Abstract

**Objective:** The Rho GTPase/Rho kinase pathway is an important target in glaucoma treatment. This study investigated the hypotensive effect of RKI-1447, a Rho kinase inhibitor developed for cancer treatment, in a porcine ex vivo pigmentary glaucoma model.

**Materials and Methods:** Twenty-eight fresh porcine anterior chambers were perfused with pigment medium (1.67×10⁷ pigment particles/ml) for 48 hours before being subjected to the RKI-1447 (n=16) or the vehicle control (n=12). Another twelve eyes with normal medium perfusion served as the control. The intraocular pressure (IOP) was recorded at two-minute intervals and the outflow facility was calculated. To investigate the intracellular mechanism of the IOP reduction, primary trabecular meshwork cells were exposed to RKI-1447 or the vehicle control and then analyzed for changes in cytoskeleton, motility, and phagocytosis.

**Results:** Compared to the baseline, the perfusion of pigment caused a significant increase in IOP in the RKI-1447 group (P=0.003) at 48 hours. Subsequent treatment with RKI-1447 significantly reduced IOP from 20.14+/−2.59 mmHg to 13.38+/−0.91 mmHg (P=0.02). Pigment perfusion reduced the outflow facility from 0.27+/−0.03 at baseline to 0.18+/−0.02 at 48 hours (P<0.001). This was partially reversed with RKI-1447. RKI-1447 exhibited no apparent changes in the micro- or macroscopic appearance, including histology. Primary TM cells exposed to RKI-1447 showed a significant disruption of the actin cytoskeleton both in the presence and absence of pigment exposure (P<0.001) but no effect on TM migration was observed. Pigment-treated TM cells exhibited a reduction in TM phagocytosis, which RKI reversed.

**Conclusions:** RKI-1447 is a novel ROCK inhibitor that significantly reduces IOP by disrupting TM stress fibers and increasing TM phagocytosis. These features may make it especially useful for the treatment of secondary glaucomas with an increased phagocytosis load but also for other open angle glaucomas.

**Keywords:** pig eye perfusion model; pigmentary glaucoma; ocular hypertension; ocular hypotension; phagocytosis; rho-kinase inhibitor
**Introduction**

The ocular hypertension that is frequently observed in glaucoma patients exhibits a complex pathomechanism that remains incompletely understood. The intraocular pressure (IOP) remains the single most important modifiable variable in glaucoma treatment. Current topical medications for glaucoma typically increase the uveoscleral outflow of aqueous humor (prostaglandin analogues) or reduce aqueous humor production (beta-adrenergic blockers, alpha-adrenergic agonists, carbonic anhydrase inhibitors). The only drugs that increase the conventional outflow that are readily available at the time of this writing are cholinergic agonists who have miosis and ciliary spasm as significant side effects although NO donors are on the horizon that relax the TM to increase outflow. In the present study we examine the hypotensive effect of RKI-1447, which was originally introduced as an anti-tumor agent in breast cancer treatment.

The Rho-associated protein kinase (ROCK) is part of the serine-threonine kinases that act on the cytoskeleton to regulate the movement and shape of cells. It plays a central role in biological functions such as stress-fibre formation and contraction, cell adhesion, migration and invasion, transformation, phagocytosis and apoptosis, cytokinesis and mitosis as well as differentiation. Previous studies found that ROCK is expressed in the TM and upregulated in the optic nerve head of glaucomatous eyes. Honjo and colleagues found that ROCK inhibitor Y-27632 increased the outflow facility in a dose-dependent manner in rabbit eyes. The investigators suggested that the hypotensive effect may result from a disruption of actin bundles and reduction in the focal adhesion of TM cells. Similarly, recent studies found that ROCK inhibitors disrupt tight junctions thereby increasing the permeability of Schlemm’s canal endothelium in addition to decreasing the episcleral venous pressure.

Ripasudil (K-115) was the first approved ROCK inhibitor for glaucoma. Two randomized trials involving 413 Japanese primary open-angle glaucoma patients found that Ripasudil achieved an average of 0.4-1.6 mmHg higher IOP reduction than the administration of timolol or latanoprost alone. Phase II/III trials that aim to investigate the IOP-lowering effect of four different ROCK inhibitors (AMA0076, AR-13324, K-115 and PG-324) are currently in process. Several trials that employed functionally and structurally similar compounds were discontinued due to the low therapeutic efficiency and high incidence of adverse events.

First characterized by Patel et al. in 2012, RKI-1447 inhibits the type I kinase by binding to the ATP binding site through interaction with the Asp-Phe-Gly motif and hinge region. In vitro, it selectively inhibits the ROCK1/2-mediated actin stress fiber formation at the low level of IC-50 (14.5 nM and 6.2 nM for ROCK1 and ROCK2, respectively) following lysophosphatidic acid stimulation. Unlike other ROCK inhibitors, RKI-1447 does not exhibit cross-reactivity with AKT, MEK, PKA, and PKG signaling, even at a high concentration of up to 10 μM, reducing the risk of side effects. Recently, our group developed an ex vivo pigmentary glaucoma model that exhibited a IOP elevation, a typical TM stress fiber formation, and a reduction in TM phagocytosis. In this paper, we examine the ocular hypotensive effect of RKI-1447 in an ex vivo anterior chamber perfusion model and investigate its possible mechanisms.
Figure 1. Molecular structure of RKI-1447. RKI-1447 is an ATP site-targeting Rho kinase inhibitor with an IC50 of 14.5 nM and 6.2 nM for ROCK1 and ROCK2, respectively (a). It has a crystal structure and works by interacting with the Asp-Phe-Gly motif and hinge region of ROCKs (b).

Materials and Methods

Pig eye perfusion, pigmentary glaucoma model, and RKI-1447 intervention

No live animals were involved in the study and the eyes were obtained from a local abattoir. As a result, no Institutional Animal Care and Use Committee protocol was required. The setup of the porcine eye perfusion system followed our prior protocols. Briefly, 40 freshly enucleated pig eyes were obtained from a local slaughterhouse (Thoma Meat Market, Saxonburg, PA) and processed within two hours of sacrifice. After the removal of extraocular tissues, the eyes were disinfected in a 5% povidone-iodine ophthalmic solution (betadine 5%; Alcon, Fort Worth, TX, USA) for two minutes, washed three times with PBS, and hemisected. The anterior chambers were then mounted on the perfusion dishes and subsequently underwent continuous perfusion with 1% FBS supplemented with DMEM and antibiotics at a constant rate of 3μl per min.

Once the baseline IOPs were obtained, 28 of the 40 eyes were perfused with the pigment medium for 48 hours (1.67×10⁷ pigment particles/ml) before being subjected to the RKI-1447 (n=16) or the vehicle control (n=12). For the RKI-1447 group, RKI-1447 was diluted into the pigment medium to a final concentration of 1μM before the solution was perfused into the eyes. For the vehicle control, the eyes were continuously perfused with the same pigment medium. A total of 12 of the 40 samples without the pigment perfusion and the RKI-1447 served as the normal control. IOPs were measured using a pressure transducer at a two-minute interval.

Production of pigment dispersion particles

Pigment particles for pigment dispersion were produced as previously described using a freeze-thaw protocol. In brief, ten porcine irises were sealed in a 50-ml tube, frozen at a temperature of -80° for 2 hours, then thawed at room temperature. After two cycles of freeze-thaw, 15 ml of PBS was added to the tube. By
pipetting up and down 100 times with a 3 ml Pasteur pipette, the pigment particles were shed from the irises. They were then collected and centrifuged at 3000 rpm for 15 min. The supernatant was discarded, and the pigment pellet was resuspended and centrifuged again at the same settings. Finally, the pigment particles were resuspended in 4 ml of phosphate-buffered saline (PBS) as the stock solution and titered using a hemocytometer (#1490, Hausser Scientific, Horsham, PA) at 1000-fold dilution as per the method previously described\textsuperscript{25}.

**Histology**

At the conclusion of the experiments, the chambers were dismounted, washed with PBS, fixed with 4\% PFA for 24 hours and paraffin embedded. The samples were sectioned at 6-micron thickness, followed by staining with Hematoxylin and Eosin.

**Primary TM culture**

Primary porcine TM cells were purified and characterized by our previous protocol\textsuperscript{25}. A porcine anterior chamber was dissected as above. After removing the extra sclera and cornea, the entire TM stripes were sectioned into 1 mm X 1 mm pieces and cultured in a T75 flask with TM-culturing medium (5\% FBS supplemented with OptiMEM and antibiotics). Primary TM cells started to migrate onto the flask on day four and formed clones. The cells were passaged at 80\% confluence and replated at a 1:3 ratio. We characterized these cells by immunostaining with a combination of TM specific antibodies (alpha smooth muscle actin [alpha-SMA] antibody, matrix gla protein [MGP] antibody and aquaporin 1 [AQP1]) and an in vitro phagocytic assay. To avoid transformation and differentiation, only the cells within the first four passages were used.

**Immunostaining**

For further characterization, we plated these primary cells onto 10 mm X 10 mm glass slides and fixed them with 4\% PFA at 80\% confluence. This was followed by washing with PBS three times and incubation with the primary antibody overnight at 4°. The primary antibodies were goat polyclonal anti-MGP antibodies (1:100 dilution, sc-32820, Santa Cruz, Dallas, Texas), rabbit polyclonal anti alpha-SMA (1:100, ab5694, Abcam, Cambridge, MA) and rabbit polyclonal anti-AQP1 antibodies (1:100, Sc-20810, Santa Cruz, Dallas, Texas). After three rinses in PBS, a mixture of secondary antibodies (donkey-anti-goat Alexa Fluor® 647 [1:200, ab150131, Abcam, Cambridge, MA] and goat anti-rabbit Alexa Fluor® 488 [1:1000, A27034, Thermo Scientific, Waltham, MA]) was incubated with the cells for 45 minutes at room temperature. The cell nuclei were counterstained with DAPI (1:1000, D1306, Thermo Fisher Scientific, Waltham, MA) for 15 minutes. Images were acquired using an upright laser scanning confocal microscope at 400x magnification (BX61, Olympus, Tokyo, Japan).

To quantify the stress fiber formation, the cells were fixed with 4\% PFA for 24 hours before being stained with Alexa Fluor® 488 Phalloidin for 30 minutes (1:20, A12379, Thermo Scientific, Waltham, MA). The cell nuclei were labeled with 4',6-diamidino-2-phenylindole (DAPI). Images were acquired using the upright confocal microscope at the same settings as those used to take images of the cell nuclei. Ten randomized visual fields were chosen to quantify the percentages of cells with stress fibers for each group.
TM motility assay

The in vitro TM cell motility was using a scratch assay with a minor modification. In brief, \(2 \times 10^5\) of primary TM cells were seeded into each well of a six-well plate and cultured in an environmental chamber that was equipped with a digital camera and image acquisition software. After reaching 80% confluency, the cells were treated with pigment particle at a concentration of \(1.67 \times 10^7\) particles/ml for 24 hours. A 10μl pipette tip was used to create a cell-free scratch that had a consistent width. Following that, RKI-1447 (final concentration: 1μM) or vehicle was applied. Pictures from ten positions of each well were acquired at a two-hour interval, up to 20 hours. The numbers of TM cells moved into the cell-free scratch were counted.

TM phagocytosis assay

The phagocytic activity of the primary TM cells was measured by flow cytometry using fluorescence microsphere ingestion test. \(2 \times 10^5\) primary TM cells were seeded into each well of a six-well plate and underwent the pigment exposure (final concentration: \(1.67 \times 10^7\) particles/ml) or vehicle treatment for seven days. Half of the cells were then treated with RKI-1447 (final concentration: 1μM) for 24 hours while the rest underwent the sham treatment. To quantify the phagocytic activity, the cells were incubated with 0.5-micron fluorescence microsphere at \(5 \times 10^8\)/ml at 37 degrees for 1 hour. After washing thoroughly with PBS, the cells were dissociated with trypsin and resuspended in 200μl PBS for flow cytometry. The percentage of cells ingested with microspheres was determined.

Statistics

Quantitative data were presented as the mean +/- standard error and processed by PASW 18.0 (SPSS Inc., Chicago, IL, USA). A paired t-test was used to compare the IOP responses from the baseline. Other quantitative data were compared by one-way ANOVA. A p≤0.05 was considered to be statistically significant.

Results

IOP reduction and increase of outflow facility

The baseline IOPs among these three groups were comparable (10.32 +/- 0.82 mmHg in the pigment group versus 12.21 +/- 1.06 mmHg in the RKI-1447 group and 10.21 +/- 1.15 mmHg in the control group, P=0.291). Compared to each baseline, the intracameral perfusion of pigment particles resulted in a significant IOP elevation in the pigment group (P=0.038) and the RKI-1447 group (P=0.003) at 48 hours, while IOPs in the control group remained unchanged (P=0.108). RKI-1447 significantly reduced IOP from 20.14 +/- 2.59 mmHg to 13.38 +/- 0.91 mmHg at 60 hours then remained at a low level throughout the study. In contrast, the IOP in the pigment group remained high in comparison to its baseline (all P<0.05). At all time points after RKI-1447, the IOP in the RKI-1447 group exhibited no statistical difference compared to the control (all P>0.05); however, both were significantly lower than those in the pigment group (all P<0.05) (Figure 2 A).

Because the episcleral venous pressure is close to zero in the perfusion system, the outflow facility is inversely correlated with IOP. In the current study, the baseline outflow facility exhibited no difference across the three
groups (P=0.316). Pigment perfusion caused a significant reduction in the outflow facility in the RKI-1447 group from 0.27+/-.03 at the baseline to 0.18+/-.02 at 48 hours (P<0.001), while RKI-1447 partially reversed this effect by 14.57% to 48.35% at the follow-up time points. In contrast, the outflow facility in the pigment group continuously decreased from a baseline of 0.31+/-.03 to 0.15+/-.01 at the end of the study (all P <0.05, compared to its baseline). In the control group, the outflow facility exhibited a slight decrease as the time elapsed (Fig. 2 B).

Figure 2. The changes of intraocular pressure and outflow facility by RKI-1447 treatment. IOP at different time points is shown. Measurements taken after 48 hrs. after pigment injection revealed that there was a significant increase in IOP in the RKI-1447 (P=0.003) and the pigment groups (P=0.038) from their baseline measurements. After treatment with RKI-1447, the IOP of the RKI-1447 group decreased significantly from 20.14 +/-2.59 mmHg to 13.38+/-0.91, while the pigment group remained significantly higher than its baseline (all P<0.05) (A). In the RKI-1447 group, the injection of pigment resulted in a significant reduction in outflow facility when measured at 48 hours (P<0.001), which was partially
reversed after RKI-1447 treatment. In the pigment group, the outflow facility was significantly reduced at all time points in comparison to baseline (all P<0.05) (B).

**TM histology**

Normal TM exhibits a light-pigmented, multilayer, strainer-like structure connected with opening Schlemm’s canals (Figure 3a). Consistent with our previous findings\textsuperscript{22,25}, pigment perfusion resulted in an increased pigmentation in the TM, while most of the pigment particles seemed to be phagocytosed by TM cells without physically obstructing the TM (Figure 3b). RKI-1447 treatment exhibited no apparent changes in TM histology (Figure 3c).

![Figure 3. TM histology.](image)

The TM in the control group presented as a lightly-pigmented strainer-like tissue, consisting of parallel collagen beams with TM cells (left). Perfusion with pigment particles resulted in an increase in TM pigmentation (middle) and was equal to RKI-1447 exposed eyes (right). TM: trabecular meshwork. SC: Schlemm’s canal-like segments of the porcine angular aqueous plexus. CE: corneal endothelium.

**Disruption of TM actin stress fibers**

The primary TM cells showed an elongated morphology (Figure 4a), active phagocytosis (Figure 4b), and were positive for TM-specific markers alpha-SMA, AQP1, and MGP (Figures 4c and 4d). Pigment exposure did not cause an apparent morphological change in TM cells\textsuperscript{25} (Figures 4e and 4g), while RKI-1447 stimulated a cell body contraction within minutes, in the presence or absence of pigment exposure (Figures 4f and 4h).

F-actin cytoskeleton labeling with Alexa Fluor® 488 Phalloidin, showed a baseline of 32.57± 2.66 % actin stress fibers in normal TM cells, compared to to 67.13± 4.00 % in the pigment-exposed TM cells (P<0.001) (Figures 4i and 4k). RKI-1447 abolished these stress fibers, both in normal TM cells (2.57± 0.86 % versus 32.57± 2.66 %, P<0.001) and pigment-exposed TM cells (2.51± 0.71 % versus 67.13± 4.00 %, P<0.001) (Figures 4j, 4i, and 4m).
Figure 4. Primary TM culture, cell morphology, and actin cytoskeleton. Primary porcine TM cells were elongated (Figure 3a) and had an active phagocytic activity (Figure 3b). They tested positive for the TM-specific markers (Figures 3c and 3d) AQP1, alpha-SMA, and MGP. Pigment exposure did not stimulate a significant morphological change. Cells contracted following RKI-1447 (Figures 3e, 3f, 3g, and 3h). RKI-1447 significantly disrupted the actin cytoskeleton regardless of presence or absence of pigment (P<0.001) (Figures 3i, 3j, 3k, 3l, and 3m).

TM motility

Since changes in TM movement have been reported in studies of glaucomatous eyes\textsuperscript{25,28}, we tested the effect of RKI-1447 on TM motility using a modified scratch assay. As shown in Figure 5, the pigment exposure statistically decreased the numbers of migrating TM cells (60.83±3.46 in the normal control versus 31.75±3.36 cells in the pigment treated group, P<0.001) while RKI-1447 seemed to have no effect on the TM migration,
either for the normal TM cells or the pigment-treated TM cells (P=0.091 and P=0.398, compared to each baseline).

**Figure 5. RKI-1447 did not effect TM motility.** The motility of TM cells was measured using a scratch assay with minor modification. Compared to the normal control, pigment exposure resulted in a significant reduction in the number of migrating TM cells (60.83±3.46 in the control versus 31.75±3.36 cells in the pigment group, P<0.001). RKI-1447 had no significant effect on the TM migration, either for the normal TM cells (P=0.091) or the pigment-treated TM cells (P=0.398) in comparison to the baseline.

Consistent with our previous results\textsuperscript{22,25}, pigment exposure caused a reduction in TM phagocytosis by 10.31% while RKI-1447 reversed this effect and increased it to 111.52% in comparison to the normal baseline.

**Discussion**

Pigmentary glaucoma (PG) is a common type of secondary open-angle glaucoma with an incidence of 1.4/100,000\textsuperscript{29,30}. A readily recognisable feature of this disease is the wide dispersion of pigment in intraocular tissues, especially on the corneal endothelium and in trabecular meshwork\textsuperscript{31}. Our previous study in a porcine eye perfusion model suggested that iris pigment particles induced TM stress fibers, reduced TM phagocytosis,
adhesion, and motility, and resulted in a significant IOP elevation. In the current study, we found that RKI-1447, a ROCK1/ROCK2 inhibitor, efficiently reduced the IOP by 33.58% and increased the outflow facility by 38.25% in the same pigmentary glaucoma model. Our in vitro results further revealed that these changes might result from the extensive disruption of TM actin stress fibers.

In the current study, we utilized a porcine anterior segment perfusion model that mimics the TM changes and IOP phenotype of human PG to examine the hypotensive effect of RKI-1447, an oncology drug used in breast cancer. Pigment dispersion caused a significant IOP elevation at the 48-hour time interval, while RKI-1447 partially reversed this effect throughout the study. The TM regulates aqueous outflow by changing its cytoskeleton, stiffness, cell adhesion, migration, contraction, and phagocytosis, and ROCK signaling plays a central role in these processes.

A close interaction between the actin cytoskeleton reorganization, cell or extracellular matrix stiffness, and aqueous outflow facility was observed. Consistent with our previous work, only a small portion of stress fibers formed in the normal TM culture while the pigment exposure increased it by 2.06-fold. Actin stress fibers provided a dominant contribution to both cell stiffness and the stiffness of the extracellular matrix that directly affected aqueous outflow facility. Gavara et al. also found that the presence of aligned and thick stress fibers in the cell periphery gave rise to reinforced cell stiffness. In general, factors that induce stress fiber formation increase TM stiffness and decrease outflow facility. For example, senescence and aging, a risk factor for primary open-angle glaucoma, has increases the stress fiber formation and TM stiffness. In a different study, dexamethasone, an inducer of cross-linked actin network, increased the stiffness of primary TM cells and extracellular matrix twofold and fourfold, respectively, after three days, and caused an IOP elevation in an ex vivo perfusion model of human eyes. In contrast, numerous reagents have been found to disrupt actin stress fiber and exhibit an ocular hypotensive effect. For instance, Y27632, but not isoproterenol, pilocarpine, or nifedipine, significantly have been found to abolish cyclic stress-induced stress fiber and reverse the elevation of intrachamber pressure. In another study, Rao et al. showed that Y27632 increased the outflow facility by 40%-80% in pig eyes. Other molecules that target the myosin light chain and its kinase have exhibited a similar effect. In the current study, RKI-1447 significantly disrupted the stress fiber in the pigment-treated TM cells, and the IOP-reducing effect could be at least partially attributed to this.

As is the case with other ROCK inhibitors, we found that RKI-1447 caused a significant contraction of TM cells. These cells exhibited a round shape and were less adhesive. We also quantified TM motility using live cell imaging. The results suggested that the pigment exposure resulted in a significant reduction in TM migration; however, it seemed unaffected by RKI-1447, indicating that the IOP-lowering effect might not be directly related to TM motility.

Phagocytosis is driven by a well coordinated rearrangement of the actin cytoskeleton. It maintains the homeostasis of trabecular outflow by removing the cell debris and melanin from outflow tracts. A reduction in TM phagocytosis has been observed in various types of glaucoma or glaucoma models. For instance, human eye perfusion with dexamethasone for 21 days resulted in a 57% decrease of TM phagocytosis without causing a significant loss in TM cells. SWAP70, VASP, and WASP, were believed to play an essential role in this process. Consistent with previous studies, we found a 10.31% reduction in TM phagocytosis following pigment exposure, while RKI-1447 increased it to 111.52% in comparison to the control.
Our study has a number of limitations. First, the anatomical difference between the human and the porcine outflow tract and their angular aqueous plexus is significant\textsuperscript{53}. Domestic pigs, even ones used as breeders, are not known to develop glaucoma. A study by Camras et al. suggested that TM stiffness was correlated with outflow facility in human eye perfusion but not in the pig specimens\textsuperscript{54}. Second, this ex vivo study does not account for important factors that can only be examined \textit{in vivo}, this study focused on the effect of RKI-1447 on the TM but it is possible that dilation of post-trabecular outflow tract structures also exhibit a hypotensive effect in human open angle glaucoma where a high resistance of often remains after trabecular ablation\textsuperscript{55–58}.

In conclusion, the ROCK inhibitor RKI-1447 reduced IOP in a pigmentary glaucoma model while disrupting TM stress fibers and increasing phagocytosis.
