Abstract: We explored the dynamics of the two interacting information systems. We show that for
the Markovian marginal systems the driving force for information dynamics is determined by both
the information landscape and information flux. While the information landscape can be used to
construct the driving force to describe the equilibrium time-reversible information system dynamics,
the information flux can be used to describe the nonequilibrium time-irreversible behaviours of
the information system dynamics. The information flux explicitly breaks the detailed balance and
is a direct measure of the degree of the nonequilibriumness or time irreversibility. We further
demonstrate that the mutual information rate between the two subsystems can be decomposed
into the equilibrium time-reversible and nonequilibrium time-irreversible parts respectively. This
decomposition of the mutual information rate (MIR) corresponds to the information landscape-flux
decomposition explicitly when the two subsystems behave as Markov chains. Finally, we uncover
the intimate relationship between the nonequilibrium thermodynamics in terms of the entropy
production rates and the time-irreversible part of the mutual information rate. We found that this
relationship and MIR decomposition still hold for the more general stationary and ergodic cases. We
demonstrate the above features with two examples of the bivariate Markov chains.

Keywords: nonequilibrium thermodynamics; landscape-flux decomposition; mutual information
rate; entropy production rate

1. Introduction

There are growing interests in studying two interacting information systems in the fields of
control theory, information theory, communication theory, nonequilibrium physics, and biophysics
[1–9]. Significant progresses have been made recently towards the understanding of the information
system in terms of information thermodynamics [10–13]. However, the identification of the global
driving forces for the information system dynamics is still challenging. Here we aim to fill this
gap by quantifying the driving forces for the information system dynamics. Inspired by the recent
development of landscape and flux theory for the continuous nonequilibrium systems [14–16] and
the Markov chain decomposition dynamics for the discrete systems [20–26], we show that at least for
the underlying marginal Markovian cases, the driving force for information dynamics is determined
by both the information landscape and information flux. The information landscape can be used to
construct the driving force responsible for the equilibrium time-reversible part of the information
dynamics. The information flux explicitly breaks the detailed balance and provides a quantitative
measure of the degree of nonequilibriumness or time irreversibility. It is responsible for the time
irreversible part of the information dynamics. The Mutual Information Rate (MIR) [18] represents
the correlation between two information subsystems. We uncovered that the MIR between the
two subsystems can be decomposed into the time-reversible and time-irreversible parts respectively.
Especially when the two subsystems act as Markov chains, this decomposition can be expressed in terms of information landscape-flux decomposition for Markovian dynamics. An important signature of nonequilibriumness is the Entropy Production Rate [17,19,20]. We also uncover the intimate relation between the EPRs and the time-irreversible part of the MIR. We demonstrate the above features with two cases of the bivariate Markov chains. Furthermore, we show that the decomposition of the MIR and the relationship between the EPRs and the time-irreversible part of the MIR still hold for more general stationary and ergodic cases.

2. Bivariate Markov Chains

Markov chains have been often assumed for the underlying dynamics of the total system in random environments. When the two subsystems together jointly form a Markov chain in continuous or discrete time, resulting chain is called Bivariate Markov Chain (BMC, a special case of the multivariate Markov chain with two stochastic variables). The processes of the two subsystems are correspondingly said to be marginal processes or marginal chain. The BMC was used to model ion channel currents [2]. It was also used to model delays and congestion in a computer network [3]. Recently, different models of BMC appeared in nonequilibrium statistical physics for capturing or implementing the Maxwell’s demon [4–6], which can be seen as one marginal chain in the BMC playing feedback control to the other marginal chain. Although the BMC has been studied for decades, there are still challenges on quantifying the dynamics of the whole as well as the two subsystems. This is because neither of them needs to be Markovian chain in general [7], and the quantifications of the probabilities (densities) for the trajectories of the two subsystems involve the complicated random matrices multiplications [8]. This leads to the problem not exactly analytically solvable. The corresponding numerical solutions often lack direct mathematical and physical interpretations.

The conventional analysis of the BMC focuses on the mutual information [9] of the two subsystems for quantifying the underlying information correlations. There are three main representations on this. The first one were proposed and emphasized in the works of Sagawa, T. and Ueda, M.[11] and Parrondo, J. M. R., Horowitz, J. M., and Sagawa, T.[10] respectively for explaining the mechanism of Maxwell’s demon in Szilard’s engine. In this representation, the mutual information between the demon and controlled system characterizes the observation and the feedback of the demon. This leads to an elegant way which includes the increment of the mutual information into a unified fluctuation relation. The second representation was proposed by the work of Horowitz, J. M. and Esposito, M.[12] in an attempt to explain the violation of the second law in a specified BMC, the bipartite model, where the mutual information is divided into two parts corresponding to the two subsystems respectively, which were said to be the information flows. This representation tries to explain the mechanism of the demon because one can see that the information flows do contribute to the entropy production to both demon and controlled system. The first two representations are based on the ensembles of the subsystem states. This means that the mutual information is defined only on the time-sliced distributions of the system states, which somehow lacks the information of subsystem dynamics: the time-correlations of the observation and feedback of the demon. The last representation was seen in the work of Barato, A. C., Hartich, D., and Seifert, U.[13] where a more general definition of mutual information in information theory was used, which is defined on the trajectories of the two subsystem. More exactly, this is the so-called Mutual Information Rate (MIR) [18] which quantifies the correlation between the two subsystem dynamics. However, due to the difficulties from the possible underlying non-Markovian property of the marginal chains, exactly solvable models and comprehensive conclusions are still challenging from this representation.

In this study, we study the discrete-time BMC in both stochastic information dynamics and thermodynamics. To avoid the technical difficulty caused by non-Markovian dynamics, we first assume that the two marginal chains follow the Markovian dynamics. The non-Markovian case will be discussed elsewhere. We explore the time-irreversibility of BMC and marginal processes in steady state. Then we decompose driving force for the underlying dynamics as the information landscape and
information flux [14–16] which can be used to describe the time-reversible parts and time-irreversible parts respectively. We also prove that the non-vanishing flux fully describes the time-irreversibility of BMC and marginal processes.

We focus on the mutual information rate between the two marginal chains. Since the two marginal chains are assumed to be Markov chains here, the mutual information rate is exactly analytically solvable, which can be seen as the averaged conditional correlation between the two subsystem states. Here the conditional correlations reveal the time correlations between the past states and the future states.

Corresponding to the landscape-flux decomposition in stochastic dynamics, we decompose the MIR into two parts: the time-reversible and time-irreversible parts respectively. The time-reversible part measures the part of the correlations between the two marginal chains in both forward and backward processes of BMC. The time-irreversible part measures the difference between the correlations in forward and backward processes of BMC respectively. We can see that a non-vanishing time-irreversible part of the MIR must be driven by a non-vanishing flux in steady state, and it can be seen as the sufficient condition for a BMC to be time-irreversible.

We also reveal the important fact that the time-irreversible parts of MIR contributes to the nonequilibrium Entropy Production Rate (EPR) of the BMC by the simple equality:

\[ \text{EPR of BMC} = \text{EPR of 1st marginal chain} + \text{EPR of 2nd marginal chain} + 2 \times \text{time-irreversible part of MIR}. \]

The decomposition of the MIR and relation between time-irreversible part of MIR and EPRs can also be found in stationary and ergodic non-Markovian cases which will be given in the discussions in the appendix. This may help to develop general theory on nonequilibrium non-Markovian interacting information systems.

3. Information Landscape and Information Flux for Determining the Information Dynamics, Time-Irreversibility

Consider the case that two interacting information systems form a finite-state, discrete-time, ergodic, and irreducible bivariate Markov chain,

\[ Z = (X, S) = \{(X(t), S(t)), t \geq 1\}, \tag{1} \]

We assume that the information state space of \( X \) is given by \( \mathcal{X} = \{1, \ldots, d\} \) and the information state space of \( S \) is given by \( \mathcal{S} = \{1, \ldots, l\} \). The information state space of \( Z \) is then given by \( \mathcal{Z} = \mathcal{X} \times \mathcal{S} \).

The stochastic information dynamics can then be quantitatively described by the time evolution of probability distribution of information state space \( Z \), characterized by the following master equation (or the information system dynamics) in discrete time,

\[ p_z(z; t+1) = \sum_{z'} q_z(z|z') p_z(z'; t), \quad \text{for } t \geq 1, \text{ and } z \in \mathcal{Z} \tag{2} \]

where \( p_z(z; t) = p_z(x; s; t) \) is the probability of observing state \( z \) (or joint probability of \( X = x \) and \( S = s \)) at time \( t \); \( q_z(z'|z') = q_z(x, s|x', s') \geq 0 \) are the transition probabilities from \( z' = (x', s') \) to \( z = (x, s) \) respectively and are with \( \sum_{z'} q_z(z'|z') = 1 \).

We assume that there exists a unique stationary distribution \( \pi_z \) such that \( \pi_z(z) = \sum_{z'} q_z(z'|z') \pi_z(z') \). Then given arbitrary initial probability distribution, the probability distribution goes to \( \pi_z \) exponentially fast in time. If the initial distribution is \( \pi_z \), we say that \( Z \) is in Steady State (SS) and our discussion is based on this SS.

The marginal chains of \( Z \), i.e., \( X \) and \( S \), do not need to be Markov chains in general. For simplicity of analysis, we assume that both marginal chains are Markov chains and the corresponding transition
probabilities are given by \( q_c(x|x') \) and \( q_s(s'|s') \) (for \( x, x' \in X \) and \( s, s' \in S \)) respectively. Then we have the following master equations (or the information system dynamics) for \( X \) and \( S \) respectively,

\[
p_x(x; t + 1) = \sum_{x'} q_x(x|x') p_x(x'; t),
\]

and

\[
p_s(s; t + 1) = \sum_{s'} q_s(s|s') p_s(s'; t),
\]

where \( p_x(x; t) \) and \( p_s(s; t) \) are the probabilities of observing \( X = x \) and \( S = s \) at time \( t \) respectively.

We consider that both Eqs.(3,4) have unique stationary solutions \( \pi_x \) and \( \pi_s \) which satisfy \( \pi_x(x) = \sum_{x'} q_x(x|x') \pi_x(x') \) and \( \pi_s(s) = \sum_{s'} q_s(s|s') \pi_s(s') \) respectively. Also, we assume that when \( Z \) is in SS, \( \pi_x \) and \( \pi_s \) are also achieved. The relations between \( \pi_x \), \( \pi_s \) and \( \pi_x \) read,

\[
\begin{align*}
\pi_x(x) &= \sum_{s} \pi_x(x,s), \\
\pi_s(s) &= \sum_{x} \pi_x(x,s).
\end{align*}
\]

In the rest of this paper, we let \( X^T = \{X(1), X(2), \ldots, X(T)\} \), \( S^T = \{S(1), S(2), \ldots, S(T)\} \), and \( Z^T = \{Z(1), Z(2), \ldots, Z(T)\} = (X^T, S^T) \) denote the time sequences of \( X \), \( S \), and \( Z \) in time \( T \) respectively.

To characterize the time-irreversibility of the Markov chain \( C \) in information dynamics in SS, we introduce the concept of probability flux. Here we let \( C \) denote an arbitrary Markov chain in \( \{Z,X,S\} \), and let \( c \), \( \pi_c \), \( \rho_c \), and \( C^T \) denote arbitrary state of \( C \), the stationary distribution of \( C \), the transition probabilities of \( C \), and a time sequence of \( C \) in time \( T \) and in SS, respectively.

The averaged number transitions from the state \( c' \) to state \( c \), denoted by \( N(c' \rightarrow c) \), in unit time in SS can be obtained as

\[
N(c' \rightarrow c) = \pi_c(c') q_c(c'|c').
\]

This is also the probability of the time sequence \( C^T = \{C(1) = c', C(2) = c\} \), \( (T = 2) \). Correspondingly, the averaged number of reverse transitions, denoted by \( N(c \rightarrow c') \), reads

\[
N(c \rightarrow c') = \pi_c(c) q_c(c'|c).
\]

This is also the the probability of the time-reverse sequence \( \tilde{C}^T = \{C(1) = c, C(2) = c'\} \), \( (T = 2) \). The difference between these two transition numbers measures the time-reversibility of the forward sequence \( C^T \) in SS,

\[
J_c(c' \rightarrow c) = N(c' \rightarrow c) - N(c \rightarrow c') = P(C^T) - P(\tilde{C}^T) = \pi_c(c') q_c(c'|c) - \pi_c(c) q_c(c'|c), \text{ for } C = X, S, \text{ or } Z.
\]

Then, \( J_c(c' \rightarrow c) \) is said to be the probability flux from \( c' \) to \( c \) in SS. If \( J_c(c' \rightarrow c) = 0 \) for arbitrary \( c' \) and \( c \), then \( C^T \) \( (T = 2) \) is time-reversible; otherwise when \( J_c(c' \rightarrow c) \neq 0 \), \( C^T \) is time-irreversible. Clearly, we have from Eq. (6) that

\[
J_c(c' \rightarrow c) = -J_c(c \rightarrow c').
\]
The transition probability determines the evolution dynamics of the information system. We can decompose the transition probabilities \( q_c(c'|c) \) into two parts: the time-reversible part \( D_c \) and time-irreversible part \( B_c \), which read

\[
q_c(c'|c) = D_c(c' \rightarrow c) + B_c(c' \rightarrow c),
\]

with

\[
\begin{align*}
D_c(c' \rightarrow c) &= \frac{1}{2\pi_c(c')} (\pi_c(c')q_c(c'|c) + \pi_c(c)q_c(c'|c)), \\
B_c(c' \rightarrow c) &= \frac{1}{2\pi_c(c')} I_c(c' \rightarrow c).
\end{align*}
\]

From this decomposition, we can see that the information system dynamics is determined by two driving forces. One of the driving force is determined by the steady state probability distribution. This part of the driving force is time reversible. The other driving force for the information dynamics is the steady state probability flux which breaks the detailed balance and quantify the time irreversibility. Since the steady state probability distribution measures the weight of the information state, therefore it can be used to quantify the information landscape. If we define the potential landscape for the information system as \( \phi = -\log \pi \), then the driving force \( D_c(c' \rightarrow c) \) is time reversible due to the decomposition construction. The steady state probability flux measures the information flow in the dynamics and therefore can be termed as the information flux. In fact, the nonzero information flux explicitly breaks the detailed balance because of the net flow to or from the system. It is therefore a direct measure of the degree of the nonequilibrium or time irreversibility in terms of the detailed balance breaking.

Note that the decomposition for the discrete Markovian information process can be viewed as the separation of the current corresponding to the \( 2B_c(c' \rightarrow c)\pi_c(c') \) here and the activity corresponding to the \( 2D_c(c' \rightarrow c)\pi_c(c') \) in a previous study [22]. The landscape and flux decomposition here for the reduced information dynamics is in the similar spirit as the whole state space decomposition with the information system and the associated environments. When the detailed balance is broken, the information landscape (defined as the negative logarithm of the steady state probability \( \phi = -\log \pi \)) is not the same as the equilibrium landscape under the detailed balance. There can be uniqueness issue related to the decomposition. To avoid the confusion, we make a physical choice, or in other words we can fix the gauge so that the information landscape always coincides with the equilibrium landscape when the detailed balance is satisfied. In other words, we want to make sure the Boltzmann law applies at equilibrium with detailed balance. In this way, we can decompose the information landscape and information flux for nonequilibrium information systems without detailed balance. By solving the linear master equation for the steady state, we can quantify the nonequilibrium information landscape and from that we can obtain the corresponding steady state probability flux. Some studies discussed various aspects of this issue [21,22,27,28].

By Eqs.(7,8), we have the following relations

\[
\begin{align*}
\pi_c(c') D_c(c' \rightarrow c) &= \pi_c(c) D_c(c \rightarrow c'), \\
\pi_c(c') B_c(c' \rightarrow c) &= -\pi_c(c) B_c(c \rightarrow c').
\end{align*}
\] (9)

As we can see in next section, \( D_c \) and \( B_c \) are useful for us to quantify time-reversible and time-irreversible observables of \( C \) respectively.
We give the interpretation that the non-vanishing information flux $J_c$ fully measures the time-irreversibility of the chain $C$ in time $T$ for $T \geq 2$. Let $C^T$ be arbitrary sequence of $C$ in SS, and with no loss of generality we let $T = 3$. Similar to Eq. (6), the measure of time-irreversibility of $C^T$ can be given by the difference between the probability of $C^T = \{C(1), C(2), C(3)\}$ and that of its time-reversal $\tilde{C}^T = \{C(3), C(2), C(1)\}$, such as

$$P(C^T) - P(\tilde{C}^T) = \pi_c(C(1))q_c(C(2)|C(1))q_c(C(3)|C(2)) - \pi_c(C(3))q_c(C(2)|C(3))q_c(C(1)|C(2))$$

Then by the relations given in Eq. (9), we have $P(C^T) - P(\tilde{C}^T) = 0$ holds for arbitrary $C^T$ if and only if $B_c(C(1) \rightarrow C(2)) = B_c(C(2) \rightarrow C(3)) = 0$ or equivalently $J_c(C(1) \rightarrow C(2)) = J_c(C(2) \rightarrow C(3)) = 0$. This conclusion can be made for arbitrary $T > 3$. Thus, non-vanishing $J_c$ can fully describe the time-irreversibility of $C$ for $C = X, S$ or $Z$.

We show the relations between the fluxes of the whole system $J_x$ and of the subsystem $J_s$ as following:

$$J_x(x' \rightarrow x) = \pi_x(x')q_x(x'|x) - \pi_x(x)q_x(x'|x) = P(\{x', x\}) - P(\{x, x'\})$$

Similarly, we have

$$J_s(s' \rightarrow s) = \sum_{x, x'} I_x((x', s') \rightarrow (x, s)).$$

These relations indicate that the subsystem fluxes $J_x$ and $J_s$ can be seen as the coarse-grained levels of total system flux $J_x$ by averaging over the other part of the system $S$ and $X$ respectively. We should emphasize that, Non-vanishing $J_x$ does not mean $X$ or $S$ is time-irreversible and vice versa. Moreover, for the completeness and uniqueness of $C$,

4. Mutual Information Decomposition to Time-Reversible and Time-Irreversible Parts

According to the information theory, the two interacting information systems represented by bivariate Markov chain $Z$ can be characterized by the Mutual Information Rate (MIR) between the marginal chains $X$ and $S$ in SS. The mutual information rates represents correlation between two interacting information systems. The MIR is defined on the probabilities of all possible time sequences, $P(Z^T)$, $P(X^T)$, and $P(S^T)$, and is given by [18],

$$I(X, S) = \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{Z^T} P(Z^T) \log \frac{P(Z^T)}{P(X^T)P(S^T)}.$$  \hspace{1cm} (12)

It measures the correlation between $X$ and $S$ in unit time, or say, the efficient bits of information that $X$ and $S$ exchange with each other in unit time. The MIR must be non-negative, and a vanishing $I(X, S)$
indicates that X and S are independent of each other. More explicitly, the corresponding probabilities of these sequences can be evaluated by using Eqs.(2,3,4), we have

\[
P(X^T) = \pi_x(X(1)) \prod_{t=1}^{T-1} q_x(X(t+1)|X(t)),
\]

\[
P(S^T) = \pi_s(S(1)) \prod_{t=1}^{T-1} q_s(S(t+1)|S(t)),
\]

\[
P(Z^T) = \pi_z(Z(1)) \prod_{t=1}^{T-1} q_z(Z(t+1)|Z(t)).
\]

By substituting these probabilities into Eq.(12) (see Appendix A), we have the exact expression of MIR as

\[
I(X, S) = \sum_{z,z'} \pi_z(z') q_x(z | z') \log \frac{q_x(z | z')}{q_x(x | x') q_z(s | s')}
= \langle i(z|z') \rangle_{z,z'} \geq 0, \text{ for } z = (x, s), \text{ and } z' = (x', s').
\] (13)

where \(i(z|z') = \log \frac{q_x(z|z')}{q_x(x|x') q_z(s|s')}\) is the conditional (Markovian) correlation between the states \(x\) and \(s\) when the transition \(z' = (x', s') \rightarrow z = (x, s)\) occurs. This indicates that when the two marginal processes are both Markovian, the MIR is the average of the conditional (Markovian) correlations. These correlations are measurable when transitions occur and they can be seen as the observables of \(Z\).

By noting the decomposition of transition probabilities in Eq. (8), we have a corresponding decomposition of \(I(X, S)\) such as

\[
I(X, S) = I_D(X, S) + I_B(X, S), \text{ with }
\]

\[
I_D(X, S) = \sum_{z,z'} \pi_z(z') D_z(z | z') i(z | z') = \frac{1}{2} \sum_{z,z'} (\pi_z(z') q_z(z | z') + \pi_z(z) q_z(z' | z)) i(z | z'),
\]

\[
I_B(X, S) = \sum_{z,z'} \pi_z(z') B_z(z | z') i(z | z') = \frac{1}{2} \sum_{z,z'} J_z(z | z') i(z | z') = \frac{1}{2} \sum_{z,z'} J_z(z | z')(i(z | z') - i(z' | z)).
\]

This means that the mutual information representing the correlations between the two interacting systems can be decomposed into time reversible equilibrium part and time irreversible nonequilibrium part. The origin of this is from the fact that the underlying information system dynamics is determined by both the time reversible information landscape and time irreversible information flux. These equations are very important to establish the link to the time-reversibility. We now give further interpretation for \(I_D(X, S)\) and \(I_B(X, S)\):

Consider a bivariate Markov chain \(Z\) in SS wherein \(X\) and \(S\) are dependent of each other, i.e.,

\[
I(X, S) = I_D(X, S) + I_B(X, S) > 0.
\]

By the ergodicity of \(Z\), we have the MIR which measures the averaged conditional correlation along the time sequences \(Z^T\),

\[
\lim_{T \to \infty} \frac{1}{T} \langle i(Z(t+1)|Z(t)) \rangle_{Z^T} = I(X, S), \text{ for } 1 < t < T.
\]

Then \(I_B(X, S)\) measures the change of averaged conditional correlation between \(X\) and \(S\) when a sequence of \(Z\) turns back in time,

\[
\lim_{t \to \infty} \frac{1}{T} \langle i(Z(t+1)|Z(t)) - i(Z(t)|Z(t+1)) \rangle_{Z^T} = 2I_B(X, S).
\]

A negative \(I_B(X, S)\) shows that the correlation between \(X\) and \(S\) becomes strong in the time-reversal process of \(Z\); A positive \(I_B(X, S)\) shows that the correlation becomes weak in the time-reversal process of \(Z\). Both two cases show that the \(Z\) is time-irreversible since we have a non-vanishing \(J_z\). But the case of \(I_B(X, S) = 0\) is complicated, since it indicates either a vanishing \(J_z\) or a non-vanishing \(J_z\). Anyway, we see that a non-vanishing \(I_B(X, S)\) is a sufficient condition for \(Z\) to be time-irreversible. On the other hand, \(I_D(X, S) = I(X, S) - I_B(X, S)\) measures the correlation remaining in the backward process of \(Z\).
5. Relationship Between Mutual Information and Entropy Production

The Entropy Production Rates (EPR) or energy dissipation (cost) rate at steady state is a quantitative nonequilibriumness measure which characterizes the time-irreversibility of the underlying processes. The EPR of a stationary and ergodic process $C$ (here $C = Z, X,$ or $S$) can be given by the difference between the averaged surprisal (negative logarithmic probability) of the backward sequences $\tilde{C}^T$ and that of forward sequences $C^T$ in long time limit, i.e.,

$$R_c = \lim_{T \to \infty} \frac{1}{T} \langle \log P(C^T) - \log P(\tilde{C}^T) \rangle_{CT}$$

$$= \lim_{T \to \infty} \frac{1}{T} \left\langle \log \frac{P(C^T)}{P(\tilde{C}^T)} \right\rangle_{CT} \geq 0,$$

(15)

where $R_c$ is said to be the EPR of $C \ [19]$; $-\log P(C^T)$ and $-\log P(\tilde{C}^T)$ are said to be the surprisal of a forward and a backward sequence of $C$ respectively. We see that $C$ is time-reversible (i.e., $P(C^T) = P(\tilde{C}^T)$ for arbitrary $C^T$ for large $T$) if and only if $R_c = 0$. And this is due to the form of $R_c$ which is exactly a Kullback–Leibler divergence. When $C$ is Markovian, then $R_c$ reduces into the following form when $Z, X$ or $S$ is assigned to $C$ respectively $[17,20]$,

$$R_c = \frac{1}{2} \sum_{z,z'} J_c(z' \to z) \log \frac{q_c(z'|z)}{q_c(z'|z)},$$

$$R_x = \frac{1}{2} \sum_{x,x'} J_x(x' \to x) \log \frac{q_x(x'|x)}{q_x(x'|x)},$$

$$R_s = \frac{1}{2} \sum_{s,s'} J_s(s' \to s) \log \frac{q_s(s'|s)}{q_s(s'|s)},$$

(16)

where total and subsystem entropy productions $R_z, R_x, \text{ and } R_s$ correspond to $Z, X, \text{ and } S$ respectively.

Here, $R_z$ usually contains the detailed interaction information of the system (or subsystems) and environments; $R_x$ and $R_s$ provide the coarse-grained information of time-irreversible observables of $X$ and $Z$ respectively. Each non-vanishing EPR indicates that the corresponding Markov chain is time-irreversible. Again, we emphasize that a non-vanishing $R_z$ does not mean $X$ or $S$ is time-irreversible and vice versa.

We are interested in the connection between these EPRs and mutual information. We can associate them with $I_B(X, S)$ by noting Eqs. (10, 11, 14). We have

$$I_B(X, S) = \frac{1}{4} \sum_{z,z'} J_c(z'|z') (i(z|z') - i(z'|z))$$

$$= \frac{1}{4} \sum_{z,z'} J_c(z'|z') \log \frac{q_c(z'|z)}{q_c(z'|z)} - \frac{1}{4} \sum_{x,x'} J_x(x'|x') \log \frac{q_x(x'|x)}{q_x(x'|x)} - \frac{1}{4} \sum_{s,s'} J_s(s'|s') \log \frac{q_s(s'|s)}{q_s(s'|s)}$$

$$= \frac{1}{2} (R_z - R_x - R_s).$$

(17)
We note that $I_B(X, S)$ is intimately related to the EPRs. This builds up a bridge between these EPRs and irreversible part of the mutual information. Moreover, we also have

$$\begin{align*}
R_z &= R_x + R_z + 2I_B(X, S) \geq 0, \\
R_x + R_z &\geq -2I_B(X, S), \\
R_z &\geq 2I_B(X, S).
\end{align*}$$

(18)

This indicates that the time-irreversible MIR contributes to the detailed EPRs. In other words, the differences of entropy production rate of the whole system and subsystems provides the origin of the time irreversible part of the mutual information. This reveals the nonequilibrium thermodynamic origin of the irreversible mutual information or correlations. Of course, since the EPR is related to the flux directly as is seen from above definitions, the origin of the EPR or nonequilibrium thermodynamics is from the non-vanishing information flux for the nonequilibrium dynamics. On the other hand, irreversible part of the mutual information measures the correlations and it contributes to the EPRs of the correlated subsystems.

Furthermore, the last expression in Eq. (17) (also the expressions in Eq. (18)) can be generalized to more general stationary and ergodic processes. Related discussion and demonstration on this can be seen in Appendix B.

6. A Simple Case: The Blind Demon

As a concrete example, we consider a two-state system coupled to two information baths $a$ and $b$. The states of the system are denoted by $\mathcal{X} = \{x : x = 0, 1\}$ respectively. Each bath sends an instruction to the system. If the system adopts one of them, it then follows the instruction and makes change of the state. The instructions generated from one bath are independently and identically distributed (Bernoulli trials). Both the probability distributions of the instructions corresponding to the baths follow Bernoulli distributions and read $\{\epsilon_a(x) : x \in \mathcal{X}, \epsilon_a(x) \geq 0, \sum_x \epsilon_a(x) = 1\}$ for bath $a$ and $\{\epsilon_b(x) : x \in \mathcal{X}, \epsilon_b(x) \geq 0, \sum_x \epsilon_b(x) = 1\}$ for bath $b$ respectively. Since the system cannot execute two instructions simultaneously, there exists an information demon that makes choices for the system. The demon is blind to care about the system and it makes choices independently and identically distributed. The choices of the demon are denoted by $\mathcal{S} = \{s : s = a, b\}$ respectively. The probability distribution of demon’s choices reads $\{P(s) : s \in \mathcal{S}, P(a) = p, P(b) = 1 - p, p \in [0, 1]\}$. Still, we use $Z = (X, S)$ with $X \in \mathcal{X}$ and $S \in \mathcal{S}$ to denote the BMC of the system and the demon.

Consequentially, the transition probabilities of the system read

$$q_x(x'|x) = p\epsilon_a(x) + (1 - p)\epsilon_b(x).$$

The transition probabilities of the demon read

$$q_s(s'|s) = P(s).$$

And the transition probabilities of the joint chain read

$$q_z(x, s|x', s') = P(s)\epsilon_s(x).$$

We have the corresponding steady state distributions or the information landscapes as,

$$\begin{align*}
\pi_x(x) &= p\epsilon_a(x) + (1 - p)\epsilon_b(x), \\
\pi_s(s) &= P(s), \\
\pi_z(x, s) &= P(s)\pi_x(x).
\end{align*}$$
We obtain the information fluxes as,

\[
\begin{align*}
J_x(x' \to x) &= 0, \text{ for all } x, x' \in \mathcal{X} \\
J_s(s' \to s) &= 0, \text{ for all } s, s' \in \mathcal{S} \\
J_z((x', s') \to (x, s)) &= P(s)P(s') (\pi_x(x')e_p(x) - \pi_x(x)e_s(x')).
\end{align*}
\]

Here, we use the notations \(\epsilon_s'(x')\) and \(\epsilon_s(x)\) \((s, s' = a \text{ or } b)\) to denote the probabilities of the instructions \(x'\) or \(x\) from bath \(a\) or \(b\) briefly. We obtain the EPRs as

\[
\begin{align*}
R_x &= 0, \\
R_s &= 0, \\
R_z &= \sum_x p(1 - p)(\epsilon_a(x) - \epsilon_b(x))(\log \epsilon_a(x) - \log \epsilon_b(x)).
\end{align*}
\]

We evaluate the MIR as

\[
I(X, S) = -\sum_x \pi_x(x) \log \pi_x(x) + p \sum_x \epsilon_a(x) \log \epsilon_a(x) + (1 - p) \sum_x \epsilon_b(x) \log \epsilon_b(x).
\]

The time-irreversible part of \(I(X, S)\) reads,

\[
I_B(X, S) = \frac{1}{2} R_z.
\]

7. Conclusion

In this work, we identify the driving forces for the information system dynamics. We show that for marginal Markovian information systems, the information dynamics is determined by both the information landscape and information flux. While the information landscape can be used to construct the driving force for describing the time reversible behavior of the information dynamics, the information flux can be used to describe the time irreversible behavior of the information dynamics. The information flux explicitly breaks the detailed balance and provides a quantitative measure of the degree of the nonequilibriumness or time irreversibility. We further demonstrate that the mutual information rate which represents the correlations can be decomposed into time reversible part and time irreversible part originated from the landscape and flux decomposition of the information dynamics. Finally we uncover the intimate relationship between the difference of the entropy productions of the whole system to those of the subsystems and the time irreversible part of the mutual information. This will help for understanding the non-equilibrium behaviour of the interacting information system dynamics in stochastic environments. Furthermore, we verify that our conclusions on the mutual information rate and entropy production rate decomposition can be made more general for the stationary and ergodic processes.

- EPR: Entropy Production Rate
- MIR: Mutual Information Rate
- SS: Steady State
Appendix A

Here, we derive the exact form of Mutual Information Rate (MIR, Eq.(13)) in steady state by using the cumulant-generating function.

We write arbitrary time sequence of $Z$ in time $T$ in the form as following

\[ Z_T = \{ Z(1), ..., Z(i), ..., Z(T) \}, \text{ for } T \geq 2, \]

where $Z(i)$ (for $i \geq 1$) denotes the state at time $i$. The corresponding probability of $Z_T$ is in the following form

\[ P(Z_T) = \pi_z(Z_1) \left\{ \prod_{i=1}^{T-1} q_z(Z_{i+1}|Z_i) \right\}, \quad (A.1) \]

We let the chain $U = (X, S)$ to denote a process that $X$ and $S$ follow the same Markov dynamics in $Z$ but are independent of each other. Then we have the transition probabilities of $U$ read

\[ q_u(u|u') = q(x,s|x',s') = q_x(x'|x)q_s(s'|s). \quad (A.2) \]

Then the probability of a time sequence of $U$, $U_T$, with the same trajectory of $Z_T$ reads

\[ P(U_T) = \pi_u(Z_1) \left\{ \prod_{i=1}^{T-1} q_u(Z_{i+1}|Z_i) \right\}, \quad (A.3) \]

with $\pi_u(x,s) = \pi_x(x)\pi_s(s)$ being the stationary probability of $U$.

For evaluating the exact form of MIR, we introduce the cumulant-generating function of the random variable $\log \frac{P(Z_T)}{P(U_T)}$,

\[ K(m, T) = \log \left\langle \exp \left( m \log \frac{P(Z_T)}{P(U_T)} \right) \right\rangle_{Z_T}, \quad (A.4) \]

We can see that

\[ \lim_{T \to \infty} \lim_{m \to 0} \frac{1}{T} \frac{\partial K(m, T)}{\partial m} = \lim_{T \to \infty} \frac{1}{T} \left\langle \log \frac{P(Z_T)}{P(U_T)} \right\rangle_{Z_T} = I(X, S). \quad (A.5) \]

Thus, our idea is to evaluate $K(m, T)$ at first. We have

\[ K(m, T) = \log \left\langle \exp \left( m \log \frac{P(Z_T)}{P(U_T)} \right) \right\rangle_{Z_T} \]

\[ = \log \left\{ \sum_{Z_T} \left( \frac{P(Z_T)}{P(U_T)} \right)^m \right\} \]

\[ = \log \left\{ \sum_{\{Z(0), Z(1), ..., Z(T)\}} \frac{(\pi_w^{m+1}(Z_0))}{(\pi_w^m(Z_0))} \prod_{i=0}^{T-1} q_w^{m+1}(Z_{i+1}|Z_i) \right\}, \quad (A.6) \]

where we realize that the last equality can be rewritten in the form of matrices multiplication.
We introduce the following matrices and vectors for Eq. (A.6) such that

\[ Q_z = \{(Q_z)_{zz'} = q_z(z|z'), \text{ for } z, z' \in Z\}, \]

\[ G(m) = \{(G(m))_{zz'} = q_m^{z+1}(z|z'), \text{ for } z, z' \in Z\}, \]

\[ \pi_z = \{(\pi_z)_z = \pi_z(z), \text{ for } z \in Z\}, \]

\[ \nu(m) = \{(\nu(m))_z = \pi_m^{z+1}(z)\}, \quad (A.7) \]

where \( Q_z \) is the transition matrix of \( Z \); \( \pi_z \) is the stationary distribution of \( Z \). It can be also verified that

\[ Q_z = G(0), \]
\[ \pi_z = \nu(0), \]
\[ \pi_z = Q_z \pi_z, \]
\[ 1^T Q_z = 1^T, \]
\[ \lim_{m \to 0} \frac{dG(m)}{dm} = \left\{ \lim_{m \to 0} \frac{dG(m)}{dm} \right\}_{zz'} = q_z(z|z') \log \frac{q_z(z|z')}{q_u(z|z')}, \text{ for } z, z' \in Z, \quad (A.8) \]

where \( 1^T \) is the vector of all 1’s with appropriate dimension.

Then \( K(m, T) \) can be rewritten in a compact form such that

\[ K(m, T) = \log \left\{ 1^T G^{T-1}(m) \nu(m) \right\}. \quad (A.9) \]

Then, we substitute Eq. (A.9) into Eq. (A.5) and have

\[ I(X, S) = \lim_{T \to \infty} \lim_{m \to 0} \frac{1}{T} \frac{\partial K(m, T)}{\partial m} \]
\[ = \lim_{T \to \infty} \lim_{m \to 0} \frac{1}{T} \frac{\partial}{\partial m} \left\{ 1^T G^{T-1}(m) \nu(m) \right\} \]
\[ = \lim_{T \to \infty} \lim_{m \to 0} \frac{1}{T} \{ (T - 1) 1^T G^{T-2}(m) \frac{dG(m)}{dm} \nu(m) + 1^T G^{T-1}(m) \frac{d\nu(m)}{dm} \} \]
\[ = \lim_{T \to \infty} \lim_{m \to 0} \frac{1}{T} \left\{ (T - 1) 1^T G^{T-2}(0) \left( \lim_{m \to 0} \frac{dG(m)}{dm} \right) \nu(0) + 1^T G^{T-1}(0) \left( \lim_{m \to 0} \frac{d\nu(m)}{dm} \right) \right\}. \quad (A.10) \]

By noting Eq. (A.8) and \( T \geq 2 \), we obtain Eq. (13) from Eq. (A.10) that

\[ I(X, S) = \lim_{T \to \infty} \lim_{m \to 0} \frac{1}{T} \left\{ (T - 1) 1^T G^{T-2}(0) \left( \lim_{m \to 0} \frac{dG(m)}{dm} \right) \nu(0) + 1^T G^{T-1}(0) \left( \lim_{m \to 0} \frac{d\nu(m)}{dm} \right) \right\} \]
\[ = \lim_{T \to \infty} \left\{ \left( 1 - \frac{1}{T} \right) 1^T \left( \lim_{m \to 0} \frac{dG(m)}{dm} \right) \pi_z + \frac{1}{T} 1^T \left( \lim_{m \to 0} \frac{d\nu(m)}{dm} \right) \right\} \]
\[ = 1^T \left( \lim_{m \to 0} \frac{dG(m)}{dm} \right) \pi_z \]
\[ = \sum_{(x,s),(x',s')} \pi_z(x',s') q_z(x,s|x',s') \log \frac{q_z(x,s|x',s')}{q_u(x|s') q_u(s|s')} \quad (A.11) \]
Appendix B

Appendix B.1

For general cases, indeed, we do not expect that both X and S are Markovian. Even the joint chain Z may be non-Markovian. This means that Eq. (2) may fail to depict the dynamics of Z. Then the landscape-flux decomposition needs to be generalized to this situation. Such decomposition was not developed yet for the non-Markovian cases. This will be discussed in a separate work. However, when Z is stationary and ergodic process (also assume that both X and S are stationary and ergodic), we show that the MIR can be decomposed into two parts as is shown in Eq. (14) and interesting relation between the MIR and EPRs can still be found in the same form of the last expression in Eq. (17).

We are interested in the correlation between the forward sequences of X and S which can be measured by \( \log \frac{P(Z^T)}{P(X^T)P(S^T)} \) (\( Z^T = (X^T, S^T) \)), then the MIR can be used to quantify the average rate of this correlation in the long time limit as shown in Eq. (12). Furthermore, we are interested in the averaged difference between the rate of the correlation of the backward processes and that of the forward processes. This comes the time-irreversible part of the MIR defined by

\[
I_B(X, S) = \lim_{T \to \infty} \frac{1}{2T} \left\{ \log \frac{P(Z^T)}{P(X^T)P(S^T)} - \log \frac{P(Z^T)}{P(X^T)P(S^T)} \right\}_{Z^T},
\]

where \( \log \frac{P(Z^T)}{P(X^T)P(S^T)} \) quantifies the correlation between the backward sequences of X and S. Clearly, the time-irreversible part of MIR depicting the correlation of the forward processes of X and S is enhanced (\( I_B(X, S) > 0 \)) or weakened (\( I_B(X, S) < 0 \)) compared to that of the backward processes. The other important part of the MIR, namely the time-reversible part, shows the averaged rate of the correlation that remains in both forward and backward processes,

\[
I_D(X, S) = \lim_{T \to \infty} \frac{1}{2T} \left\{ \log \frac{P(Z^T)}{P(X^T)P(S^T)} + \log \frac{P(Z^T)}{P(X^T)P(S^T)} \right\}_{Z^T},
\]

Consequently, the MIR \( I(X, S) \) is decomposed into two parts shown as \( I(X, S) = I_D(X, S) + I_B(X, S) \). In Markovian cases, each part of the MIR reduces into the form in Eq. (14) respectively.

The relation between the time-irreversible part of the MIR and EPRs can be shown as follows,

\[
I_B(X, S) = \lim_{T \to \infty} \frac{1}{2T} \left\{ \log \frac{P(Z^T)}{P(X^T)P(S^T)} - \log \frac{P(Z^T)}{P(X^T)P(S^T)} \right\}_{Z^T} = \frac{1}{2} (R_x - R_X - R_s),
\]

which is in the same form of Eq. (17). And due to the non-negativity of the EPRs, the inequalities in (18) still hold for general cases.

Appendix B.2 The Smart Demon

To verify the conclusions in more general cases, we constructed a model of smart demon which reflects a more general situation in the nature – the two information subsystems play feedback to each other. A three-state information system is connected to two information baths labelled by \( a \) and \( b \) respectively. The states of the system are denoted by \( X = \{ x : x = 0, 1, 2 \} \) respectively. Each bath sends an instruction to the system. If the system adopts one of them, it then follows the instruction and makes a change of the state. The instructions generated from arbitrary one bath are independent, and identically distributed. The probability distributions of the instructions corresponding to the baths read
The behavior of the demon can be seen as a Markovian process in steady state. The corresponding transition probabilities of the system read

\[ q(x'|x, s, s') = d(s|x', s') \epsilon_s(x), \]

where \( \epsilon_s(x) \) denotes the probability of the instruction \( x \) from bath \( s = a, b \). We assume that there is a unique stationary distribution of \( z, \pi_z \) such that

\[ \pi_z(z) = \sum_{z'} q_z(z'|z) \pi_z(z'). \]

The stationary distribution of \( S \) and \( X \) then reads

\[
\begin{align*}
\pi_S(s) &= \sum_x \pi_z(x, s) , \\
\pi_X(x) &= \sum_x \pi_z(x, s).
\end{align*}
\]

The behavior of the demon can be seen as a Markovian process in steady state. The corresponding transition probabilities of the system read

\[ q_x(s'|s, \epsilon) = \frac{1}{\pi_x(s')} \sum_{x'} d(s|x', s') \pi_z(x', s'). \]

It can be verified that \( \pi_x \) is the unique stationary distribution of \( S \). However, the dynamics of the system always behaves as a non-Markovian process in general.

To characterize the time-irreversibility of \( Z, X, \) and \( S \), we use the definition of EPR in Eq. (15) and have

\[
\begin{align*}
R_z &= \frac{1}{2} \sum_{z, z'} I_z(z' \rightarrow z) \log \frac{q_z(z'|z)}{q_z(z'|z')}, \\
R_s &= \frac{1}{2} \sum_{s, s'} I_s(s' \rightarrow s) \log \frac{q_s(s'|s)}{q_s(s'|s')} = 0, \\
R_X &= \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{X^T} P(X^T) \log \frac{P(X^T)}{P(X^T)},
\end{align*}
\]

where

\[ P(X^T) = \sum_{S^T} P(Z^T = (X^T, S^T)). \]

To quantify the correlation between the system and demon, we use the definition of MIR in Eq. (12).

We are also interested in the time-irreversible part of MIR, \( I_B(X, S) \) which influences the EPR of the system, \( R_s \). This can be seen from Eq. (B.3) such that

\[ R_s = R_z - R_s - 2I_B(X, S). \]
We use numerical simulations which evaluate $R(X)$, $I(X, S)$, and $I_{gb}(X, S)$ directly from the typical sequences of $Z$ (see [7,8]). The corresponding results can be given by

$$R(X) \approx \frac{1}{T} \log \frac{P(X^T)}{P(X^T|\tilde{S})} \quad \text{for large } T,$$

$$I(X, S) \approx \frac{1}{T} \log \frac{P(X,S)^T}{P(X^T)^{P(S)/T}} \quad \text{for large } T,$$

$$I_{gb}(X, S) \approx \frac{1}{2T} \log \frac{P(Z)^T}{P(Z|X)^{P(S)/T}} - \frac{1}{2T} \log \frac{P(Z^T)}{P(Z^T|X^T)^{P(S)/T}} \quad \text{for large } T,$$

where $Z^T = (X^T, S^T)$ is a typical sequence of $Z$ (hence $X^T$ and $S^T$ are typical sequences of $X$ and $S$ respectively). The convergence of this numerical simulation can be observed as $T$ increases. To confirm the result $R_{x} = R_{y} - R_{z} - 2I_{gb}(X, S)$, we use different typical sequences in calculating $R(X)$ and $I_{gb}(X, S)$ respectively. $R(z)$ and $R(s)$ are calculated by using the corresponding analytical results shown above.

For numerical simulations, we randomly choose two groups of the parameters: the probabilities of the instructions of the baths $e_a$ and $e_b$, and probabilities of the demon choices $d$ (see Tables A.1 and A.2). We evaluate $R(X)$, $I(X, S)$, and $I_{gb}(X, S)$ for all two groups. The values of numerical results are listed in Table A.3.
