increasing since the economic crisis in 2007[2]. In the past years, many epidemiology studies have been done, and many datasets containing information on suicidal behavior are available. Still, we understand little of the aetiology and development of suicidal behavior, only that it is highly complex interplay between psychological, social and biological factors[3,4]. Traditional epidemiological analysis has resulted mostly in static, general risk factors such as age and gender. This is interesting from a public health care perspective, but not of much use for the individual patient, or his therapist. The notion that older males are at higher risk for suicide than younger females is not specific enough to be of clinical relevance. Recent models of suicidal behavior agree that suicidal behavior is the end result of the complex interaction between psychological, social and biological factors [5]. To help thinking about the complexity of suicidal behavior, the Integrated Motivational Volitional Model (IMV) was developed[3].

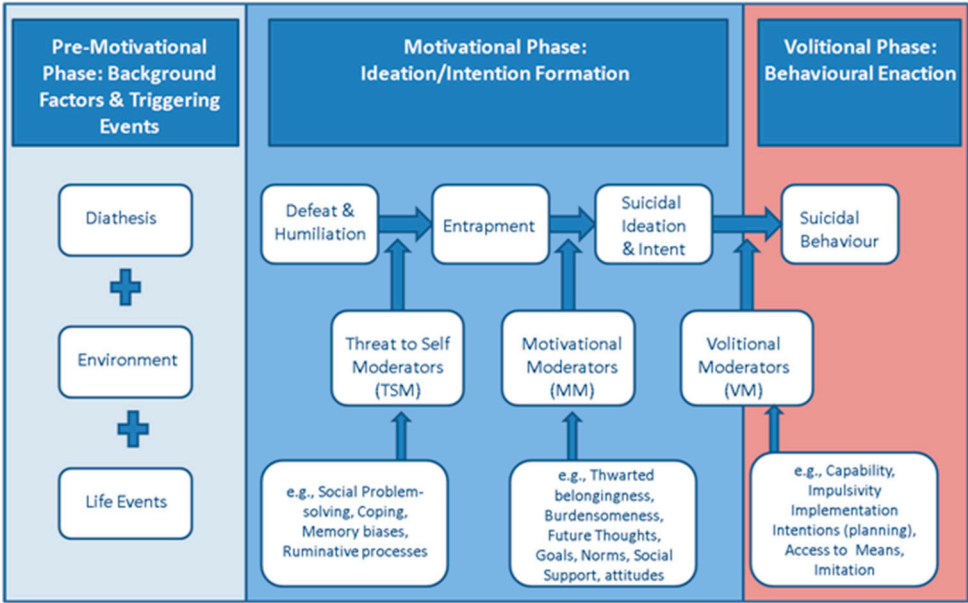

Figure one: The Integrated Motivational Volitional (IMV) model of suicidal behavior

The IMV model defines suicidal behavior as a complex interaction between many different (pre)motivational and volitional phase factors. The motivational phase of the model describes the symptoms that are associated with the emergence of suicidal thoughts. Examples are entrapment coping, rumination etc. By contrast, volitional phase symptoms are defined as those symptoms that govern the transition from suicidal thinking (ideation/intent) to suicidal behaviour, i.e., when a suicide attempt is more likely. Several studies have validated central aspects of the model. Entrapment and low levels of future thinking have been found to play a role in repeat suicidal behavior[6]. Also, as predicted by the IMV model, volitional factors were found to differentiate between suicide attempters and people with only suicidal thoughts[7]. As these studies focused on separate elements of the IMV model, the next logical step is to test the correlations between the different factors simultaneously. To understand the complex interaction between the many variables as proposed in complex models such as the IMV model, a new psychometric technique called network analysis has been proposed.

1.2. From latent variable modelling to network analysis

Traditional, the variation between psychopathological symptoms is thought to be explained by one or more common latent variables [8,9]. For example, the most used scale for suicide ideation, the Beck Scale for suicide ideation (SSI) assesses several different suicidal symptoms, such as the desire to die , the intensity of suicidal thoughts, and the planning of a suicidal act. The scores on these different symptoms are then often summed into one total sum score[10,11]. In many studies, the total score on the SSI is interpreted as an indication of the overall level of suicidality, meaning that the covariance between the scores on the separate suicidal symptoms are caused by one latent variable, suicidality (e.g. [11–13]). Indeed, traditional factor analysis found that the 19 items of the SSI are best explained by one underlying latent construct [5,14] (Fig 2).

Figure 2: The latent variable model. Suicidal symptoms such a desire to die and the intensity of suicidal thoughts can be explained by an underlying latent trait called suicidality.

This latent variable model is recently being questioned. It is argued that in psychiatry, there is no common cause, such as a tumor that causes symptoms (for example coughing). Rather, psychiatric symptoms are thought to cause each other [8,9] (Fig 2).

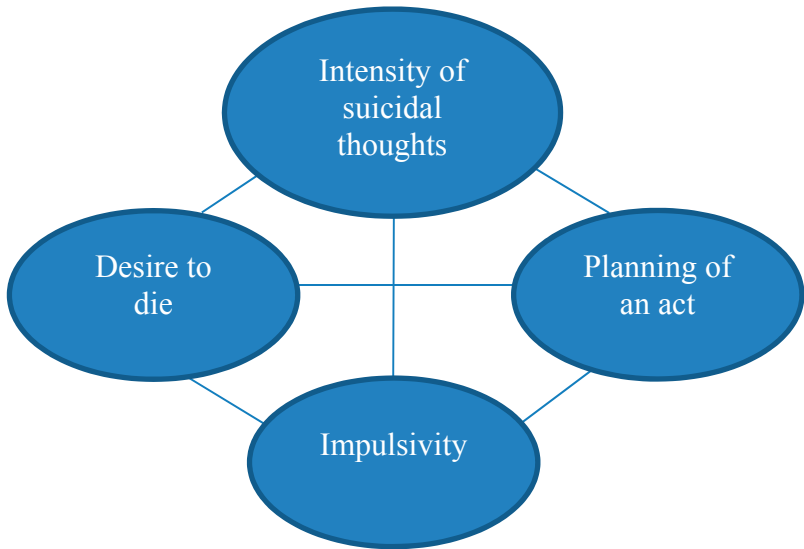

Figure 3. A network perspective on the interaction between four symptoms

In figure three, intensity of suicidal thoughts, the desire to die, planning of an act and impulsivity are related to each other, and thereby influence each other. This differs from traditional latent variable modelling which assumes that variables are explained by underlying latent variable(s). Additionally, latent modelling assumes locally independent of symptoms, i.e. the symptoms have to been independent of each other after conditioning on the latent variable. This assumption of local

dependence has been criticized due to the unlikeliness in psychopathology. For example, the wish to die and the intensity of suicidal thoughts are likely to be strongly related. This shift in thinking about psychopathology is called a network perspective [8,15]. In a network approach to psychopathology, there is no underlying disorder anymore, but only the pairwise interaction between separate symptoms (fig 2). A network perspective can help us understand how risk factors for suicidal behaviour such as intensity of suicidal thoughts and impulsivity interact and how their interaction is related to future suicidal behaviour. Within the field of psychopathology, it has been applied to the field of depression [16], psychosis [17] and Post Traumatic Stress disorder[18] , but not yet to the field of suicidology. As suicidal behavior is argued to be trans diagnostic [19]and the end result of the highly complex interaction between many factors [3], it is highly suited to be analyzed from a network perspective.

In the remainder of this paper, I will argue that a network perspective on suicidal behavior can help us to 1) Validate complex explanatory models of suicidal behavior, 2) Understand the differences between subgroups of patients, and 3) help the personalized treatment of suicidal behavior

2. Application of network analysis within the field of suicide prevention

2.1 Validating complex explanatory models of suicidal behavior

Within a network perspective, separate symptoms from the IMV model such as desire to die or impulsivity can be viewed upon as nodes in a network (Fig 4). Two nodes are connected by a line if there is any relevant association between the two nodes. Whether there is a relevant association is determined by a partial correlation matrix, in which spurious (non relevant) correlations are set to zero[20]. The freely available software package qgraph[21] lets you estimate and visualize such a network. This results can result in a graph such as shown in figure 4.

Figure 4:Hypothetical example of a network of suicide symptoms and future suicidal behavior.

Int; intensity of suicidal thoughts, pla; planning of actual suicidal behavior, imp; impulsivity, die; desire to die. sui; suicidal behavior at follow up. Green lines represent positive relationship. The thicker the line, the stronger the association.

Figure 4 is a hypothetical representation of a possible network of 4 suicide symptoms and their relation to suicidal behavior at follow up. It is not based on actual data, but illustrates that the relationship between different symptoms and suicidal behavior at follow up can be visualized as a network. In this hypothetical network, all four suicidal symptoms are related to each other, although some more strongly than others. Next, only impulsivity is directly related to suicidal behavior at follow up. More generally, one can see the network as the development of the suicidal process. One can calculate which symptoms are most central or important, i.e. connected to other symptoms[15]. These central symptoms are argued to be most contagious, and change on that symptom is most likely to trigger a negative feedback loop. Early identification and early treatment can focus on this most contagious symptom, as any interventions will likely influence other symptoms, and this symptom may serve as a smoke detector for the start of a (new) suicidal crisis.

2.2 Understanding the differences between subgroups of patients

Suicidal behavior is likely to differ between subgroups of patients. For example, it is widely known that male suicidal behavior differs from female suicidal behavior[19] [22]. Still, many studies do not take subgroup differences into account (e.g. [7,13,23]). This resulted in non-specific risk factors for suicidal behavior, that are of limited use when predicting suicidal behavior. Understanding the difference in symptom structure between subgroups of patients will help develop more sensitive diagnostics. Network analysis allow for the comparison of the network structure of subgroups of patients. As an example , I simulate the same network as in figure 4, separate for males and females.

Figure 5a and b : hypothetical network of 4 suicidal symptoms and future suicidal behavior for males and females. Int; intensity of suicidal thoughts, pla; planning of actual suicidal behavior, imp; impulsivity, die; desire to die. sui; suicidal behavior at follow up. The thicker the line, the stronger the association.

One sees that there are subtle differences in network structure for males and females. Within the network of males, impulsivity seems to be stronger related to suicidal behavior at follow up when compared to females. Also within the network of males, suicidal behavior and planning are directly related, whereas they do not seem to be related within the network of females. Additionally, it is possible to formally test the difference between networks using the R package NCT[16]. This non-empirical example gives an insight in the potential of network analysis to better understand differences between subgroups of patients. These insights can then be translated into more calibrated diagnostic criteria to determine if somebody is in risk for suicidal behavior.

2.3 Personalized treatment using networks based on individual data

When data is collected on multiple time point per patients (for example via a mobile phone[24]) it is possible to form a unique network per patient. The network is then not based on group level models, but on personal statistical models. Through this unique network, the patient can learn how different psychopathological symptoms interact within himself, and how to recognize the start of a new suicidal crisis. A patient can use his unique network as a tool to improve and personalize treatment. In a unique $n = 1$ study, a patient monitored her psychotic symptoms over the course of one year, answering 10 assessments a day, four days a week[25]. When presented as a network, the data provided clinically useful insights in the underlying symptom-to-symptom and symptom-to-context dynamics. It helped the patient to predict relapse, empowering the patient to gain more control over her recovery. Ideally, the unique network should be shared with professionals and significant others, and the three actors should consider the network structure when discussing therapy and safety planning. Such a research program on mobile phone data and suicidal behavior has just been started at the VU Amsterdam. The program is called CASPAR (Continuous Assessment for Suicide Prevention and Research) and will collect data among 30-60 patients in treatment of specialized health care. This data will be available end of 2017 and will offer the first opportunity to develop individual networks of suicide symptoms.

3. Discussion

Network analysis can help us to better understand the complex interaction between symptoms that result into suicidal behavior, and it can help us better differentiate between subgroups of patients. Network studies in other field of psychiatry have resulted in new insights. For one, it was found that a more densely connected network at baseline predicts the presence of depression at follow up[16]. Within the field of psychosis, network analysis revealed the relationship between childhood trauma and psychotic symptoms[17]. For individual suicidal patients, the main asset lies in the fact that they can get insights in their own unique personalized network, making personalized treatment and safety planning much more likely. As suicidal behavior is both trans diagnostic and highly complex, a network analysis of has much to offer to suicidologist, clinicians and suicidal patients.

3.2 Social networks and suicidal behavior

Within the field of sociology, a network theory of suicide was introduced as early as 1989[26]. The authors re-evaluated Durkheim's influential theory regarding the protective power of religion with regard to suicidal behavior, and showed that the impact of religion is depended on the strength of the social network it offers. Within their framework, a network theory of suicide does not exist of the relation between individual symptoms, but rather in terms of social capital and suicidal behavior[27]. As the work of Durkheim and contemporary sociologists is highly influential in the field of suicidology, I want to emphasize that this network theory is definitely of relevance, with a large tradition of research behind it[27]. It does however differ largely from the psychometric network analysis discussed in this paper.

3.3 Future studies

For the application of network analysis on suicidal behaviour, two things are needed: A large enough dataset containing relevant suicidal symptoms, and the software program R. R has a steep learning curve, but R studio offers an intuitive user interface. Additionally, there have been published many tutorial papers, and the R package qgraph offers easy to use syntax[21]. Sites like psychosystems.org offer a lively community of scientists using network analysis within the field of psychiatry.

Together with an international consortium of suicide researchers, I am reanalyzing national and internationally datasets with information on suicidal behavior from a network perspective. In the Netherlands, there are several large databases such as the NESDA (Netherlands study of depression and anxiety[28]). The NESDA is a longitudinal cohort study that collected the depressive, anxiety and suicidal symptoms of about 3000 patients. Within the Scottish Wellbeing study from the Suicidal Behavior Research Laboratory, data is collected among 3500 Scottish adolescents on many different suicidal symptoms such as entrapment, defeat, social exclusion, intrusion of images, perceived burdensomeness etc. Other datasets of interest are the national inquiry into suicide and homicide of the university of Manchester, and the Belgium self-harm database that contains data on over 15.000 patients treated for a suicide attempt in Belgium hospitals during a 26-year study period[29]. By re-analyzing these large datasets, I expect to better understand the interaction between many different suicidal symptoms, learn about the differences between male and female suicidal behavior, and zoom in on the difference between depressed patients that show suicidal behavior, and depressed patients that do not.

As network analysis is relatively new technique, there are some important disclaimers to make. For one, it is of importance to have large datasets before one can estimate a stable analysis. Although the psychometrics are still being tested, as a rule of thumb, it is argued that you need at least as many observations as you have parameters. So, for 10 symptoms, you need at least 55 observations (10 nodes + $10 \times 9/2$ possible interactions), for 20 210 and for 50 already 1250[30]. This means that when testing a complex model such as the IMV, one needs a large sample size. The only databases that are likely to be large enough are general population databases such as the Scottish Well Being study. Within these kind of data, one has to be aware of too low levels of psychopathology within the sample. Items with a low level of variability (due to the low frequency of actual "sick" people in the database), will have a low centrality within the total sample. Comparing the network structure of the total sample with the network of people with higher scores on psychopathology items is then recommended[31]. Additionally, as the example in this article is based on cross-sectional data, there is no direct evidence of causality[15]. Longitudinal studies have to prove that intervening on central symptoms indeed results in less psychopathology at follow up.

I want to point to a recent article that combined network analysis with latent trait analysis[32]. It shows that latent analysis such as structural equation modelling still is very useful, and can add novel information when combined with network analysis. Also, many other statistical innovations are being developed. For example, a recent application of machine learning algorithm using existing clinical data found indicators of patients who are likely to respond to specific antidepressants[33]. Finally, both the network theory and software are still being improved. I therefore recommend anyone interested in these kind of analysis to closely follow the papers of the psychosystems.org group.

4. Conclusion

Network analysis can help us better understand suicidal behavior as it allows to visualize and quantify complex association between many suicidal symptoms and their relation with future suicidal behavior.
