Abstract: Continuous ultrasonic in-situ monitoring for industrial applications is difficult owing to the high operating temperatures in industrial fields. It is expected that ultrasonic transducers consisting of CaBi$_4$Ti$_4$O$_{15}$(CBT)/Pb(Zr,Ti)O$_3$(PZT) sol-gel composite could be one solution for ultrasonic nondestructive testing (NDT) above 500 °C because no couplant is required and CBT has a high Curie temperature. To verify the high temperature durability, CBT/PZT sol-gel composite films were fabricated on titanium substrates by spray coating, and the CBT/PZT samples were tested in a furnace at various temperatures. Reflected echoes with a high signal-to-noise ratio were observed up to 600 °C. A thermal cycle test was conducted from room temperature to 600 °C, and no significant deterioration was found after the second thermal cycle. To investigate the long-term high-temperature durability, a CBT/PZT ultrasonic transducer was tested in the furnace at 600 °C for 36 h. Ultrasonic responses were recorded every 3 h, and the sensitivity and signal-to-noise ratio were stable throughout the experiment.

Keywords: ultrasonic transducers; high temperature measurement; nondestructive testing; thin film sensor

1. Introduction

Ultrasonic monitoring at elevated temperatures is desired in industrial fields because it can detect failure phenomena such as thickness reduction, corrosion cracks, micro-void generation, and processed material deterioration in an early stage [1-3]. Even though ultrasonic nondestructive testing (NDT) is one of the common NDT techniques [4], long-term high-temperature application of ultrasonic NDT is difficult. For the general ultrasonic transducer using the contact method, an acoustic couplant to transmit ultrasound into test objects and a backing material to achieve a broad frequency bandwidth are used [5]. However, these materials cannot withstand elevated temperatures in the long term. Non-contact ultrasonic methods, such as air-coupled ultrasonic transducers [6], electromagnetic ultrasonic transducers (EMATs) [7], and laser-ultrasound [3], seem to be good solutions for these problems, but each technique has some drawbacks. Air-coupled ultrasonic transducers have good acoustic impedance matching with air; therefore, it is suitable for the NDT of light materials such as graphite composites but not for the NDT of metals, which are the main target of high-temperature ultrasonic NDT. EMATs have poor signal-to-noise ratio (SNR) in general. The installation cost of a laser ultrasound system is high, and it is difficult to monitor many points of unmovable objects simultaneously. The use of a delay line is another method to avoid the direct contact of the ultrasonic measurement system with high temperatures [8], though the measurement system becomes bulky. Therefore, the development of an ultrasonic NDT method for metals at high temperature is still desired.
Sol-gel composite ultrasonic transducers have been investigated for the industrial NDT applications [9-16]. Sol-gel composites consist of ferroelectric powders and a dielectric sol-gel solution. Sol-gel composite ultrasonic transducers are suitable for high temperature applications because they achieve a broad frequency bandwidth without any backing material owing to the presence of micro pores inside the sol-gel composite. If sol-gel composite films are directly fabricated on the test object, an acoustic couplant is no longer necessary since sol-gel composite films establish high acoustic bonding with the substrates during the fabrication process. Furthermore, it is possible to fabricate sol-gel composite films on targets with complex geometry by using the spray technique [10-16]. Therefore, sol-gel composite ultrasonic transducers are applicable for industrial ultrasonic NDT at elevated temperatures.

\[ \text{CaBi}_4\text{Ti}_4\text{O}_{15} \text{ (CBT)} / \text{Pb(Zr,Ti)}\text{O}_3 \text{ (PZT) sol-gel composite, consisting of CBT powders and PZT sol-gel, has been developed for high-temperature applications above 500 }^\circ\text{C} \text{ [14]. CBT powders were chosen because of their high Curie temperature (~790 }^\circ\text{C} \text{ [17]. PZT sol-gel solution was selected because it simultaneously satisfies a high dielectric constant and relatively high Curie temperature.} \]

The authors found that Mn-doped CBT/PZT ultrasonic transducers showed sufficiently good sensitivity and SNR at 550 °C for thickness measurement [14]. However, the maximum operating temperature has not been determined yet since Mn-doped CBT/PZT ultrasonic transducers operated successfully at the maximum operating temperature of the hotplate used in the previous experiment. Furthermore, the long-term durability was not tested. In this study, the maximum operating temperature and long-term high-temperature durability of CBT/PZT ultrasonic transducers were investigated [15, 16].

2. Materials and Methods

CBT/PZT films were fabricated on titanium substrates with ~3 mm thickness, ~30 mm length, and ~30 mm width. Titanium was chosen as the substrate material because of its high-temperature durability and light weight so that its temperature quickly becomes equal to that of the furnace atmosphere. CBT/PZT films were manufactured by a sol-gel spray technique, and the details of the fabrication process can be found in elsewhere [9-16]. First, 0.5wt% Mn-doped CBT raw material was manufactured by a conventional solid-state reaction method [14]. Then, synthesized CBT bulk ceramics was pulverized to fine CBT powders by a commercial milling device. CBT powders were mixed with self-manufactured PZT sol-gel solution. The mixture was ball-milled for more than one day until a suitable viscosity for spray coating was achieved. When the mixture was ready for spray coating, the titanium substrates were covered with 80-µm-thick masks having windows ~20 mm in length and ~20 mm in width; then, the mixture of PZT sol-gel and CBT powders was sprayed on the titanium substrate by an air brush. After the spray-coating process, the thermal process, which involved drying at 150 °C for 5 min and firing at 650 °C for 5 min, was carried out. The spray-coating process and thermal process were repeated until the target thickness was achieved. In this research, these processes were repeated 5 times to obtain 50-µm-thick CBT/PZT films. A typical optical image of the manufactured sample is shown in Figure 1.

A platinum top electrode with a diameter of ~5 mm was fabricated on each CBT/PZT sample. Platinum was used as the top electrode material because of its high temperature stability. Positive corona discharge was used for the poling process because a high electrical field could be applied on the porous piezoelectric films without dielectric breakdown. During the poling process, the samples were heated at 400 °C by a hotplate. It is general to pole ferroelectric material with high Curie temperature at elevated temperature, and it could assist to supply electric field efficiently to CBT ferroelectric phase because dielectric constant of PZT sol-gel phase was nearly maximum around 400 °C of hot plate temperature. The piezoelectric constant $d_{33}$ was measured using a commercial $d_{33}$ meter, and it was determined to be ~10 pC/N for every sample in this study.

A schematic of the ultrasonic measurement is shown in Figure 2. Platinum wires were connected to both the platinum top electrode and the titanium substrate by high-temperature silver paste. A CBT/PZT sample with platinum wires was placed in a furnace. Two platinum wires passed through the holes, which were created at the upper surface of the furnace, and were connected to the coaxial cable. The other side of the coaxial cable was connected to a pulser/receiver (P/R) machine to measure ultrasonic responses in pulse-echo mode. The output of the P/R machine was recorded using a digital oscilloscope.

3. Results and discussions

3.1. Maximum operating temperature test

The maximum operating temperature of Mn-doped CBT/PZT was determined. Ultrasonic responses were recorded at room temperature (23 °C), 50 °C, and then for every 50 °C increase in temperature, up to 600 °C. Between 600 °C and 700 °C, the data were recorded for every 20 °C increase in temperature. A holding time of 5 min was set before data recording. Figures 3-7 show the ultrasonic measurement results at room temperature, 200 °C, 400 °C, 600 °C, and 700 °C, respectively. The dead-zone length varied intricately, and electrical impedance changed, presumably owing to the curing effect of the top electrode and resistance reduction of CBT at high temperatures. Clear reflected echoes were observed at all temperatures except 700 °C (Figure 7). It is worth noting that SNR was significantly deteriorated in Figure 7 as well.

In order to clarify the experimental results, the sensitivity $S$ was calculated using the following equation:

$$S = -\{\log_{10}(V_1 / V_2 + P / R \ Gain)\},$$

(1)
where $V_1$ is the reference peak-to-peak voltage amplitude ($V_{p-p}$), which was 0.4 V in this paper, and

$V_2$ is the amplitude of the third reflected echo. That is, the sensitivity $S$ is determined as the negative

value of P/R gain at which 0.4 $V_{p-p}$ amplitude is achieved for the third echo. The fourth reflected echo

was chosen because the first, second, and third reflected echoes disappeared at high temperatures

because of the dead zone. The negative value was used to help intuitive understanding. The

sensitivity at various temperatures is shown in Figure 8. At temperatures less than 300 °C, the sensitivity is very stable. The sensitivity decreases linearly from 300 °C to approximately 600 °C, and it decreases exponentially beyond 600 °C. From this result, we assumed that the maximum operating temperature of Mn-doped CBT/PZT ultrasonic transducers for thickness measurement is 600 °C.

Based on this result, the following experimental conditions were determined.

3.2. Thermal cycle test

To ensure 600 °C durability, a thermal cycle test between room temperature and 600 °C was conducted for another CBT/PZT sample. The measurement system was the same as that of the previous experiment. The ultrasonic responses were recorded in pulse-echo mode at room temperature, 100 °C, 200 °C, 300 °C, 400 °C, 500 °C, and 600 °C, after a holding time of 5 min for each
temperature. During the cooling process, the furnace was turned off without ultrasonic monitoring. Figure 9 shows the sensitivity at various temperatures during three thermal cycles. The sensitivity was calculated by Eq. (1) as in the previous section. The tendency was similar to that in Figure 8 i.e. the sensitivity was stable at temperatures less than 300 °C, and beyond 300 °C the sensitivity decreased monotonically. The sensitivity of CBT/PZT decreased after the first thermal cycle. We suggest that the irreversible depoling of the PZT sol-gel phase is the mechanism of sensitivity reduction after the first thermal cycle. The sensitivities of the second and third thermal cycles were nearly identical. This reversible action mainly caused by the reversible depoling of the CBT powder phase and scattering loss of the titanium substrate. The SNR was stable between 15 and 20 dB. Therefore, CBR/PZT is suitable for thermal cycles ranging from room temperature to 600 °C.

Figure 9. Sensitivity of CBT/PZT films fabricated on 3-mm-thick 900-mm² titanium substrate at various temperatures during thermal cycle.

3.3. Long-term ultrasonic monitoring at 600 °C

After the third temperature rise, the furnace temperature was maintained at 600 °C for the long-term thermal durability test. Ultrasonic measurement in pulse-echo mode was performed every 3 h until 36 h have passed. Figures 10-14 show the ultrasonic responses of the CBT/PZT sample at 600 °C after 0 h, 6 h, 12 h, 24 h, and 36 h, respectively. Even though the dead-zone length changed slightly, sufficiently clear multiple reflected echoes for thickness measurement were observed throughout the experiment. A change in dead-zone length would occur because of the deterioration of high-temperature silver paste, and further improvement is required for the electrical connection. It seems that SNR was also stable at approximately 17 dB. Figure 15 shows the sensitivity at 600 °C during the thermal durability test for 36 h. The sensitivity was calculated by Eq. (1) as in the previous section. The sensitivity was stable, and it could be concluded that CBT/PZT is a promising material for ultrasonic monitoring at 600 °C.

4. Conclusions

To confirm the ultrasonic measurement capability of CBT/PZT at high temperatures, 50-µm-thick CBT/PZT sol-gel composite films with ~400 mm² area were fabricated on 3-mm-thick titanium substrates by the sol-gel spray technique. A platinum top electrode was fabricated on each film, and platinum wires were connected to both the platinum top electrode and the titanium substrate using high-temperature silver paste. To determine the high-temperature durability of the manufactured transducers, one CBT/PZT sample was tested in the furnace from room temperature to 700 °C. It was found that CBT/PZT showed reasonable performance for thickness measurement below 600 °C. The thermal cycle was repeated thrice between room temperature and 600 °C. The sensitivity lowered but became stable after the second thermal cycle. Subsequently, CBT/PZT was tested in the furnace at 600 °C for 36 h. The sensitivity of CBT/PZT was stable for 36 h. Therefore, it was concluded that the transducer made by the CBT/PZT sol-gel composite is promising for long-term monitoring in NDT application at 600 °C.
