Abstract: A new method, the sessile drop accelerometry (SDACC) for the study and measurement of the interfacial energies of solid-liquid-gas systems, is tested and discussed in this study. The laboratory instrument and technique –a combination of a drop shape analyzer with high-speed camera and a laboratory drop tower– and the evaluation algorithms, were designed to calculate the interfacial energies as a function of the geometrical changes of a sessile droplet shape due to the effect of “switching off” gravity during the experiment. The method bases on the thermodynamic equilibrium of the system interfaces and not on the balance of bi-dimensional tensions on the solid-liquid-gas contour line. A comparison of the mathematical model that supports the method with the widely accepted Young’s equation is discussed in this study.

Keywords: surface energy, interfacial energy, surface tension, wetting model, wetting thermodynamics, sessile drop shape, microgravity.

1. Background

Young [1] proposed two hundred years ago that the contact angle of the three-phase contact line results from the balance of three tensors. This idea can be expressed by the following equation:

$$\gamma_s = \gamma_{sl} + \gamma_l \cos\theta_Y \quad (1)$$

where γ_s , γ_{sl} , and γ_l represent the interfacial tensions per unit length of the solid-vapor, solid-liquid, and liquid-vapor contact line respectively, i.e. the surface tensions, and θ_Y is the contact angle.

In principle, there are three important conditions for applying Young’s equation [2]: the surface has to be chemically homogeneous, completely flat and smooth, and the solid-liquid-vapor system must be free of the effects of gravity. Under these conditions, the Equation 1 represents the mechanical balance of three surface tensions along the contour line of the three phases. This balance has also been derived using the principle of minimizing the total free energy of the system [3-5]. Most recent thermodynamic derivation relies on interpreting γ_s , γ_{sl} , and γ_l as scalar thermodynamic surface energies instead of tension vectors [4].

According to Makkonen [6], a very important reason for adopting the surface energy interpretation is that, while γ_{sl} and γ_l can be interpreted either way, the surface tension on a dry solid, γ_s , is a contentious concept [3, 7-11]. Bikerman [8] and Ivanov et al. [9] have argued that Young’s equation is not a balance of forces. At the same time, the surface energy interpretation has led to many misunderstandings of the wetting phenomenon on patterned surfaces [12, 13]. The validity of Young’s equation was questioned [6] at the nanoscale [14-17] and on flexible surfaces [17-18] as well.

According to Leger and Joanny, [19] the effect of body forces such as gravity on the contact line is small for small drop volumes. Gravity would affect the shapes of wetting liquid drops in their central region where they are flattened, but in a small region, close to the contact line, one would expect that the liquid-vapor and liquid-solid interfaces to make an angle given by Young’s law.

These observations were supported by the theoretical calculations of Fujii and Nakae [20]. According to Leger, Joanny, Fujii and Nakae, only forces that become increasingly large at the contact line such as the viscous force on an advancing liquid can affect Young's law. However, recent experimental evidence using microgravity by parabolic arc flights [21] and microgravity drop towers [22-23] have demonstrated that the effect of gravity on the contact angle is relevant even at very small drop volumes such as 5 μL . According to Allen [24], who studied the wetting of very small drops with small contact angles, a drop is small enough to neglect gravitational influences only if its volume is less than 1 μL .

Of the four parameters of Young's equation, only γ_L and θ_Y can be readily measured; hence, this equation can only provide the difference between the solid-vapor surface tension γ_S and the solid-liquid interfacial tension γ_{SL} . For this reason, an additional equation providing a relation among the surface tensions in Young's equation is required, i.e.,

$$\gamma_{SL} = f(\gamma_S, \gamma_L) \quad (2)$$

Such an equation is referred to as an equation of state for interfacial tensions [25]. Combining Equation 1 with Equation 2, yield:

$$\gamma_L \cos\theta_Y = \gamma_S - f(\gamma_S, \gamma_L) \quad (3)$$

This equation was the start point for several attempts to obtain mathematical expressions or numerical procedures able to provide the values of γ_S and γ_{SL} when only the values of γ_L and θ_Y are known. The most relevant solutions [26] were given by Fox and Zisman [27], Owens and Wendt [28], Janczuk and Bialopiotrowicz [29], Wu [30], van Oss, Chaudhury and Good [31], Li and Neumann [25], Kwok et al. [32], Shimizu and Demarquette [33] and Chibowski et al. [34]. Except for the Li-Neumann method, all the mentioned solutions use a pair or more liquids to calculate the surface energy of the solid and the interface solid-liquid. Experimental results of Hejda et al. [24] show that the solution of the mathematical approaches strongly depends on the liquids used. According to these authors, the approach proposed by Li and Neumann is also impractical because its strong dependence on the liquids used for the calculations.

More recently [35], a lab-scale microgravity tower was used to calculate the surface energies by means of sessile drops. This new method, the Sessile Drop Accelerometry (SDACC), revisits the phenomenon of wetting paying more attention to its surface nature as much as the derived approaches of Young's equation have been put in the balance on the contact line of the three phases.

2. Theoretical Fundamentals of the Method

The major thermodynamic quantity which characterizes a surface or an interface is the reversible work, γ , to create a unit area of surface at constant temperature (T), volume (V), and chemical potential of component i (μ_i). This quantity is not equal to the surface free energy except under certain conditions [36]. The term surface tension was used to describe the contractile nature of surface films, i.e. their tendency to minimize surface area. This term became so entrenched in the literature that it is widely used today. Thus γ is widely called the surface tension, though the meaning of those words may have little physical significance in many situations. As mentioned above, the quantity γ is the scalar thermodynamic surface energy that characterizes the thermodynamic property of an interface.

The γ of a newly created surface is defined as:

$$\gamma = \frac{dw}{d\Omega} \quad (4)$$

i.e., the specific surface work to form $d\Omega$ new surface area.

The thermodynamics of interfaces is the same as the thermodynamics of homogeneous systems except that the work term of conventional thermodynamics must include all the $\gamma d\Omega$ components for the heterogeneous (interface-containing) systems [36]. In systems where charges or

electrical potentials are present, the electrical work must also be included. This is usually done using the electrochemical potential.

By open systems with surfaces, in the absence of other forms of work, e.g. electrical, magnetic, gravitational, etc., the Internal Energy E can be defined as:

$$dE = T dS - P dV + \sum_i \mu_i dN_i + \gamma d\Omega \quad (5)$$

The Enthalpy H is:

$$dH = T dS - V dP + \sum_i \mu_i dN_i + \gamma d\Omega \quad (6)$$

The Helmholtz energy A is:

$$dA = -S dT - P dV + \sum_i \mu_i dN_i + \gamma d\Omega \quad (7)$$

And the Gibbs free energy G is:

$$dG = -S dT + V dP + \sum_i \mu_i dN_i + \gamma d\Omega \quad (8)$$

By these systems, the creation of a new area of surface, $d\Omega$, may cause a flow of dN molecules to or from the surface region, resulting in concentration profiles [37], which lead to a surface excess (or deficiency) of component i :

$$\Gamma_i = \frac{dN_i}{d\Omega} \quad (9)$$

As a consequence:

$$\sum_i \mu_i dN_i = \sum_i \mu_i \Gamma_i d\Omega \quad (10)$$

From basic thermodynamics, the chemical potential of component i , μ_i , is given as:

$$\mu_i = \left(\frac{\partial A}{\partial N_i} \right)_{T, V, N_j, \Omega} \quad (11)$$

$$\mu_i = \left(\frac{\partial G}{\partial N_i} \right)_{T, P, N_j, \Omega} \quad (12)$$

$$\mu_i = \left(\frac{\partial E}{\partial N_i} \right)_{S, V, N_j, \Omega} \quad (13)$$

Where P = Pressure, S = Entropy, N_j = the number of molecules other than type i , and Ω = the surface area.

Using Equation 9 and applying basic thermodynamics, one can develop expressions for surface energy, surface Gibbs free energy, and surface Helmholtz energy:

$$(dE)_V = T dS + \gamma d\Omega + \sum_i \mu_i d\Gamma_i d\Omega \quad (14)$$

$$(dA)_{T,V} = \gamma d\Omega + \sum_i \mu_i d\Gamma_i d\Omega \quad (15)$$

$$(dG)_{T,P} = \gamma d\Omega + \sum_i \mu_i d\Gamma_i d\Omega \quad (16)$$

The corresponding specific energy and specific free energies are:

$$\left(\frac{dE}{d\Omega}\right)_V = e_s = T \frac{dS}{d\Omega} + \gamma + \sum \mu_i \Gamma_i = \text{specific surface energy} \quad (17)$$

$$\left(\frac{dA}{d\Omega}\right)_{T,V} = a_s = \gamma + \sum \mu_i \Gamma_i = \text{specific surface Helmholtz energy} \quad (18)$$

$$\left(\frac{dG}{d\Omega}\right)_{T,P} = g_s = \gamma + \sum \mu_i \Gamma_i = \text{specific surface Gibbs free energy} \quad (19)$$

At constant T, P, S, V , and if $\Gamma_i = 0$, $\gamma = e_s = a_s = g_s$, but only under these conditions.

In general, the surface Helmholtz and Gibbs free energies and the surface “internal” energy are different quantities. Because pressure is a more constant parameter than volume in heterogeneous systems, Helmholtz energy is usually preferred over Gibbs free energy [36].

The process of forming a new surface can be divided into two parts:

1. The phase must be cleaved to expose the new surface
2. Atoms in the surface plane rearrange to assume their equilibrium positions

In a multicomponent system, part 2 may also be combined with the migration of bulk atoms to or from the interface, i.e., the development of surface excesses or deficiencies, Γ_i . In a liquid, parts 1 and 2 occur nearly instantaneously. In a solid, part 2 may occur very slowly or not at all [36].

In a one-component system, $\Gamma_i = 0$ unless there is such a stoichiometric restructuring around the interface so as to significantly change the density of the phase near the surface.

Therefore, at a constant density in a single-component system $\gamma = a_s = g_s$, or γ is both the specific Gibbs free energy and the specific Helmholtz energy. Thus, γ can be called the specific surface free energy. At constant S (no morphological restructuring), γ will also be the specific surface energy.

γ is a thermodynamic property of an interface; it is not in general g_s , a_s , or e_s , though it may be equal to one, two, or all three of these quantities under certain conditions. The specific surface work of Equation 4 is commonly called the “surface tension”. For this reason, “surface tension” and “surface free energy” are synonymous with the understanding that both really are the specific surface Helmholtz energy.

On the other hand, surface stress is the work necessary to stretch or compress an existing surface. In a liquid this cannot be done without causing more atoms to join the surface; i.e., creating a new surface. Hence in liquids, the surface stress is γ_L (the reversible work to form new surface; i.e., surface tension. In a solid, this is not so because the lack of mobility of atoms means that a process can stretch them without causing bulk atoms to join the surface planes. Thus, the process may stretch or compress the surface of a solid without changing the number of atoms in the surface, only their distances of separation, thus producing a surface stress [36].

Figure 1. In the absence of gravity, the droplet of the state A_o (a) spontaneously spreads on the surface and reaches the state A_κ (b).

Let's consider a system where, in the initial condition that we will call the configuration o , the lower end of a liquid droplet is at an infinitesimal distance from a smooth solid flat surface of area Ω_S^o in a gas medium (Figure 1a). No force field is affecting the system (the acceleration of the system is zero, i.e. $a^*=0$). Due to the absence of gravity, the shape of the droplet is a perfect sphere of area $\Omega_L^o=4\pi r_o^2$, where r_o is the radius of the sphere. Under these conditions, and only due to the work developed by the surface energies of the system, the droplet spontaneously spreads the surface (Figure 1b) up to reach the configuration κ . This results in the formation of Ω_{SL}^κ , an interfacial area between the solid and the liquid. The area of a perfect spherical dome formed by the interface liquid-gas is Ω_L^κ .

A quantity of importance in this analysis, as demonstrated above, is the change –the difference– of Helmholtz energy between each two contiguous j -configurations of the system during the spontaneous wetting process [38]. The term “configuration” refers to a state in which the droplet is at rest in a position of stable or metastable equilibrium. All the transient states among them are also thermodynamic configurations. Associated with each configuration are the characteristic interfacial areas $\Omega_{SL}^j, \Omega_L^j$ and a characteristic Helmholtz energy, A_j .

For a given configuration, according to the Equation 18, and at constant T, V , and if $\Gamma_i = 0$ (one-component liquid, solid and gas):

$$\Delta A_j = \Delta \sum (\gamma \Omega)_j - \Delta \sum (\gamma \Omega)_i \quad (20)$$

Let's take as an example a system in which $\gamma_L > \gamma_{SL} > \gamma_S$. During the spontaneous wetting of the droplet of Figure 1, the Helmholtz energy of the system decreases because part of the liquid-gas interface creates a new solid-liquid interface (Figure 2, left). The energy of the solid-gas interface contributes additionally to the creation of the solid-liquid interface. The wetting process ends when the system reaches the equilibrium in the configuration κ .

The wetting process could end precisely at the configuration d' , where the Helmholtz energy of two contiguous j -configurations presents no more change ($\Delta A_j = 0$). However, the internal energy stored inside the drop during the wetting between o and d' can make the work necessary to continue wetting from d' up to the equilibrium configuration κ , i.e., $\Delta E = A_\kappa - A_{d'}$. At this point, the configuration κ ; the Helmholtz energy of the system recovers the value of the initial configuration o . In other words, comparing the configurations o and κ , no work has been done on the system, nor has it done any work on its surroundings. The net change of Helmholtz energy during the wetting process is zero.

$$\Delta A_{o \rightarrow \kappa} = A_\kappa - A_o = 0 \quad (21)$$

Equation 20 represents the ideal wetting in the absence of gravity. In a real process without gravity, part of the available surface energy will be lost in the form of entropy during wetting and

A_k will be slightly smaller than A_o . This fact will ensure that the wetting continues from d' to κ and not go back to the initial configuration o .

Figure 2. Schematic representation of the energetic changes of a system while a drop spontaneously wets a solid surface without the effect of gravity.

Continuing with the ideal model of spontaneous wetting, from Equation 20:

$$\Delta A_{o \rightarrow \kappa} = \gamma_L \Omega_L^\kappa + \gamma_{SL} \Omega_{SL}^\kappa + \gamma_S (\Omega_S^o - \Omega_{SL}^\kappa) - \gamma_L \Omega_L^o - \gamma_S \Omega_S^o = 0 \quad (22)$$

That results in:

$$\gamma_L (\Omega_L^\kappa - \Omega_L^o) + (\gamma_{SL} - \gamma_S) \Omega_{SL}^\kappa = 0 \quad (23)$$

A parameter κ can be now defined as:

$$\kappa = \frac{\Omega_L^o - \Omega_L^\kappa}{\Omega_{SL}^\kappa} \quad (24)$$

κ is a dimensionless parameter that characterizes a liquid drop at equilibrium, resting on a flat surface without the effect of gravity. Under the condition of weightlessness, this parameter is, in principle, independent of the size of the drop and not equivalent to the cosine of the contact angle of Young's model:

$$\gamma_{SL} - \gamma_S = \kappa \gamma_L \quad (25)$$

In the Young's model, $\cos \theta_Y$ represents the bi-dimensional fraction of the liquid surface tension acting horizontally on the triple contact point solid-liquid-gas. By contrast, for SDACC, κ represents the ratio of the liquid-gas interface area-decrease and the solid-liquid interface area created by wetting (Eq. 24). In other words, for a defined solid surface, κ represents the balance between the surface tension of the liquid and the interfacial solid-liquid energy. While $\cos \theta_Y$ applies only to the boundary line of the bi-dimensional drop profile, κ applies to all the interfaces of the three-dimensional system.

Let's consider now, as initial condition –configuration G_- , a drop resting in equilibrium on a solid and flat surface under the effects of the terrestrial gravitational field ($a_1 = -g_E$, $g_E = 9.81 \text{ m/s}^2$), see Figure 3a. Suppose that the system is inside a closed capsule that is submitted to the free fall under controlled conditions.

If a_2 is the acceleration of the uniformly accelerated motion of the capsule downwards, in the case of the free fall, its value is obviously $-g_E$. This will switch off the effects of the gravitational field inside the capsule that contains the surface and the drop. The resulting acceleration of this system will be given by:

$$a^* = -a_2 + a_1 \quad (26)$$

Figure 3. By the free fall, the energy that the terrestrial gravitational field is producing on the droplet (a) is released, letting the droplet reach a new equilibrium only governed by the interfacial energies (b), which shape is a spherical dome.

So, in the case of free fall, $a^* = 0$, that corresponds to an inertial system inside the capsule. To reach this condition, the energy with which the terrestrial gravitational field is flattening the drop must be released, letting the drop reach a new equilibrium state (Figure 3b) only governed by the interfacial energies –the configuration κ' . Macroscopically, it will result in the receding of the drop by the decrease of the interfacial area and its “deformation” to a perfect sphere due to the increase of its height. The acceleration that modifies the drop shape during the very short time of the mentioned energy release process is given by a_f :

$$a_f = -a_2 \quad (27)$$

During the energy release process, the receding of the drop will result in contact angle hysteresis. The multiplicity of apparent contact angles, which is an essential feature of contact angle hysteresis, is associated with the multiplicity of equilibrium states that a drop may assume on a rough or heterogeneous surface [39]. One apparent contact angle is associated with the stable equilibrium state (the global minimum in the free energy of the system). The others are linked to metastable equilibrium states (local minima in the free energy). The transition between metastable states, toward the stable equilibrium state, depends on the energy available to the drop for overcoming the energy barriers which inherently exist between the metastable states [39].

By definition, the phenomenon of hysteresis is observed when a parameter of the system, such as the volume of a drop placed on a solid, is varied back and forth, or when an external force is making the drop move in one direction (ie., by the tilting table experiment). In SDACC, the release of gravitational energy makes the contour of the drop recede on the surface and experience hysteresis. For this reason, this microgravity model is, in principle, oriented to characterize chemically homogeneous and smooth surfaces.

According to Grundke [40], while the advancing contact angle is expected to represent the property of the predominant material of the surface, the receding contact angle is only a manifestation of the impurities of that solid surface. It has been shown [39], that the contact angles assumed by the drop during advancing or receding is oscillatory. These oscillations may explain the macroscopic stick-slip behavior which is observed during contact angle hysteresis measurements. SDACC does not take into account the contact angle values, because they only provide information about balance on the drop line contour. However, the hysteresis effect occurs during the drop recedes, and it can modify the increase-decrease of the interfacial areas during de-wetting. In any case, SDACC evaluates the shape of the droplet in the stable equilibrium state (κ'), when the transition between metastable states (hysteresis) is already concluded. In this configuration, without the effects of gravity, the drop shape is a spherical dome.

Going back to the case of the sessile drop in the free fall, the acceleration experienced by the drop for the short time of the energy release is $a_f = +g_E$, i.e., a short duration force acting upwards.

The mechanical work that the drop must make to modify its shape and release surface energy is given by W_M .

$$-W_M = \Delta A = A_{\kappa'} - A_G \quad (28)$$

From the standpoint of the drop, this work can also be divided into two components: the work W_P necessary to move up its center of mass and the work W_S necessary to radially move the contour line solid-liquid-gas during a short de-wetting process (Figure 4).

$$W_M = W_P + W_S \quad (29)$$

Figure 4. The free-fall makes the system release the energy with which the gravitational field was deforming the drop. The Helmholtz energy of the drop in the form of interfacial energies is released, resulting in a drop with a spherical dome shape, the configuration κ' .

The change in the potential energy of the droplet can be calculated by measuring the change in the position of all the liquid particles, by considering for a moment the liquid as a particle system. If a particle system is changing from the state 1 to the state 2, their potential energies under a force field that produces the acceleration a_f , can be described by:

$$e_{p1} = \sum_i^n m_i a_f z_{1i} \quad (30)$$

$$e_{p2} = \sum_i^n m_i a_f z_{2i} \quad (31)$$

Where m_i is the mass of each particle and n the total number of particles. The change in potential energy from state 1 to state 2 is given by:

$$W_p = a_f \left(\sum_i^n m_i z_{2i} - \sum_i^n m_i z_{1i} \right) \quad (32)$$

The center of mass of a particle system is defined by:

$$z_c = \frac{\sum_i^n m_i z_i}{m} \quad (33)$$

Then, the Equation 32 for the potential energy necessary to move all the liquid particles from the state G to κ' , can be written as:

$$W_p = m a_f (z_{c\kappa'} - z_{cG}) = \rho V a_f (z_{c\kappa'} - z_{cG}) \quad (34)$$

Where ρ is the density of the liquid and V is the drop volume.

The second component of the work that the drop must make, the energy necessary to produce the receding wetting during its deformation from the state G to κ' , can be calculated by the integration of all the differentials of energy needed to move the contour line on the surface in the radial direction (Figure 5):

Figure 5. The drop profile observed from above: the release of the force field leads to dewetting. A receding work decreases the interfacial area from Ω_{SL}^G to $\Omega_{SL}^{\kappa'}$.

$$\int_G^{\kappa'} dW_s = \int_G^{\kappa'} \tau l dr \quad (35)$$

Where τ is tension necessary for the drop to move the contour line on the surface, l is the length of the contour line and r the radius of the wetting area Ω_{SL} . These considerations result in:

$$W_s = 2\pi\tau \int_G^{\kappa'} r dr \quad (36)$$

Which, in turn, results in:

$$W_s = \tau\pi(r_{\kappa'}^2 - r_G^2) = \tau(\Omega_{SL}^{\kappa'} - \Omega_{SL}^G) \quad (37)$$

At the equilibrium, the work made by the drop –the energy released– will result in energy changes on the system surfaces. Equations (28), (29), (34) and (37) result in:

$$-\rho V a_f (z_{c\kappa'} - z_{cG}) - \tau(\Omega_{SL}^{\kappa'} - \Omega_{SL}^G) = \gamma_L(\Omega_L^{\kappa'} - \Omega_L^G) + \gamma_{SL}(\Omega_{SL}^{\kappa'} - \Omega_{SL}^G) + \gamma_S(\Omega_S^o - \Omega_{SL}^{\kappa'} - \Omega_S^o + \Omega_{SL}^G) \quad (38)$$

Making the corresponding arrangements:

$$(\gamma_{SL} - \gamma_S + \tau)(\Omega_{SL}^{\kappa'} - \Omega_{SL}^G) = -\gamma_L(\Omega_L^{\kappa'} - \Omega_L^G) - \rho V a_f (z_{c\kappa'} - z_{cG}) \quad (39)$$

In the case of a free fall, both terms at the left side of Eq. 38 must give negative values because the drop must release energy to deform its shape, i.e. it must do work. By the first term, the acceleration and the difference of center of mass are both positive, resulting in a negative term due to the minus sign ahead of it. The second term is also negative, because the minus sign, the negative value of the areas difference –receding wetting– and the value of τ , which is negative due to the following reason: during the dewetting of the drop contour, the tension τ is the force that the liquid must overcome to recede on the solid surface, i.e., to “create” solid surface. This surface tension is the opposite of the previously defined surface energy of the solid γ_s :

$$\tau = -\gamma_s \quad (40)$$

Under this consideration, the Equation 39 can be written as:

$$\gamma_{SL} - 2\gamma_s = \frac{-\rho V a_f (z_{c\kappa'} - z_{cG}) - \gamma_L (\Omega_L^{\kappa'} - \Omega_L^G)}{\Omega_{SL}^{\kappa'} - \Omega_{SL}^G}, \quad a_f = +g_E, \text{ free fall} \quad (41)$$

Summarizing, in the case of the free fall, $a_2 = -g_E$ (capsule is falling) and $a_1 = -g_E$ (terrestrial acceleration acting on the droplet in rest). So, the net acceleration that deforms the droplet for a very short time during the free fall is $a_f = +g_E$, i.e. a short duration deformation force from bottom to up. However, once the drop reaches the equilibrium inside the capsule, it will be found within a system with zero acceleration, i.e. $a^* = 0$ (weightless). In consequence, at the end of the experiment (configuration κ'), the drop will be resting in stable equilibrium inside an inertial system.

The configuration κ , as mentioned before, is reached ideally after the end of a very fast wetting process that started spontaneously with the configuration o without the effect of the gravity. In the microgravity method, however, the configuration κ is quantified in a special way: the capsule with a drop in the configuration G , i.e., resting under the effects of the terrestrial gravity ($a_1 = -g_E$, $g_E = 9.81 \text{ m/s}^2$) is moved downward with $a_2 = -g_E$ (free fall). This results, as seen above, in a sudden upward acceleration $a_f = +g_E$ that deforms the drop for some moment (milliseconds in practice) until it reaches the weightlessness state ($a^* = 0$) inside the capsule (inertial system), the so-called configuration κ' . The present model proposes that the configuration κ' resulting from this forced de-wetting process is the same as the configuration κ , or at least quite similar.

By analyzing the images provided by the high-speed camera using Axisymmetric Drop Shape Analysis (ADSA) or ellipse matching, it is possible to find the frames where the droplet is resting free of vibrations with a perfectly spherical shape (the ellipse matching is highly recommended). These images correspond to the configuration $\kappa = \kappa'$ of the model. The values of the interfacial areas Ω_L^o , Ω_L^{κ} , and Ω_{SL}^{κ} can be obtained by the drop volume, the matching method and the formulas that are presented below, to obtain the value of the parameter κ , using the Eq. 24.

It is important to mention, that for the application of any drop-shape analysis method it is essential that the drop is completely axisymmetric. In other words, the wetting has to be completely isotropic. In the case of topographic anisotropy, it should be only nanometric and not affect wetting. Otherwise, it would be necessary to analyze the geometry of the drop in three dimensions. Some manufacturers of drop shape analyzers, like Krüss GmbH (Germany), have already begun to develop top-view distance optical methods for capturing the curvature of the drop to measure contact angles on curved solid surfaces and in depressions which are not easily accessible to the classical drop shape analysis. The combination of this technology with SDACC could make possible its application for non-axisymmetric drops on anisotropic surfaces.

The values of the interfacial areas Ω_L^G and Ω_{SL}^G can be obtained from the first frames some milliseconds before starting the free fall. This instant corresponds to the drop resting in equilibrium under the effects of gravity, the configuration G . The drop centers of mass z_{cG} and $z_{c\kappa'}$ can be calculated from the initial images and the images of configuration $\kappa = \kappa'$, by applying the Equation 51 given below. The exact value of the acceleration a_f can be obtained from the accelerometer of the instrument (see the Experimental Section).

The values of γ_s and γ_{SL} can be obtained by solving the system given by the equations 25 and 41. For the application of the microgravity method, it is only necessary to know the value of the surface tension of the liquid, its density, and the drop volume.

The precision of SDACC is highly dependent on the precision of the interfacial areas measurement. During the energy release of the drop, it could move some micrometers on the camera view-axis. As a consequence, the scale of the frames could change a little bit during the process. For this reason, the drop shape matching algorithms must be carefully scaled to evaluate the drop shapes of the configurations $\kappa \approx \kappa'$ and G with the same drop volume.

The artificial accelerations produced inside the capsule result in drop deformations given by a_f . Two cases of spheroidal caps [41-44] must be differentiated to calculate the values of the solid-liquid Ω_{SL} and the liquid-air Ω_L interfacial areas: $a^* = 0$ and $a^* < 0$.

Case I: sphere cap [42], $a^* = 0$

The radius of the solid-liquid interface is given by:

$$R = \sqrt{h(2b - h)} \quad (42)$$

Where h is the height and b the radius of the partial sphere, according to Figure 6a.

The volume of the partial sphere is given by:

$$V = \frac{\pi}{6} h (3R^2 + h^2) \quad (43)$$

The surface area –the interfacial area liquid-gas– is given by:

$$\Omega_L = \pi(R^2 + h^2) = 2\pi b h \quad (44)$$

And the interfacial area solid-liquid is given by:

$$\Omega_{SL} = \pi R^2 \quad (45)$$

Figure 6. Profiles of the two possible spheroids of the droplet shape during the free fall: (a) sphere and (b) oblate. The 2D- profiles of the spheroid caps are in gray.

Case II: oblate cap [41], $a^* < 0$

The radius of the solid-liquid interface is given by:

$$R = b \sqrt{1 - \left(1 - \frac{h}{c}\right)^2} \quad (46)$$

The volume of the oblate is given by:

$$V = \frac{\pi}{3} b^2 c \left(\frac{h}{c} \right)^2 \left(3 - \frac{h}{c} \right) \quad (47)$$

where b , c and h are the magnitudes according to Figure 6b.

The interfacial area solid-liquid is given by:

$$\Omega_{SL} = \pi b^2 \left[1 - \left(1 - \frac{h}{c} \right)^2 \right] \quad (48)$$

And the surface area –the interfacial area liquid-gas- is given by:

$$\Omega_L = \pi b c \left\{ \frac{b}{c} - \left(1 - \frac{h}{c} \right) \left[1 + \varepsilon^2 \left(1 - \frac{h}{c} \right)^2 \right]^{1/2} + \frac{1}{\varepsilon} \left(\operatorname{ar sinh}(\varepsilon) - \operatorname{ar sinh} \left[\varepsilon \left(1 - \frac{h}{c} \right) \right] \right) \right\} \quad (49)$$

where:

$$\varepsilon^2 = \frac{b^2}{c^2} - 1 \geq 0 \quad (50)$$

In both cases: sphere and oblate cap, the center of mass of the cap can be calculated using [41]:

$$z_c = \frac{h}{4} \frac{4 - \frac{h}{c}}{3 - \frac{h}{c}} \quad (51)$$

3. Experimental Section

The instrument [35] consists of a vertical tower three meters tall with all the necessary elements to control the accelerated movement of a capsule containing the solid-liquid-gas system during a time span from 600 to 750 milliseconds. The tower (Figure 7) was originally constructed to allow the motion of the capsule under different acceleration values upwards and downwards. However, the present study is focused on the free-fall mode, i.e. the instrument as a microgravity tower.

The components of the instrument are: the upper ignition device (1), the lower ignition device (2), the displacement tower (3), the acceleration device (4), the braking or damping mechanism (5) the liquid dosing device (6) and the capsule with the sample (7). Further, the instrument is connected to a computer with the software necessary to control the devices and evaluate the data.

The upper ignition device (1), as well as the lower ignition device (2), are electromagnetic mechanisms designed to release the anchored capsule so it can move freely by the action of the acceleration device. They are designed to minimize the vibrations during the ignition. The displacement tower (3) is designed to guide the capsule in the vertical direction without vibration and minimizing the effects of friction. The acceleration device (4) actuates the capsule in values of constant acceleration using the linear increase of the speed starting from the rest (zero velocity). This device is capable of moving the capsule both upwards and downwards. In the case of the downward drive with the acceleration of $-g_E$ (Earth gravitational field), it is possible to let the capsule simply fall free with the help of the guide elements of the shift tower. The acceleration device may be a servo motor capable of producing constant accelerations upwards or downwards of any value or a mechanical device which, based on a combination of pulleys, moves the capsule in discrete acceleration values.

Figure 7. The measure capsule (7) can be moved upwards or downwards.

The damping mechanism (5) consists of a mechanical, pneumatic or hydraulic arrangement capable of decreasing the velocity without increasing the acceleration above $20g_E$ to not damage the devices inside the measuring capsule. Depending on the orientation of the movement, it can be installed on the top or bottom of the tower.

The liquid dosing device (6) must be able to dose small droplets from $5\mu\text{L}$ to $100\mu\text{L}$ on the sample surface inside the capsule. It can consist of an arrangement of a micro-pump and dosing cannula or a mechanic or electronic micropipette. In the first case, it could be attached and moved together with the microcapsule. In the case of a micropipette, it could be triggered independently of the tower structure.

Figure 8. Measuring capsule with the high-speed camera, XYZ-stage, light diffusion source, accelerometer and vibrometer and cooling system.

The measuring capsule consists of a high-speed camera (100 – 1000 frames per second, fps), a sample stage (XYZ), a diffuse light source, an accelerometer, a vibrometer and a refrigeration unit (ventilator) (Figure 8). This device can obtain images or video of the drop during its motion with good resolution at higher fps values. The diffuse light must provide a good illumination and allows

a good contrast to obtain sharp drop contours. The stage will be used to put the sample in the optimal position for the experiment. The accelerometer and the vibrometer measure the values of the acceleration (Z-Axis) inside the capsule and the values of the accelerations in X- and Y-axis to evaluate the vibration during the experiment, respectively. The ventilator is used to cool the high-speed camera between the measurements.

The first published results of SDACC [35] were realized using polypropylene (PP) and polytetrafluoroethylene (PTFE) surfaces. For the present study, new tests were realized using seven smooth polymer surfaces -including new PP and PTFE-, which details and relevant topographic parameters are listed in Table 1.

Table 1. Polymer surfaces and roughness

Polymer material	Description	$Sa^{(1)}$, nm	$Sdr^{(2)}$, %	$Iso^{(3)}$, %
Polypropylene, PP	5 mm thickness, translucent with protection film (al-intech, Germany)	28	0.236	66,13
Polyethylene, PE	High density (HD) PE, 5 mm thickness, black (al-intech, Germany)	128	0.606	70,10
Polytetrafluoroethylene, PTFE	Teflon, 2 mm thickness, white, (Alt Industriebedarf, Germany)	301	6.070	23,13
Polyethylene terephthalate, PET	Polyester PET-G, 1 mm thickness, transparent with protection film (Hbholzmaus Kunststoffe, Germany)	3	0.026	65,07
Polystyrene, PS	2 mm thickness, black, (az-reptec, Germany)	698	3.097	68,47
Polymethyl methacrylate, PMMA	Acrylglas, 2 mm thickness, transparent with protection film (GeerGroup UG, Germany)	2	0.019	62,10
Polyvinylchloride, PVC	2 mm thickness, white with protection film (kunststoff-city, Germany)	230	2.667	6,97

¹ Surface arithmetic mean roughness; ² Developed surface area ratio; ³ Texture Isotropy

The topographic characterization was carried out using high-resolution ScanDisk Confocal Microscopy (SDCM). The SDCM device was a μ surf explorer (Nanofocus AG, Germany). An objective with the magnification 100X was used, which provides a measure length of 160 μ m and lateral and vertical resolutions of 0.3 μ m and 2 nm respectively. Three measurements were carried out on different positions of the samples. The topographic parameters arithmetic mean roughness Sa and developed surface area ratio Sdr (Table 1) show that the roughness of the materials is small enough to consider the surfaces smooth for the experiments. The texture isotropy, calculated using the MountainsMap® Premium Software (Digital Surf sarl, France) show that the PP, PE, PET, PS and PMMA surfaces are isotropic enough to consider that the drop will form axisymmetric shapes. The morphology of these surfaces was only slightly affected by negligible scratches due to manipulation. In case of PTFE and PVC, however, the anisotropy is structural. However, the nanometric- scale roughness of these surfaces, 301 and 230 nanometers respectively, should not significantly affect the axisymmetry of the 15 μ L water droplets (approx. 4-5 mm of base diameter) that will be deposited on them.

The materials were cut into 5 x 5 cm² samples and submitted to the tests with the microgravity lab tower.

4. Results

The calibration of the apparatus was realized according to [35], using a *R-DAS Tiny rocket accelerometer V4.0* (AED Electronics, USA) to measure the microgravity and a *USB Vibration Logger DL-131G* (Votcraft, Germany) to determine and control the lateral vibrations during the gravitation release. After a couple of mechanical improvements on the original prototype to control the vibrations during the ignition and decrease the friction during the fall, the resulting reduced gravity [42] inside the capsule was $a^* = +0.0018 g_E$

The effect of gravity on the macroscopic advancing contact angle was studied in 2005 by Ababneh et al. [21] using experiments in a specially modified FALCON 20 business jet (NRC Flight Research Laboratory, Canada) that flies a parabolic arc to produce short periods of reduced net acceleration force. The authors reported important irreproducibility of the contact angle due to the airplane vibration. The use of drop towers also presents the difficulty of the vibration produced during the ignition, i.e. during the release of the capsule to the free fall. Recent experiments realized in 2012 by Diana et al. [22] using the Drop Tower Facility of the Queensland University of Technology (Queensland, Australia) and Zhu et al. [23] using the Drop Tower of Beijing (National Microgravity Laboratory, Beijing, China) showed that the simple wire cutting release mechanism that initiates the drop of the experimental rack induces vibrations on the drop. According to [22], the sudden variation of the gravity force induces oscillations in the sessile drop. Indeed, at the beginning of the test, the energy stored in the thin wire that was holding the experimental package and drag shield was released resulting in vibrations in the sessile droplet. The vibrations using the microgravity tower prototype for the present study are important during the first 250 milliseconds of the experiment. From 450 milliseconds onwards they are negligible.

The experiments using the Drop Tower of Beijing [23] report a stabilization time from 0.8 to 1.2 seconds in the case of sessile drops, while by the experiments using the Drop Tower Facility of Queensland [22], the vibration time for sessile drops to reach equilibrium is less than 0.5 seconds. These authors carefully observed the transition from formal to reduced gravity using a 30 fps camera.

It is important to mention that the study of Diana et al. [22] was oriented to present an initial work to develop a database of contact angles of sessile droplets in reduced gravity and to study the dimensional variations due to the increase of the drop size regarding Bond number. The study of Zhu et al. [23] was oriented to investigate the influence of Bond number on behaviors of liquid drops deposited onto solid substrates and to probe the effectiveness of a simulation model. None of these studies was oriented to study or measure the surface energies of the substrates.

Small drop towers only exist for educational and demonstrative purposes [45-46]. However, apart from the study of Calvimontes [35], which is the basis for the present work, there are currently no reports about the study of wetting and measurement of surface energies using the release of gravitation.

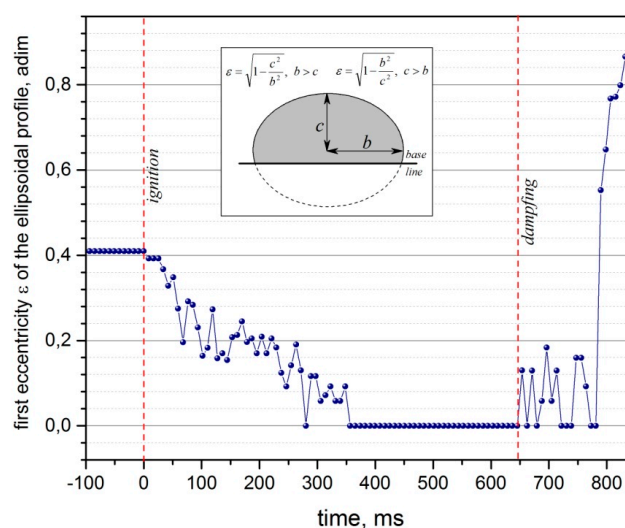

Figure 9. Vibration release of water drops on a PP surface regarding drop shape eccentricity. 76 frames were analyzed from the 480 available (750 fps video recording) [35].

To quantify the stabilization time of the droplets during the experiment, the first eccentricity, ε , was used in [35]. This parameter was defined in the equation 50 for the oblate ($b > c$) case. A perfect sphere ($b = c$) with $\varepsilon = 0$ in the microgravity region confirms that the effects of vibration were released. According to Figure 9, the eccentricity for doubled distilled water droplets of 20 μL on the PP surface shows that the vibration is completely released after 350 milliseconds of the ignition.

The calculation of the interfacial areas is possible using the equations 44 and 45. The values obtained for the parameter κ' on all the seven surfaces are listed in Table 2. Ten measurements corresponding to ten different drops were made for 15 μL bi-distilled water droplets on each surface at 22 ± 1 °C of temperature and 60 ± 2 % of relative humidity. According to [35], the optimal volume for the experiment using water is between 10 and 20 μL because in this interval both, the surface tension and the gravitation, are governed the wetting and the drop shape. According to [22], there are two forces that principally produce the droplet shape: the surface tension of the liquid, which tends to minimize the area of the surface (producing the spherical shape) and the gravitational force which tends to flatten the droplet.

Before initiating the free fall, the interfacial areas at the G -configuration, i.e. the sessile droplet under the effects of the gravity, were measured using the droplet images. The droplet mass centers in the G and κ' configurations were also measured for each experiment.

The interfacial energies were calculated by solving the system given by the equations 25 and 41 for each experiment, i.e., for each pair of images corresponding to the G and κ' configurations. The results are presented in Table 2.

Table 2. Results of the surface characterization

Polymer	κ'	γ_s , mJ/m ²	γ_{SL} , mJ/m ²
Polypropylene, PP	0.5287 \pm 0.0058	30.8708 \pm 0.4070	69.3591 \pm 0.2354
Polyethylene, PE	0.4030 \pm 0.0127	34.0385 \pm 0.5512	63.3805 \pm 0.7212
Polytetrafluoroethylene, PTFE	0.6199 \pm 0.0037	20.1871 \pm 0.5006	65.3167 \pm 0.5071
Polyethylene terephthalate, PET	0.3564 \pm 0.0123	41.3845 \pm 0.3405	67.3328 \pm 0.9448
Polystyrene, PS	0.3376 \pm 0.0372	43.4610 \pm 0.7066	68.0411 \pm 2.5544
Polymethyl methacrylate, PMMA	0.1528 \pm 0.0192	49.2423 \pm 0.6394	60.3631 \pm 0.9917
Polyvinylchloride, PVC	0.3764 \pm 0.0073	34.5522 \pm 0.4563	61.9534 \pm 0.4893

During the free fall, the water droplet experienced receding wetting during approximately 450 milliseconds in case of the PP surface [35]. During this period, the system went through multiple transient and metastable states that can be observed by the contact angle hysteresis in Figure 10. In this example, the contact angles decrease from 93.8° to 92° due to the release of gravity. The oscillations due to the energy barriers of the surface combined by the mechanical micro vibrations due to the electromagnetic release of the capsule lead the droplet to the equilibrium (κ') through multiple metastable states.

Figure 10. Contact angle hysteresis of a 20 μL water droplet on a PP surface [35]. The transition from stable state G , followed by metastable states (energy release) toward the stable equilibrium state of the configuration κ' .

To compare the microgravity method with the Owens-Wendt [28] and Wu [30] methods, measurements with a Mobile Surface Analyzer –MSA (Krüss GmbH, Germany) were realized using doubled distilled water and diiodomethane (Sigma-Aldrich). For each of the seven surfaces, ten drops of 1 μL were used. The results are presented in Figure 11.

Figure 11. Comparison between the calculated values of γ_s for the seven polymer surfaces obtained by the methods Owens et al., Wu, and SDACC.

5. Discussion

According to the results, the SDACC correlates well with the results obtained by the method of Owens et al. [28] for Polypropylene (PP), Polyethylene (PE) and Polyethylene terephthalate (PET). The values obtained for the surfaces of Polytetrafluoroethylene (PTFE), Polystyrene (PS), Polymethyl methacrylate (PMMA) and Polyvinylchloride (PVC) are intermediate between the values obtained by the methods of Owens et al. and Wu. In all the cases, the values obtained by Wu tend to be considerable higher.

As mentioned above, recent experimental evidence using microgravity by parabolic arc flights [21] and microgravity drop towers [22-23] have demonstrated that the effect of gravity on the contact angle is relevant even at very small drop volumes such as 5 μL . According to Allen [24], who studied the wetting of very small drops with small contact angles, a drop is small enough to neglect gravitational influences only if its volume is less than 1 μL . For the present study, small droplets of only 1 μL volume were used while applying the Owens et al. and Wu methods. However, the effects of the gravity are still significant on these droplets. To probe this, the eccentricity values of very small droplets on a PP and PTFE surfaces were measured using the Mobile Surface Analyzer –MSA (Krüss GmbH, Germany) instrument. The results can be seen in Figure 12. According to this, water droplets of only 1 μL are still deformed by the gravitation: on PP surfaces, the eccentricity of the water droplet is 0.2179, while on PTFE surfaces is 0.1466.

Figure 12. The eccentricity of different water droplets volumes on PP and PTFE surfaces. The drops are deformed by gravity even when they are very small.

The deforming effect of the gravity on the droplet is not the only problem for determining the interfacial energies using the typical contact angle methods like Owens et al. and Wu. The use of small droplets leads additionally to the increase of the effects of the roughness on the contour line. Even smooth surfaces have micro- and nanometric inhomogeneities that could affect the solid-liquid-gas contour line of the droplet. And this is very relevant when the method used is based only on the geometry of the boundary solid-liquid-gas.

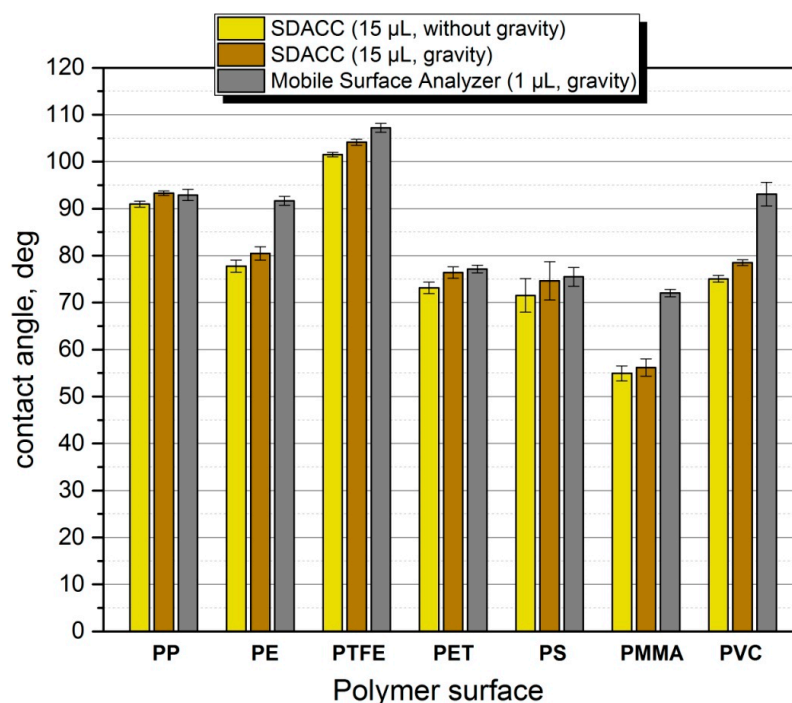

Figure 13. Comparison of the measured contact angles of a 15 μL water droplet with and without the effect of gravity, and 1 μL droplet under the effect of gravity.

Figure 13 compares the measured contact angles before and after the gravitation release using 15 μL drops, with the contact angles measured by the MSA instrument using 1 μL drops under the effect of gravity. According to this data, the measured contact angles in the microgravity are always

lower than the measured under the gravitational effects. This is to be expected for contact angles greater than 90 degrees –PP and PTFE–, according to [21]. However, when the contact angles in the microgravity are lower than 90 degrees it would be predictable, according to [21], that the gravitation decreases the contact angles slightly by promoting wetting. However in all the studied cases –especially for PE, PMMA and PVC measured by the MSA device (Krüss Germany) using 1 μL drop volume–, the contact angles are larger under the effects of gravity.

There are, in principle, two explanations for this effect while comparing the droplets of 15 μL with and without the effects of gravity. The first hypothesis is that the gravity release leads to receding wetting due to the release of gravitation: in all the cases, larger or smaller contact angles, the effect of micro- and nano-roughness of the surfaces by the stick-slip effect would also be modifying –decreasing– the contact angles on the contour line of the droplet at equilibrium (configuration κ'). However, this small alteration of the wetting due to the contact angle hysteresis would affect principally the boundary of the droplet and would be negligible for the resulting value of the whole interfacial area solid-liquid. In any case, the vibrations due to the gravitation release during the experiment could also help the droplets to recede and overcome the energy barriers easily. The second hypothesis, that will be discussed in detail later, is related with the singular hydrophobicity-hydrophilicity threshold of SDACC at the value $\kappa=0$ ($\theta_Y=42.88^\circ$).

To explain the considerable larger contact angles of PE, PMMA and PVC under gravity while using 1 μL after a dosing process by advancing wetting (MSA instrument, see Figure 12), it is necessary to take a look at the micro- and nanoroughness, that would be stopping wetting on the solid-liquid-gas contour line –and consequently increasing the contact angles–, due to the small drop size (1 μL). The effect of advancing and receding wetting is the main cause of inaccuracy when the surface energy characterization is based on the measurement of apparent contact angles on the boundary line only –even if they are at stable equilibrium–, and not on the changes on the interfacial surfaces.

Figure 14. The relationship between Young's contact angle (equivalent to the contact angle without gravity, θ_κ) and the parameter κ :

As mentioned above, in Young's model $\cos\theta_Y$ represents the bi-dimensional fraction of the liquid surface tension acting horizontally on the triple contact point solid-liquid-gas. By contrast, in SDACC, κ represents the ratio of the liquid-gas interface decrease and the solid-gas interface created by wetting (Eq. 24). While $\cos\theta_Y$ applies only to the boundary line of the bi-dimensional droplet profile, κ applies to all the interfaces of the three-dimensional system.

A relationship between κ and θ_Y can be built by means of a mathematical simulation considering a spherical drop of any liquid that virtually wets and spreads from $\theta_\kappa=180^\circ$ to $\theta_\kappa=0^\circ$ on any smooth surface in absence of gravity. By the definition of Young's equation, $\theta_Y=\theta_\kappa$, because

the Young's model considers no effect of gravity. According to Figure 14, the relationship between θ_Y and κ is near to a sigmoid. For the wetting models based on the Young's equation, the transition hydrophobic-hydrophilic is given by definition at 90 degrees. By SDACC, $\theta_\kappa = 90^\circ$ corresponds to $\kappa = 0.5218$ and, apparently, does not represent any relevant point for the function $\theta_Y = f(\kappa)$, as can be seen in Figure 14. The threshold between hydrophobicity and hydrophilicity at $\theta_Y = 90^\circ$ is a characteristic result of the force balance in the three-phase contact point of Young's model. Instead, by SDACC, the pole $\kappa = 0$ represents a very interesting point: in this, according to Equation 24, the interface liquid-air of the sessile drop equals the value of the liquid-air interfacial area of the original spherical drop before wetting. As mentioned before, by the Young's equation (Eq. 1), if the surface energy (in mJ/m^2) of the solid equals the tensor (in mN/m) of the solid-liquid contour, then the contact angle is 90 degrees ($\cos\theta_Y = 0$), while by SDACC, the surface energy of the solid equals the energy of the solid liquid interface only if $\kappa = 0$. The contact angle, in this case, is $\theta_\kappa = 42.88^\circ$. This value is the threshold hydrophobicity-hydrophilicity of the thermodynamic model for SDACC.

Young's model considers an interfacial solid-liquid tensor on the contour line. Let's rename this parameter σ_{LS} to differentiate from the interfacial energy γ_{SL} defined for SDACC. By combining the Equations 1 and 25:

$$\gamma_{SL} - \sigma_{SL} = \gamma_L (\kappa + \cos\theta_Y) \quad (52)$$

According to Equation 52, there is a difference between the interfacial energies measured on the interfacial area solid-liquid (γ_{SL}) and on the contour line (σ_{LS}) solid-liquid-gas. This difference is controlled by the liquid surface tension and by $\kappa + \cos\theta_Y$. Figure 15 shows the behavior of this difference as a function of Young's contact angle. According to this, the interfacial energy solid-liquid measured by Young's model on the contour line is only valid for the solid-liquid interface in the case of complete wetting ($\theta_Y = 0^\circ$).

By Young's model, complete wetting means $\gamma_S = \sigma_{LS} + \gamma_L$, because the contact angle is zero ($\cos\theta_Y = 1$). In this wetting case, SDACC predicts $\kappa = -1$, which leads to $\gamma_S = \gamma_{LS} + \gamma_L$. According to this, at complete wetting both models match, ie. $\gamma_{SL} = \sigma_{LS}$.

At the opposite end, by $\theta_Y = 180^\circ$ ($\cos\theta_Y = -1$), the Young's model predicts that $\gamma_S = \sigma_{LS} - \gamma_L$, that means that $\sigma_{LS} = \gamma_L$, because, by definition, γ_S is zero by non-wetting. By SDACC however, non-wetting means that κ tends to infinity (see Figure 14). While in this case, γ_S tends to zero, then γ_{SL} tends to infinity (see Eq. 25). In other words, SDACC predicts that a contact angle $\theta_\kappa = 180^\circ$ would be only possible, if the solid-liquid interfacial energy γ_{SL} is so high and unattainable, that it is impossible for the system to create any interfacial area Ω_{SL} . This interesting prediction is a clear result of applying a thermodynamic model of wetting that considers all the interfacial energies as surface properties.

Figure 15. Comparison between the relevant parameters of Young's model and the SDACC model.

As mentioned above, by Young's model, at $\theta_Y = 90^\circ$ the surface energy of the solid equals the tensor solid-liquid on the contact point, ie., $\sigma_{SL} = \gamma_S$. This point represents the transition hydrophilic-hydrophobic by Young's model. Instead, by SDACC, the case $\gamma_{SL} = \gamma_S$ occurs when $\kappa = 0$, at $\theta_Y = 42.88^\circ$. In this case, the area of the liquid-air interface at the equilibrium is the same as before starting the wetting process ($\Omega_L = \Omega^0$). Indeed, this can occur only if the energy of the solid-air interface is the same of the energy of the solid-liquid interface. As already mentioned, this would represent the transition hydrophobic-hydrophilic by using the SDACC model. This wetting threshold could also help to explain why the microgravity decreases the contact angles of all the polymer surfaces that have contact angles lower than 90 degrees but higher than 42.88 degrees. Those surfaces are, according to the SDACC, still hydrophobic ($\gamma_S < \gamma_{SL}$). But, if $\kappa' < 0$, then $\theta_{\kappa'} < 42.88^\circ$, and $\gamma_S > \gamma_{SL}$, according to Equation 25. This condition -the hydrophilicity by SDACC- would increase wetting easily by applying a gravitational force and, in consequence, decrease considerably the contact angle, see the explanation of Figure 16. New tests using hydrophilic surfaces with contact angles lower than 42.88 degrees need to be realized in the future to probe this hypothesis.

Figure 16. The effect of gravity on the contact angle depends on the value of κ' , which defines the threshold $\theta_{\kappa'} = 42.88^\circ$. (a) and (b) represent the case $\kappa' > 0$. The case (c) occurs if $\kappa' < 0$. Only in this case the gravity leads to a smaller contact angle than the microgravity.

Another point of interest, as mentioned before, occurs at the local minimum $\theta_Y = 160^\circ$, where $\kappa = 1$ and $\gamma_S = \gamma_{SL} - \gamma_L$. At this point, the values of σ_{SL} (Young's model) and γ_{SL} (SDACC) are quite close ($\kappa + \cos \theta_Y = 0.061$ in Figure 14).

Figure 17. Relevant parameters of SDACC for a 1 mm radius droplet that wets a smooth surface.

All the contrasts between Young's model and SDACC mentioned so far are the result of using two completely different thermodynamic concepts. In the first case, the energetic balance is applied on the contour line solid-liquid-gas, while in the second case, on all the interfacial areas of the system. Figure 17 is a diagram of the SDACC-parameters for any system consisting of a 1 mm radius droplet of any liquid on any smooth solid surface.

6. Conclusion

A new method for the surface characterization, the Sessile Drop Accelerometry (SDACC), was studied and discussed using new experimental data. This method can measure the interfacial solid-gas and solid-liquid energies by submitting a sessile drop to uniform and controlled microgravity environment using a small acceleration tower designed for the use inside the laboratory.

The method bases on the thermodynamic equilibrium of the interfaces and not on the balance of bi-dimensional tensions on the contour line and, in consequence, does not follow Young's equation, as the current surface wetting characterization techniques usually do. For that reason, the measurement of the apparent contact angles is not a requirement for the application of SDACC.

The experimental results of seven different smooth polymer surfaces were compared with the measurements using the conventional methods of Owens et al. and Wu. The results show that SDACC provides similar values of the obtained by Owens et al. with good reproducibility. The effect of the receding wetting during the experiment and its implication on the results was also discussed.

For the application of the method, only one liquid with a known value of surface tension is needed. The values of the interfacial energies can be obtained by solving a linear system of two equations. No correlations or numerical methods are needed. The greatest obstacle to the method accuracy is the vibration produced during the start of the wetting process. However, the experimental results are showing that the release of these vibrations occurs for a very short time and could help the receding wetting. The high-speed camera of the instrument allows obtaining images of the droplets for an additional time free of vibrations.

The thermodynamic model that supports SDACC allows to measure the interfacial solid-liquid energy directly and not only the value of the tensor in the solid-liquid-air contour line. This is the most important advantage of SDACC over Young's equation based methods. The second important advantage is to allow the study of wetting phenomena without the effect of the terrestrial gravity.

In contrast to the universally accepted boundary wetting threshold of 90 degrees (Young's model), the thermodynamic model of SDACC proposes that the surface wetting threshold between hydrophobic and hydrophilic characters occurs when the contact angle on the drop boundary is 42.88 degrees ($\gamma_{SL} = \gamma$). This is probably the most challenging proposal of SDACC.

The instrument and its evaluation method open new possibilities to develop surface characterization procedures by submitting the solid-liquid-system to artificial generated and uniform force fields.
