12
13

14 **Abstract:** The lymphocyte function-associated antigen-1 (LFA-1) (also CD11a/CD18 and ⍺L β2), is
15 just one of many integrins in the human body, but its significance derives from its exclusive presence
16 in leukocytes. In this review, we summarize the studies relating LFA-1 and its major ligand ICAM-
17 1 (CD54) with cancer, through the function of lymphocytes and myeloid cells on tumor cells. We
18 consider how LFA-1 mediates the interaction of leukocytes with tumors and the role of ICAM-1 in
19 tumor dynamics, which can be independent of its interaction with LFA-1. A more detailed
20 examination of LFA's role within B-cell chronic lymphocytic leukemia is made. Finally, we discuss
21 the role of LFA-1-harboring exosomes in tumor growth and metastasis.

22 **Keywords**: cancer metastasis, chronic lymphocytic leukemia, exosomes, tumor microenvironment
23

24 1. Introduction

25   LFA-1 is widely expressed in hematopoietic cells, mediating intercellular interactions within the
26 immune system and between leukocytes and non-blood cells. Several intercellular adhesion
27 molecules (ICAM), including ICAM-1 (CD54) are common ligands for LFA-1 [1] [2]. The strength of
28 LFA-1 adhesion varies by adjusting the affinity (conformation), the level of LFA-1 clustering and the
29 force applied by the ligand [3] [4] [5]. LFA-1 can adopt different conformations, from a folded low-
30 affinity inactive one to an open active conformation. The stimulation of cells by receptors like the T-
31 cell receptor or chemokine receptors changes the adhesive properties of LFA-1 in a process called
32 "inside-out" signaling that may open the conformation of LFA-1 and expose its ligand-binding site
33 [6]. In addition, it should be noted that the characteristics of the external ligand binding to LFA-1
34 initiates a signaling cascade in LFA-1 (named "outside-in" signaling), giving rise to various cellular
35 changes [7]. As with other integrins, LFA-1 is not a mere adhesive contact between cells, but it also
36 mediates signals that modulate the growth, differentiation and survival of the cell.

37 2. LFA-1 participates in the cytotoxic immune response against tumors

38   The T cell cytotoxic response against cancer cells starts when the T cell receptor recognizes a
39 specific tumor antigen on the surface of the cancer cell; this is normally followed by delivery of toxic
40 granules that kill the target cell. In the cytolytic response against virus-infected cells, the adhesion
41 between the cytotoxic lymphocyte and the target cell is not strictly dependent on LFA-1, this however
42 is necessary in the cytolytic response to immunogenic tumors [8] [9]. LFA-1 is an essential initiator of
43 the immunological synapse that forms between the cytotoxic T or NK cell and the cancer cell, and
44 mediates the firm adhesion to the target cell and the polarization of cytotoxic granules towards the

45 target [7] [10] [11]. There is a positive correlation between the maturation state of NK cells, their
46 cytotoxic potential and the activation level of LFA-1 [12].

3. Tumor infiltrating lymphocytes need LFA-1 to adhere to target cells

48 Cancer cells can escape from the immune response by changing the tumor microenvironment
49 into an immune-suppressive one [13]. Indeed, the presence of an immune-suppressive regulatory T
50 cell infiltrate within a tumor correlates with reduced survival [14], but not if the nature of the T cell
51 infiltrate is inflammatory [15].
52 The tumor infiltrating lymphocytes (TIL) can be purified from solid tumors and expanded in
53 vitro before being used as an effective therapeutic tool. However, TIL are not fully functional when
54 first obtained from tumors. The presence of a galectin lattice covering the surface of TIL interferes
55 with the adhesion of T cell LFA-1 to ICAM-1 on the target cell [16]. These galectins impair the
56 recruitment and activation of LFA-1 into the immunological synapse formed between TIL and tumor
57 cells [16]. The extent of LFA-1-ICAM-1 interaction affects the quantity of secreted cytokines by TIL
58 [16].

4. Leukocytes in the tumor stroma can play a positive or negative role in tumor growth

60 Cancer cells develop in a dynamically changing microenvironment that constitutes a safe zone
61 for their survival and proliferation. Through the interaction with stromal cells, cancer cells receive
62 survival signals and produce proteins and metabolites that suppress and modify the activity of the
63 immune system. This dependence of the tumor on its microenvironment could also be the tumor's
64 Achilles heel, since tumor-supporting stromal cells could be targeted therapeutically.
65 Myeloid cells can either, contribute to tumor development or restraint tumor growth, depending
66 on the tumor context. Below is a summary of studies where LFA-1 has been related to myeloid cell
67 function in the tumor microenvironment.
68 • Neutrophils
69 In mouse breast cancer models, neutrophils are the main drivers of metastasis [17]. By producing
70 leukotrienes, neutrophils contribute to the expansion of cancer cells with high tumorigenic potential
71 and to metastasis [17]. Hence, targeting the production of leukotrienes in neutrophils had a
72 therapeutic effect on metastasis. In a similar mouse model of estrogen receptor-positive breast cancer,
73 neutrophils were recruited into the tumor via increased expression of LFA-1, provoked by estradiol
74 and TGF 1 [18]. Neutrophil adhesion to endothelial cells by means of LFA-1, is associated with
75 prolonged survival of the cell [19]. Importantly, the neutrophil-cancer cell interactions mediated by
76 LFA-1 facilitated breast cancer dissemination [18]. In ovarian cancer patients, the adhesive properties
77 of blood neutrophils are increased, due to a higher expression of CD11b/CD18 integrin, suggesting
78 that the neutrophil-cancer cell contacts modify the properties of neutrophils to facilitate tumor
79 dissemination [20].
80 By contrast, in other types of cancer, neutrophils play a surveillance role against tumor
81 development [21]. When this is the case, it would be desirable to potentiate neutrophil infiltration
82 into the tumor to increase its elimination. Due to the contrasting roles of neutrophils in cancer, it will
83 be necessary to categorize tumors, to determine the convenience of improving the neutrophil
84 response against the tumor or by the contrary, blocking the neutrophil help to the tumor.
85 • Macrophages
86 Macrophages are an abundant component of many solid tumors and can play varied functions,
87 depending on the acquired phenotype of the macrophage and the tumor context. These tumor-
88 associated macrophages contribute to the epithelial-mesenchymal transition (EMT) and tumor
89 dissemination [22] [23] [24] [25]. The metastasis-promoting effect of macrophages is exerted through
90 cytokine secretion such as TGFß [23]. In an in vitro model of EMT, it was shown that M2-type
91 macrophages in direct contact with carcinoma cells facilitated the dispersion of the latter via ICAM-
92 1 and integrin CD18 interaction [26]. Similarly, in a mouse ovarian cancer model, the initial steps of
93 spheroid formation and transcoelomic metastasis were facilitated by the attachment of cancer cells to

94   macrophages via CD11b/CD18 – ICAM-1 adhesion [25]. If binding to ICAM-1 was neutralized with
95   antibodies, spheroid formation and ovarian cancer progression were impaired [25].
96   • Eosinophils
97   Eosinophils are potential players in the anti-tumor arsenal. In a mouse melanoma model which
98   depends on the anti-tumor activity of cytotoxic CD8 T cells for survival, eosinophils played an
99   essential role in the recruitment of cytotoxic T cells into the tumor [27]. In addition, in this melanoma
100   model, eosinophils normalized the tumor vasculature and reprogrammed tumor-associated
101   macrophages into inflammatory M1 type [27]. Similarly to eosinophils, when basophilia was induced
102   in these mice by treatment with interleukin-13, enhanced T-cell infiltration and tumor rejection was
103   obtained, indicating a similar anti-tumor role for basophils [28]. Other studies attribute an antitumor
104   role to eosinophils in colon cancer [29]. The cytotoxic activity against tumor cells that eosinophils can
105   display in vitro depends on the interaction LFA-1 - ICAM-1, which is upregulated by interleukin-18
106   [30].

5. LFA-1 in chronic lymphocytic leukemia

108   Because there are studies describing alterations of LFA-1 signaling pathway in chronic
109   lymphocytic leukemia (CLL), these studies are being considered here. CLL, the most common
110   leukemia in the Western world, is characterized by the accumulation of clonal mature B cells in blood
111   and lymphoid tissues [31]. Circulating normal B cells continuously home to secondary lymphoid
112   organs in search of antigen and to acquire survival signals. Similarly, B-CLL cells take advantage of
113   this survival path by increasing the expression of homing chemokine receptors CXCR4 and CCR7,
114   and decreased expression of the egress receptor S1P1, to home to lymphoid organs, an environment
115   that favors clonal expansion [32]. The gathering of CLL cells with other stromal cells, macrophages
116   and T cells defines a pseudo-follicle, which supports CLL cell proliferation [33]. The importance of
117   migration and adhesion in determining pathogenesis in this leukemia type is exemplified by
118   treatment with a Bruton tyrosine kinase inhibitor, that mobilizes leukemic cells out of the supportive
119   lymphoid organs resulting in CLL regression [32] [34]. The inhibition of Bruton tyrosine kinase
120   impedes chemokine- and B-cell receptor-derived signaling governing adhesion and migration of CLL
121   cells.
122   In addition to chemokines, migration of CLL cells requires the participation of the two
123   lymphocyte integrins VLA-4 (CD49d/CD29) and LFA-1, which show varied levels of expression in
124   CLL cells [35]. VLA-4 (CD49d/CD29) contributes to homing of CLL cells to bone marrow [36].
125   However, the activation of LFA-1 is impaired in CLL cells due to defective signaling by Rap1 GTPase,
126   a major signaling element of the inside-out signaling cascade, impeding proper clustering of LFA-1
127   [37]. Moreover, signaling by Rac1 and CDC42 GTPases to activate LFA-1 shows extensive degrees of
128   alteration in CLL patients, so that some authors suggested that progression to CLL requires bypassing
129   these GTPases [38]. The defective LFA1-dependent endothelial transmigration could play a role in
130   survival of CLL cells [39]. Despite the necessity of CLL B cells to home to lymph nodes and bone
131   marrow, it is not uncommon to observe a lower CD18 expression in B-CLL than that of normal B cells
132   in healthy individuals [35]. Recently, a CD18 variant present in CLL patients has been associated with
133   increased disease susceptibility [40]. The variant shows a glutamate to lysine E630K change, which
134   probably impairs CD18 function. The expression of the CD18 variant in patients' B cells is even lower
135   than that of the wild-type form [40]. By contrast, a CLL subgroup of patients harboring trisomy 12
136   (approximately 16% of CLL patients) show an important increase of LFA-1 and other integrins,
137   associated with high cell proliferation and lymph node infiltration [41] [42]. These data do not clarify
138   the role of LFA-1 in disease progression in CLL and suggest a complex interplay with other adhesion
139   molecules and signaling pathways.
140   Patients with CLL show impaired T cell function which results from the direct contact of normal
141   T cells with B-CLL [43] (reviewed in reference [44]). Thus, the cytotoxic activity of CD8 T cells and
142   the differentiation of T helper 1 are deficient in CLL patients. The inefficient T cell function probably
143   contributes to CLL expansion. These T cells display low conjugation to CLL B cells *in vitro* and
144   impaired immune synapses, characterized by impaired LFA-1 clustering at the immune synapse [45].

145 Importantly, pretreatment of CLL B cells with anti–ICAM-1 monoclonal antibody improved the
146 conjugation of CLL B cells with T cells and F-actin polymerization at the immune synapse [45].
147 Furthermore, T cells in CLL patients exhibit defective LFA-1-mediated migration, due to
148 dysregulated Rho GTPase signaling [46]. Treatment with lenalidomide, a clinically active drug used
149 in hematologic cancers [47], restored Rho GTPase signaling in T cells, rescued LFA-1 function [46]
150 and improved immune synapse formation between T cells and B-CLL [45]. It is surprising that T cells
151 in CLL patients show a dysfunctional adhesion and signaling through the LFA-1/Rho-family GTPase
152 pathway, resembling that of B-CLL, what highlights the importance of the LFA-1 signaling pathway
153 in this leukemia.

6. Targeting LFA-1 in cancer

155 Tumors of hematopoietic origin normally express LFA-1, and could potentially be targeted with
156 anti-LFA-1 antibodies [48]. In certain conditions LFA-1 is expressed by tumor cells as well, such as in
157 brain metastasis [49] [50]. In a mouse model of a brain tumor, the presence of LFA-1 on metastatic
158 cells contributed importantly to tumor growth [50]. LFA-1 has also been found on *in vitro* cultured
159 melanoma cells, allowing their transmigration through endothelial cells [51]. However, whether LFA-
160 1 is also expressed in melanoma cells *in vivo* is unknown. The presence of LFA-1 on tumors of non-
161 hematopoietic origin will need further confirmation before it can be considered a therapeutic target.
162 A different approach could be targeting LFA-1 in the leukocyte infiltrates, which often play a
163 pro-tumorigenic role. For instance, the presence of regulatory T cells, which are immunosuppressive,
164 in the microenvironment of many solid tumors and the importance of LFA-1 in the function of these
165 cells [52], suggests that targeting LFA-1 in these tumors would limit the function of regulatory T cells
166 and improve the action of the immune system against the tumor [27] [28]. The acquired knowledge
167 from targeting LFA-1 in the treatment of inflammatory diseases can be helpful here [53].
168 Unfortunately, attempts to functionally antagonize integrins in tumors have generally failed [54]
169 [55]. This is the case of efalizumab, a humanized monoclonal antibody directed against CD11a, which
170 blocks the interaction between LFA-1 and ICAM-1 [56]. Initially used in the treatment of psoriasis, it
171 had to be withdrawn in 2009 after the unexpected appearance of progressive multifocal
172 leukoencephalopathy in 4 patients receiving it. Unforeseen effects when targeting LFA-1 are not
173 uncommon, for instance, the use of antibodies against CD11a/CD18 can affect indirectly the function
174 of the integrin α4β1, inhibiting it selectively [57].
175 Recently, a different approach has been tested, where the host immune system is redirected
176 against integrin-bearing tumors [58]. Also, the design and applicability of new LFA-1 antagonists is
177 a potential field for therapy development [53] [59].

7. The effect of leukotoxin

179 The liganded and unliganded states of integrins can determine the life or death of the cell,
180 respectively [60]. It is therefore not surprising that pathogens may utilize these membrane receptors
181 to modulate the immune response. This is the case of leukotoxin, a protein produced by
182 *Aggregatibacter actinomycetemcomitans,* that induces apoptosis in leukocytes [61]. It binds to activated
183 LFA-1 and induces apoptosis by several mechanisms [62]. Leukotoxin shows a tendency to kill
184 leukemic cells in a LFA-1-dependent manner [63] [64]. Whereas normal hematopoietic cells might be
185 partially sensitive, leukotoxin shows preferential activity against active LFA-1 and spares most blood
186 cells. The death of tumor lymphocytes occurred by a Fas-dependent mechanism [64]. Besides the
187 advantage of counting with a potential therapeutic tool, working out the mechanism behind
188 leukotoxin's action on LFA-1 leading to cell death, will provide new knowledge linking adhesion to
189 cell fate decisions.

8. The role of ICAM-1 in tumors

191 ICAM-1 is expressed in several tumors, and as a major LFA-1 ligand, it may help in the
192 immunosurveillance process [65] [66] [67] [68] [69] [70] [71] [72] [73]. Along this line, the presence of

ICAM-1 in colorectal cancer has been associated with better prognosis [71] [72]. Moreover, the transfection of ICAM-1 in colorectal cancer cell lines inhibits tumor growth and metastasis [74]. Similar observations were obtained from colon epithelium cell lines derived from mice presenting transforming mutations in the adenomatous polyposis coli gene, the gene mutated in patients affected by familial adenomatous polyposis. When these colonic cell lines were incubated with intraepithelial T lymphocytes, they expressed ICAM-1, which mediated the interaction with T cells [75].

The production of prostaglandin E2 in the tumor microenvironment limits the expression of ICAM-1 on tumor cells, reducing the cytotoxic effectivity of T cells [76]. Mouse melanoma tumors that regress due to adoptive T cell therapy, show increased expression of ICAM-1 [77]. By contrast, upon tumor relapse, ICAM-1 and other adhesion molecules are found in lesser levels [77].

Other potential mechanisms by which ICAM-1 could retard tumor cell metastasis have been proposed. Hence, the inhibitory effect of cannabinoids on lung cancer cell invasion and metastasis has been suggested to occur via up-regulation of ICAM-1, which then increases the tissue inhibitor of matrix metalloproteinases-1 [78]. ICAM-1 has also been suggested to mediate the differentiation properties of gastrin-releasing peptide on colon cancer cells by enhancing cell-matrix attachment [79].

On the contrary, in some reports, the expression of ICAM-1 has been correlated positively with a more aggressive tumor phenotype and metastatic potential [70] [80]. Hence, the invasiveness of breast cancer cells has been positively correlated with the expression of ICAM-1 [81]. Also, an ICAM-1 – ICAM-1 homophilic interaction between breast cancer cells and mesenchymal stem cells in bone marrow has been proposed to mediate the metastatic expansion of cancer cells, displacing hematopoietic stem cells of its niche [82].

Importantly, tumor-associated fibroblasts in colorectal cancer tissue sections also show increased ICAM-1 expression in comparison to healthy mucosa [83]. When colorectal cancer tissue sections are examined for expression of ICAM-1, the number of positive fibroblasts is increased in comparison to healthy mucosa [83].

9. Exosomes carrying LFA-1 and ICAM-1

It is increasingly clear that exosomes released by cancer cells play a key role in metastasis [84]. Homing of exosomes released by cancer cells to specific body tissues is mediated by integrins [84]. However, the function of LFA-1 in exosome-directed mutagenesis and metastasis is poorly defined. LFA-1 is present in exosomes released by mast cells, dendritic cells and T cells [85] [86] [87], and mediates exosome uptake during T cell - dendritic cell contact [86] [87] [88]. Exosomes harboring ICAM-1 can be captured by LFA-1 present in dendritic cells [89]. ICAM-1-presence in exosomes released by dendritic cells is necessary for stimulation of naive T cells [90] [91]. However, ICAM-1– bearing exosomes produced by cancer cells, can block leukocyte adhesion to endothelial cells [92].

The cellular origin of exosomes is important in determining their inhibitory or activation function. Thus, dendritic cell-derived exosomes target other recipient dendritic cells via LFA-1-ICAM-1 and increase their capacity of stimulating T cell tumoricidal activity [93], whereas T cell-derived exosomes, when introduced in mice, target dendritic cells via LFA-1 and modulate their function, inhibiting CD4 and CD8 T cell anti-tumoral activity [87] [88].

Despite the great potential of exosomes in cancer therapy, their capacity to interact with different cellular partners and produce varied biological outcomes requires a deeper knowledge of their biology, before a therapeutic use is possible.
