Abstract: We study the existence or absence of non-Shannon inequalities for variables that are related by functional dependencies. Although the power-set on four variables is the smallest Boolean lattice with non-Shannon inequalities there exist lattices with many more variables without non-Shannon inequalities. We search for conditions that excludes the existence of non-Shannon inequalities. It is demonstrated that planar modular lattices cannot have non-Shannon inequalities. The existence of non-Shannon inequalities is related to the question of whether a lattice is isomorphic to a lattice of subgroups of a group.

Keywords: conditional independence; entropy function; functional dependence; lattice; non-Shannon inequality; polymatroid function; subgroup

1. Introduction

The existence of non-Shannon inequalities has received a lot of attention since the first inequality of this type was discovered by Z. Zhang and R. W. Yeung [1]. The basic observation is that any four random variables $X, Y, Z,$ and $W$ satisfy the following inequality

$$2I(Z;W) \leq I(X;Y) + I(X;Z \cup W) + 3I(Z;W|X) + I(Z;W|Y) . \quad (1)$$

Here $C \cup D$ here denotes the random variable that takes values of the form $(c,d)$ where $c = C$ and $d = D$. As usual $I(\cdot ; \cdot)$ and $I(\cdot ; \cdot | \cdot)$ denote mutual information and conditional mutual information given by

$$I(X;Y) = H(X) + H(Y) - H(X \cup Y) , \quad (2)$$

$$I(X;Y | Z) = H(X \cup Z) + H(Y \cup Z) - H(X \cup Y \cup Z) - H(Z) . \quad (3)$$

where $H$ denotes the Shannon entropy. The inequality (1) is non-Shannon in the sense that it cannot be deduced from positivity, monotonicity, and submodularity of the entropy function on the variables $X, Y, Z,$ and their joins, i.e. satisfaction of the following inequalities

| Positivity | $H(X) \geq 0,$ |
| Monotonicity | $H(X \cup Y) \geq H(X),$ |
| Submodularity | $H(X \cup Z) + H(Y \cup Z) \geq H(X \cup Y \cup Z) + H(Z),$ |

Positivity and monotonicity were recognized by Shannon [2] while submodularity was first observed by McGill [3]. It is easy to show that any inequality involving only three variables rather than four can be deduced from Shannon’s inequalities [4]. The power set of four variables is a Boolean algebra with 16 elements and any smaller Boolean algebra corresponds to a smaller number of variables, so in a trivial sense the Boolean algebra with 16 elements is the smallest Boolean algebra with non-Shannon inequalities.

In the literature on non-Shannon inequalities all inequalities are expressed in terms of sets of variables and their joins. Another way to formulate this is that the inequalities are stated for the
free \( \cup \)-semi-lattice generated by a finite number of variables. In this paper we will also consider intersections of sets of variables. We note that for sets of variables we have the inequality

\[
I(X;Y | Z) \geq H(X \cap Y | Z).
\]

Inequality (7) has even inspired some authors to use \( I(\cdot \lor \cdot) \) as notation for mutual information.

Although non-Shannon inequalities have been known for two decades they have found remarkably few applications compared with the Shannon inequalities. One of the reasons is that there exists much larger lattices than the Boolean algebra with 16 elements for which the Shannon inequalities are sufficient. The simplest examples are the Markov chains

\[
X_1 \rightarrow X_2 \rightarrow X_3 \rightarrow \cdots \rightarrow X_n
\]

where any variable \( X_j \) is determined by its predecessor, i.e. the conditional entropies \( H(X_{j+1} | X_j) \) are zero for \( j = 1, 2, \ldots, n - 1 \). For such a chain one has

\[
H(X_1) \geq H(X_2) \geq H(X_3) \geq \cdots \geq H(X_n) \geq 0.
\]

The inequalities (9) are all instances of the entropy function being monotone, and it is quite clear that these inequalities are sufficient in the sense that for any sequence of values that satisfies these inequalities there exists random variables related by a deterministic Markov chain with these values as entropies.

In this paper we look at entropy inequalities for random variables that are related by functional dependencies. Functional dependencies give an ordering of sets of variables into a lattice. Such functional dependence lattices have many applications in information theory, but in this paper we will focus on determining whether a lattice of functionally related variables can have non-Shannon inequalities. In order to achieve interesting results we have to restrict our attention to special classes of lattices.

Non-Shannon inequalities have been studied using matroid theory, but finite matroids are given by geometric lattices, i.e. atomistic semimodular lattices (see the textbook of Stern [5] for definitions). For the study of non-Shannon inequalities it is more natural to look at general lattices rather than geometric lattices because many important applications involve lattices that are not atomistic or not semimodular. For instance, a deterministic Markov chain gives a lattice that is not atomistic. It is known that a function is entropic if and only if it is (approximately) equal to the logarithm of the index of a subgroup in a group [6]. Therefore it is natural to study entropic functions on lattices and their relations to subgroup lattices.

Some of the results presented in this paper have been published in preliminary form and without proof [7,8], but since then most of the results have now been strengthened or reformulated. In this paper all proof details will be given.

In this paper we bridge lattice theory, database theory and the theory of conditional independence, but sometimes the terminology in these fields do not match. In such cases we give preference to lattice theory over database theory and preference to database theory over the theory of conditional independence. Conflicting terminology are commented in footnotes.

### 2. Lattices of functional dependence

In this section we shall briefly describe functional dependencies and their relation to lattice theory. The relation between functional dependence and lattices has previously been studied [7,9–13]. This is also closely related to minimal sets of Shannon-type Inequalities [14,15]. Relations between functional dependencies and Bayesian networks have also been described [8,16]. Many problems in information theory and cryptography can be formulated in terms of functional dependencies.
Example 1. Consider a group consisting of $n$ agents. One might be interested in giving each agent in the group part of a password in such a way that no single agent can recover the whole password, but any two agents are able to recover the password. Here the password should be a function of the variables known by any two agents, but must not be a function of a variable held by any single agent. The functional dependence structure is a lattice illustrated in the Hasse diagram Figure 1. The node in the top illustrates the password. Each of the intermediate nodes presebs the knowledge of an agent. The bottom node represents no knowledge.

![Hasse diagram](image)

**Figure 1.** Hasse diagram of the lattice $M_n$ for $n = 5$.

A $\wedge$-semilattice is a set equipped with a binary operator $\wedge$ that satisfies the following properties:

- **Commutativity** \[ X \wedge Y = Y \wedge X, \]
- **Associativity** \[ (X \wedge Y) \wedge Z = X \wedge (Y \wedge Z), \]
- **Idempotens** \[ X \wedge X = X. \]

For a $\wedge$-semilattice the relation $X \wedge Y = X$ defines a preordering that we will denote $X \leq Y$. In this paper we will assume that all semilattices and all lattices are finite. If a $\wedge$-semilattice $(\mathcal{L}, \wedge)$ has a maximal element then a binary operator $\vee$ can be defined as

\[ X \vee Y = \bigvee_{Z \geq X, Z \geq Y} Z \]

and then $(\mathcal{L}, \wedge, \vee)$ is a lattice.

Let $(\mathcal{L}, \leq)$ denote a lattice with $\mathcal{M}$ as a sub-semilattice, i.e. a subset that is closed under the $\wedge$ operation and with the same maximal element as $\mathcal{L}$. Then a unary operator $cl : \mathcal{L} \to \mathcal{L}$ can be defined by

\[ cl (X) = \bigvee_{Z \in \mathcal{M}} Z \]

The operator $cl$ is a closure operator \cite{17}, i.e. it satisfies:

- **Extensivity** \[ X \leq cl (X), \]
- **Monotonicity** \[ X \leq Y \text{ implies } cl (X) \leq cl (Y), \]
- **Idempotens** \[ cl (cl (X)) = cl (X). \]

For any closure operator $cl$ the element $X$ is said to be closed if $cl (X) = X$. If $X$ and $Y$ are closed then $X \wedge Y$ is closed \cite[Lemma 28]{18} so the closed elements of a lattice under a closure operator form a $\wedge$-semilattice.

**Proposition 1.** Let $(\mathcal{L}, \leq)$ denote a finite lattice. Assume that a subset $\mathcal{M}$ of $\mathcal{L}$ is closed under the meet operation and has the same maximal element as $\mathcal{L}$. Then $\mathcal{M}$ is a lattice under the ordering $\leq$ with lattice operations in $\mathcal{M}$ are given by $X \wedge_{\mathcal{M}} Y = X \wedge Y$ and $X \vee_{\mathcal{M}} Y = cl (X \vee Y)$. 
Let \((\mathcal{L}, \leq)\) denote a lattice. Let \(\downarrow X = \{Y \in \mathcal{L} \mid Y \leq X\}\). Then \(\downarrow (X \cap Y) = (\downarrow X) \cap (\downarrow Y)\). Therefore we can identify any finite lattice with a \(\cap\)-semilattice in a powerset. Since we will normally identify the lattice elements with sets of variables we will often use \(\subseteq\) and \(\cap\) to denote the ordering and the meet operation. Then the join operation is \(\text{cl}_{\cdot\circ} (X \cup Y)\) and this operation will be denoted by \(X \cup Y\).

**Example 2.** If \(G\) is a group then a subgroup is defined as a subset that is closed under the group operations. The closure of a subset of \(G\) is the subgroup generated by the subset. The lattice of subgroups form a \(\cap\)-semilattice in the lattice of all subsets of the group. Let \(G\) denote a finite group. For any subgroup \(\tilde{G} \subseteq G\) we associate the variable \(X_{\tilde{G}}\) that map an element \(g \in G\) into the left coset \(g\tilde{G}\). Then the subgroup lattice of \(G\) is mapped into a lattice of variables where the subset ordering of subgroups is equivalent to functional dependences between the corresponding variables.

**Proposition 2.** If \(\text{cl}\) is a closure operator on a lattice then the relation \(X \rightarrow Y\) defined by \(\text{cl}(X) \supseteq Y\) satisfies the following properties.

- **Extensivity** \(X \rightarrow Y\) implies \(X \rightarrow X \cup Y\), \((18)\)
- **Monotonicity** \(X \supseteq Y\) implies \(X \rightarrow Y\), \((19)\)
- **Transitivity** If \(X \rightarrow Y\) and \(Y \rightarrow Z\), then \(X \rightarrow Z\). \((20)\)

If the properties \((18-20)\) are satisfied we say that the relation \(\rightarrow\) satisfies Armstrong's axioms \([19]\). \(^2\)

**Proof.** To prove extensivity \((18)\) assume that \(\text{cl}(X) \supseteq Y\). Using extensivity \((15)\) we also get \(\text{cl}(X) \supseteq X\). Combining these two inequalities gives \(\text{cl}(X) \supseteq X \cup Y\) as desired.

To prove monotonicity \((19)\) assume that \(X \supseteq Y\). Extensivity \((15)\) gives \(\text{cl}(X) \supseteq X\) and transitivity of \(\supseteq\) then implies \(\text{cl}(X) \supseteq Y\).

To prove transitivity \((20)\) assume that \(\text{cl}(X) \supseteq Y\) and \(\text{cl}(Y) \supseteq Z\). Using monoticy \((16)\) gives \(\text{cl}(\text{cl}(X)) \supseteq \text{cl}(Y)\). Idempotence \((17)\) implies \(\text{cl}(X) \supseteq \text{cl}(Y)\). Transitivity of \(\supseteq\) gives \(\text{cl}(X) \supseteq Z\). \(\square\)

If \(\mathcal{L}\) is a lattice with a relation \(\rightarrow\) that satisfies Armstrong’s axioms then we say that a lattice element \(X\) is \(\rightarrow\)closed if \(X \rightarrow Y\) implies that \(X \supseteq Y\).

**Theorem 1.** Let \(\mathcal{L}\) be finite lattice with a relation \(\rightarrow\) that satisfies Armstrong’s axioms. Then the set of \(\rightarrow\)closed elements form a lattice with the same maximal element as \(\mathcal{L}\). The relation \(X \rightarrow Y\) holds if and only if \(\text{cl}(X) \supseteq Y\) where \(\text{cl}\) denotes the closure operator with respect to the semilattice.

**Proof.** Assume that \(X_1 \) and \(X_2\) are closed and that \(X_1 \cap X_2 \rightarrow Y\). Monotonicity \((19)\) implies \(X_i \rightarrow X_1 \cap X_2\) and then transitivity \((20)\) implies that \(X_1 \rightarrow Y\). Since \(X_1\) is closed we have \(X_1 \supseteq Y\). Since this holds for both \(i = 1\) and \(i = 2\) we have \(X_1 \cap X_2 \supseteq Y\) implying that \(X_1 \cap X_2\) is closed. Monotony \((19)\) also implies that the maximal element of \(\mathcal{L}\) is closed so that the set of closed elements \(\mathcal{M}\) form a \(\cap\)-semilattice with a closure operator \(\text{cl}_{\cdot\circ}\).

Let \(\text{cl}\) denote the closure with respect to \(\mathcal{M}\). We will prove that \(X \rightarrow \text{cl}(X)\). Let \(X_1 = X\). Assume that \(X_1\) is not \(\rightarrow\)closed. Then there exists \(Y_1\) such that \(X_1 \rightarrow Y_1\) and \(X_1 \supseteq Y_1\). Using extensivity \((18)\) we get \(X_1 \rightarrow X_1 \cup Y_2\). Define \(X_2 = X_1 \cup Y_1\). Then \(X_1 \rightarrow X_2\) and \(X_1 \subseteq X_2\). Iterate this construction so that

\[
X_1 \rightarrow X_2 \rightarrow \cdots \rightarrow X_n, \quad (21)
\]

\[
X_1 \subseteq X_2 \subseteq \cdots \subseteq X_n. \quad (22)
\]

\(^1\) Monotonicity of \(\rightarrow\) is called reflexivity in the literature on databases. We reserve the notion of reflexivity to the relation \(X \rightarrow X\) in accordance with the terminology for ordered sets. In database theory the property \(X \rightarrow X\) is called self determination.

\(^2\) In the literature on databases extensivity \((18)\) is replaced by an apparently stronger property called augmentation, but in a finite lattice augmentation can be proved from extensivity, monotonicity, and transitivity. See Appendix A for details.
Since the lattice is finite the construction must terminate and when it terminates \( X_n \) is closed. Using transitivity we get \( X \rightarrow X_n \) and \( X \subseteq X_n \). Since \( cl(X) \) is the smallest closed element greater than \( X \) we have \( X \rightarrow cl(X) \).

If \( cl(X) \supseteq Y \) then \( cl(X) \rightarrow Y \) by monotonicity (19) and then \( X \rightarrow Y \) by transitivity (20). If \( X \rightarrow Y \) then \( cl(X) \rightarrow Y \). Using that \( cl(X) \) is \( \rightarrow \) closed we get \( cl(X) \supseteq Y \). \( \square \)

We will look at functional dependencies in databases. Assume that a set of records are labeled by elements in a set \( A \). In statistics the records are the individual elements of a sample. For each record \( a \in A \) the database contain the values of various attributes given by a number of functions from \( A \) to the set of possible attributes. Sets of such functions will be denoted by capital letters and these will be our variables. We say that \( X \) determines \( Y \) and write \( X \rightarrow Y \) if there exists some function \( f \) such that \( Y(a) = f(X(a)) \) for any record \( a \in A \). Then \( \rightarrow \) gives a relation that satisfies Armstrong’s axioms. Armstrong proved that these axioms form a complete set of inference rules [19]. That means that if a set \( A \) of functional dependencies is given and a certain functional dependence \( X \rightarrow Y \) holds in any database where all the functional dependencies in \( A \) hold, then \( X \rightarrow Y \) holds in that database. Therefore, for any functional dependence \( X \rightarrow Y \) that cannot be deduced using Armstrong’s axioms, there exists a database where the functional dependence is violated [20,21]. As a consequence, there exists a database where a functional dependence holds if and only if it can be deduced from Armstrong’s axioms. Using the result that Armstrong’s axioms are equivalent to that the closed sets form a lattice this result is easy to prove.

**Theorem 2.** For any finite lattice \( L \) there exist a database with a set of related variables such that the elements of the lattice corresponds to closed sets under functional dependence.

**Proof.** As set of records we take the elements of the lattice \( L \). To each \( Y \in L \) we associate a function \( f_Y : L \rightarrow L \) given by \( f_Y(X) = Y \cap X \). If \( Y_1 \supseteq Y_2 \) then

\[
\begin{align*}
  f_{Y_2}(X) &= Y_2 \cap X \\
  &= Y_2 \cap (Y_1 \cap X) \\
  &= f_{Y_1}(X)
\end{align*}
\]

so that \( f_{Y_2} = f_{Y_2} \circ f_{Y_1} \). Therefore \( f_{Y_1} \rightarrow f_{Y_2} \).

Assume that \( f_{Y_1} \rightarrow f_{Y_2} \). Let \( X_1 = Y_1 \) and \( X_2 = Y_1 \cup Y_2 \). Then \( f_{Y_1}(X_1) = f_{Y_1}(X_2) = Y_1 \) while \( f_{Y_2}(X_1) = Y_1 \cap Y_2 \) and \( f_{Y_2}(X_2) = Y_2 \). Using that \( f_{Y_1} \rightarrow f_{Y_2} \) we get \( Y_1 \cap Y_2 = Y_2 \) so that \( Y_1 \supseteq Y_2 \). \( \square \)

We have seen that to a subgroup lattice of a group there exists a lattice of functional dependence. The opposite is also true. To each database with attributed related by functional dependence there is a group. The construction is as follows. Let \( A \) denote a set of records. Let \( G = Sym(A) \) the symmetric group consisting of permutations of the records. If \( X \) is a function on \( A \) then we define the stabilizer group \( G_X \) as the set of permutations that leave \( X \) invariant, i.e. permutations \( \pi \in Sym(A) \) such that \( X(\pi(a)) = X(a) \) for all \( a \in A \). Then \( X \rightarrow Y \) if and only if \( G_X \subseteq G_Y \). In this way the lattice of functional dependence lattice of a database can be mapped into a lattice of subgroups of a group.

Combining Theorem 2 with the stabilizers subgroups of the symmetric group of a database we get the following result that was first proved by Whitman in 1946 [22].

**Corollary 1.** Any finite lattice can be represented as a functional dependence lattice generated by subgroups of a group.
3. Polymatroid functions and separoids

**Definition 1.** On a lattice submodularity of a function \( h \) is defined via the inequality \( h(X) + h(Y) \geq h(X \cup Y) + h(X \cap Y) \). If the submodular inequality holds with equality we say that function is modular. A polymatroid function on a lattice is a function that is non-negative, increasing, and sub-modular.

**Example 3.** Let \( L \) be finite atomistic lattice with a ranking function \( r : L \to \mathbb{R} \). Then \( L \) is a geometric lattice if and only if the function \( r \) is polymatroid [5, Cor. 1.9.10].

For a polymatroid function \( h \) on a lattice one may introduce a function \( I_h(\cdot; \cdot | \cdot) \) that corresponds to conditional mutual information by

\[
I_h(X; Y | Z) = h(X \cup Z) + h(Y \cup Z) - h(X \cup Y \cup Z) - h(Z).
\]

(24)

One can rewrite \( I_h(\cdot; \cdot | \cdot) \) as

\[
I_h(X; Y | Z) = h(X \cup Z) + h(Y \cup Z) - h(X \cup Y \cup Z) - h((X \cup Z) \cap (Y \cup Z))
\]

\[+ h((X \cup Z) \cap (Y \cup Z)) - h(Z). \quad (25)\]

**Positivity** \( I_h(X; Y | Z) \geq 0.\)

(26)

It is straightforward to verify that

**Symmetry** \( I_h(X; Y | Z) = I_h(Y; X | Z), \)

(27)

**Chain rule** \( I_h(X; Y \cup Z | W) = I_h(X; Y | W) + I_h(X; W | Y \cup W). \)

(28)

We will say that a function \( I(\cdot; \cdot | \cdot) \) that satisfies positivity (26), symmetry (27) and the chain rule (28) is a separoid function.

**Proposition 3.** If \( I(\cdot; \cdot | \cdot) \) is a separoid function then the following property is satisfied.

**Monotonicity** \( Y \subseteq Z \) implies \( I(X; Y | Z) = 0. \)

(29)

**Proof.** Assume that \( Y \subseteq Z \). We can use the chain rule (28) to get

\[
I(X; Y | Z) = I(X; Y \cup Y | Z)
\]

\[= I(X; Y | Z) + I(X; Y | Y \cup Z)
\]

\[= 2 \cdot I(X; Y | Z). \quad (30)\]

Hence monotonicity (29) is satisfied. \( \square \)

The relation \( I_h(X; X | Z) = 0 \) is equivalent to \( h(X \cup Z) = h(Z) \), and this relation will be denoted \( X \rightarrow_h Z \). The relation \( \rightarrow_h \) satisfies Armstrong’s axioms and the most instructive way to see this is via separoid relations.
If \( h \) is a polymatroid function then the relation \( I_h (X, Y | Z) = 0 \) will be denoted \( X \perp_h Y | Z \). Following Dawid et. al. [23,24] we say that a relation \( (\perp \cdot | \cdot) \) on a lattice \((L, \cap, \cup)\) is a separoid relation, if it has the following properties:

**Monotonicity**\(^3\) \( Y \subseteq Z \) implies \( X \perp Y | Z \), \hspace{1cm} (31)

**Symmetry** \( X \perp Y | Z \) implies \( Y \perp X | Z \), \hspace{1cm} (32)

**Chain rule** \( X \perp Y \cup Z | W \), if and only if \( X \perp Y | W \) and \( X \perp Z | Y \cup W \). \hspace{1cm} (33)

With this definition we see that \( \perp_h \) is a separoid relation. The properties (31-33) should hold for all \( X, Y, Z, W \in L \). In this paper we are particularly interested in the case where the subsets are not disjoint. In the literature on Bayesian networks and similar graphical models the focus has been on disjoint sets where only the last two properties (32-33) are used to define a semi-graphoid relation [26]. See also [27, Remark 2.5] where it is noted that semi-graphoid relations can be defined on join semi-lattices.

A long list of properties for the notion of independence was given by Paolini [25], but Studený has proved that one cannot deduce all properties of statistical conditional independence from a finite list of axioms [27,28].

**Proposition 4.** A separoid relation \((\perp \cdot | \cdot)\) on a lattice satisfies the following properties.

**Extensivity**\(^4\) \( X \perp Y | Z \) implies \( X \perp Y \cup Z | Z \), \hspace{1cm} (34)

**Transitivity** \( X \perp Y | W \) and \( X \perp Z | Y \cup W \), then \( X \perp Z | W \). \hspace{1cm} (35)

**Proof.** To prove extensivity (34) assume that \( X \perp Y | Z \), which is equivalent to \( X \perp Y | Z \cup Z \). Monotonicity (31) gives \( X \perp Z | Z \). The conclusion \( X \perp Y \cup Z | Z \) can be obtained by the chain rule (33).

To prove transitivity (35) assume that \( X \perp Y | W \) and \( X \perp Z | Y \cup W \). The chain rule (33) applied twice gives \( X \perp Y \cup Z | W \) and \( X \perp Z | W \). \( \square \)

In a set of random variables we note that if \( Y \) is independent of \( Y \) given \( X \), then \( Y \) is a function of \( X \) almost surely. If \( Y \perp Y | X \) we write \( X \rightarrow_\perp Y \).

**Theorem 3.** If \((L, \cap, \cup)\) is a lattice with a separoid relation \((\perp \cdot | \cdot)\) then the relation \( \rightarrow_\perp \) satisfies Armstrong’s axioms. The relation \((\perp \cdot | \cdot)\) restricted to the lattice of closed lattice elements is separoid.

**Proof.** Extensivity (18) of \( \rightarrow_\perp \) follows directly from extensivity (34) of \( \perp \).

Monotonicity (19) follows directly from monotonicity (31).

To prove transitivity of \( \rightarrow_\perp \) assume that \( X \rightarrow_\perp Y \) and \( Y \rightarrow_\perp Z \). Monotonicity (31) implies that \( Z \perp X | Z \cup Y \), which by the chain rule (33) implies \( Z \perp Z \cup X | Y \). By the chain rule (33) we have \( Z \perp Z | Y \cup X \). Monotonicity (31) also gives \( Z \perp Y | Y \cup X \), which together with \( X \rightarrow_\perp Y \) together imply that \( Z \perp Y | X \) by transitivity (35). Transitivity (35) then implies \( Z \perp Z | X \).

To prove that the relation \((\cdot \cdot \cdot | \cdot)\) restricted to the lattice of closed lattice elements is separoid one just has to prove that \( X \perp Y | Z \) if and only if \( Y \perp cl_\perp (Y) | Z \) if and only if \( X \perp Y | cl_\perp (Z) \). This follows from Armstrong’s results. \( \square \)

The significance of this theorem is that if we start with a separoid relation on a lattice then this separoid relation is also separoid when restricted to elements that are closed under the relation \( \rightarrow_\perp \).

---

\(^3\) The term monotonicity was used for a different concept by Paolini [25]. In [23,24] a weaker condition than monotonicity was used but their condition together with the chain rule implies monotonicity.

\(^4\) The property that we call extensivity (34) was called normality by Paolini [25].
Theorem 4. Any finite lattice can be represented as a closure system of an separoid relation defined on a power-set.

Proof. For any finite lattice $L$ one identify the elements with subgroups of a group $G$. If the group $G$ is assigned a uniform distribution, then the variable corresponding to a subgroup will also have a uniform distribution. With this distribution a variable is independent of itself given another variable if and only if the other variable determines the first variable. Therefore statistical independence with respect to the uniform distribution on $G$ gives a separoid relation for which the closure is the original lattice.

Assume that $X$ and $Y$ are $\rightarrow_{h}$ closed. Then

$$h(\text{cl}_{h}(X \cup Y)) + h(X \cap Y) = h(X \cup Y) + h(X \cap Y) \leq h(X) + h(Y).$$

(36)

Therefore $h$ restricted to the $\rightarrow_{h}$ closed elements is polymatroid. We may summarize these observations in the following proposition.

Proposition 5. If $h$ is a polymatroid function defined on the lattice $(L, \subseteq)$ then the relation $\rightarrow_{h}$ satisfies Armstrong’s axioms. The function $h$ restricted to the lattice of $\rightarrow_{h}$ closed elements is polymatroid.

We recall that a pair of point $(Y, Z)$ is said to be a modular pair and we write $Y M Z$ if $Y \cap Z \subseteq X \subseteq Z$ implies that

$$(X \cup Y) \cap Z = X.$$ (37)

If all pairs are modular we say that the lattice is modular and we have

The modular law

$$X \cup (Y \cap Z) = (X \cup Y) \cap Z.$$ (38)

when $X \subseteq Z$.

Proposition 6. If $(\cdot \upmodels \cdot, \cdot \upmodels \cdot)$ is a separoid relation on a lattice and

$$Y \upmodels Z \mid Y \cap Z$$ (39)

then $Y M Z$ in the lattice of closed elements. In particular, if $h$ is a polymatroid function on a lattice and

$$h(Y) + h(Z) = h(Y \cap Z) + h(Y \cup Z),$$ (40)

then $Y M Z$ in the lattice of closed elements.

Proof. If $Y \cap Z \subseteq X \subseteq Z$ then we have the following sequence of implications.

$$Y \upmodels Z \mid Y \cap Z, \quad Y \upmodels X \upmodels Z \mid Y \cap Z, \quad Y \upmodels Z \mid X \upmodels (Y \cap Z), \quad Y \upmodels Z \mid X, \quad X \upmodels Y \upmodels Z \mid X,$$

$$X \cup Y \upmodels Z \mid X, \quad (X \cup Y) \cap Z \upmodels (X \cup Y) \cap Z \mid X.$$ (46)

Hence $X \rightarrow_{h} (X \cup Y) \cap Z$ and $\text{cl}(X) = \text{cl}((X \cup Y) \cap Z).$ □
If \( \equiv \) is separoid then according to extensivity (34) the relation \( X \equiv Y \mid Z \) implies
\[
X \psi Z \equiv Y \psi Z \mid Z \tag{48}
\]
so that \( Z \supseteq (X \psi Z) \cap (Y \psi Z) \supseteq Z \). We define the relation \( X \equiv_M Y \mid Z \) by
\[
Z = (X \psi Z) \cap (Y \psi Z) . \tag{49}
\]

**Theorem 5.** If a polymatroid function \( h \) on a lattice is modular then the lattice of \( \rightarrow_h \) closed elements is modular. If the lattice is modular then \( X \equiv_M Y \mid Z \) if and only \( X \equiv_M Y \mid Z \) in the lattice of closed elements.

**Proof.** If the function \( h \) is modular then all pairs of elements are modular in the lattice of \( h \)-closed elements so the lattice of closed elements is modular. In a modular lattice
\[
I_h (X, Y \mid Z) = h ((X \psi Z) \cap (Y \psi Z)) - h (Z) \tag{50}
\]
so that \( X \equiv_M Y \mid Z \) holds when \( Z \rightarrow_h (X \psi Z) \cap (Y \psi Z) . \)

The following result appear in [23] with a longer proof.

**Corollary 2.** For a lattice the relation \( X \equiv_M Y \mid Z \) is separoid if and only if the lattice is modular.

**Proof.** Assume that the lattice is modular. Then the ranking function \( r \) is modular and \( X \rightarrow_r Y \) if and only if \( X \supseteq Y \). Therefore \( X \equiv_M Y \mid Z \) is equivalent to the separoid relation \( I_r (X, Y \mid Z) = 0 \).

Assume that the relation \( \equiv_M \) is separoid. Since \( X \equiv_M Y \mid X \cap Y \) we have that \( X \cap Y \). Since all pairs are modular the lattice is modular.

### 4. Entropy in functional dependence lattices

Let \( L \) denote a lattice with maximal element \( m \). Let \( \Gamma (L) \) denote the set of polymatroid functions on \( L \). The set \( \Gamma (L) \) is polyhedral and often we may normalize the polymatroid functions by by replacing \( h(\cdot) \) by \( h(\cdot)/h(m) \). In this way we obtain a polytop that we will denote \( \Gamma_1 (L) \).

**Definition 2.** A function \( h \in \Gamma (L) \) is said to be entropic if there exists a function \( f \) from \( L \) into a set of random variables such that \( h(X) = H (f(X)) \) for any element \( X \) in the lattice.

Let \( \Gamma^*_1 (L) \) denote the set of normalized entropic functions on \( L \) and let \( \Gamma^*_1 (L) \) denote the closure of \( \Gamma^* (L) \).

**Definition 3.** A lattice is said to be a Shannon lattice if any polymatroid function can be realized approximately by random variables, i.e. \( \Gamma_1 (L) = \Gamma^*_1 (L) \).

One may then check whether a lattice is a Shannon lattice by checking that the extreme polymatroid functions are entropic or can be approximated by entropic functions.

**Example 4.** Let \( G \) denote a finite group. For any subgroup \( \bar{G} \subseteq G \) we associate the variable \( X_{\bar{G}} \) that map an element \( g \in G \) into the left coset \( g\bar{G} \). The number of possible values of \( X_{\bar{G}} \) is \( |G : \bar{G}| = \frac{|G|}{|\bar{G}|} \). Assume that the subgroups are given a functional dependence structure where where a variable \( X \) is given by a function \( A \rightarrow_B \). If \( A \) has \( n \) elements then the groups of permutations \( G \) has \( n! \) elements. The subgroup that leaves \( X \) invariant has
\[
\Pi_{b \in B} (n \cdot P (X = b))! \tag{51}
\]
element. Therefore

\[ \ln (|G : G_X|) = \ln \left( \frac{n}{\prod_{b \in B} (n \cdot P(X = b))!} \right) \]

\[ \approx -n \cdot \sum_{b \in B} P(X = b) \ln (P(X = b)) \]

\[ = n \cdot H(X). \] (52)

If \( U \) is the uniform distribution on the finite group \( G \) then the distribution of \( X \), \( X_\ell \) is uniform and the entropy is

\[ H(X) = \ln(|G|) - \ln(|M|). \]

It has been proved that set of entropic functions generated Therefore the polymatroid functions generated by groups has \( \Gamma^* (L) \) as closure [4].

From Definition 3 we immediately get the following result.

**Proposition 7.** If \( L \) is a Shannon lattice and \( M \) is a subset that is a \( \cap \)-semi-lattice then \( M \) is a Shannon lattice. In particular all sub-lattices of a Shannon lattice are Shannon lattices.

**Proof.** Assume that \( L \) is a Shannon lattice and that \( M \) is a sub-lattice. Let \( h : M \to \mathbb{R} \) denote a polymatroid function. For \( \ell \in L \) let \( \tilde{h} \) denote the \( m \in M \) that minimize \( h(m) \) under the constraint that \( m \geq \ell \). Define the function \( \tilde{h}(\ell) = h(\tilde{\ell}) \). Now \( \tilde{h} \) is an extension of \( h \) and with this definition \( \tilde{h} \) is non-negative and increasing. For \( x, y \in L \) we have

\[ \tilde{h}(X) + \tilde{h}(Y) = h(\tilde{X}) + h(\tilde{Y}) \]

\[ \geq h(\tilde{X} \cup \tilde{Y}) = h(\tilde{X} \cap \tilde{Y}) \]

\[ \geq \tilde{h}(X \cup Y) + \tilde{h}(X \cap Y) \] (53)

because \( \tilde{X} \cup \tilde{Y} \geq X \cup Y \) and \( \tilde{X} \cap \tilde{Y} \geq X \cap Y \). Hence \( \tilde{h} \) is submodular. By the assumption \( \tilde{h} \) is entropic so the restriction of \( \tilde{h} \) to \( M \) is also entropic. \( \square \)

With these results at hand we can start hunting non-Shannon lattices. We take a lattice that may or may not be a Shannon lattice. We find the extreme normalized polymatroid functions. These extreme polymatroid functions can be found either by hand or by using some suitable software that can find extreme points of a convex polytope specified by a finite set of inequalities. For instance the R program with package rcdd can find all extreme points of a polytope. For each extreme point we determine the lattice of closed elements using Proposition 5. These lattices of closed sets will often have a much simpler structure than the original lattice and the goal is to check if these lattices are Shannon lattices or not. It turns out that there are quite few of these reduced lattices and they could be considered as the building blocks for larger lattices.

We recall that an element \( i \) is \( \cup \)-irreducible if \( i = X \cup Y \) implies that \( i = X \) or \( i = Y \). An \( \cap \)-irreducible element is defined similarly. An element is double irreducible if it is both \( \cup \)-irreducible and \( \cap \)-irreducible. The lattice denoted \( M_n \) is a modular lattice with a smallest element, a largest element and \( n \) double irreducible elements arranged in-between.

**Theorem 6.** For any \( n \) the lattice \( M_n \) is a Shannon lattice.

**Proof.** The proof is essentially the same as the solution to the cryptographic problem stated in the beginning of Section 3. The idea is that one should look for groups with a subgroup lattice \( M_n \) and then check that the subgroups of such group have the right cardinality.

Let the values in the double irreducible elements be denoted \( h_1, h_2, \ldots, h_n \). If \( n = 1 \) the extreme polymatroid functions are \( h_1 = 0 \) and \( h_1 = 1 \) and these points are obviously entropic. If \( n = 2 \) the extreme points are \( (h_1, h_2) = (0, 1) \) and \( (h_1, h_2) = (1, 0) \) and \( (h_1, h_2) = (1, 1) \), which are all entropic.
Assume \( n \geq 3 \). Then the values should satisfy the inequalities
\[
0 \leq h_i \leq 1, \\
h_i + h_j \geq 1.
\] (54) (55)

If \((h_1, h_2, \ldots, h_n)\) is an extreme point then each variables should satisfy one of the inequalities with equality. Assume \( h_i = 0 \). Then sub-modularity implies that \( h_j = 1 \) for \( j \neq i \). The extreme point \((1, 1, \ldots, 1, 0, 1, \ldots, 1)\) is obviously entropic. If \( h_i = 1 \) this gives no further constraint on the other values, so it corresponds to an extreme point on a lattice with one less variable. Finally assume that \( h_i + h_j = 1 \) for all \( i, j \). Then \( h_i = \frac{1}{2} \) for all \( i \).

**Corollary 3.** Any polymatroid function that only takes the values \(0, \frac{1}{2}, \) and \(1\) is entropic.

**Proof.** Assume that the polymatroid function \( h \) only takes the values \(0, \frac{1}{2}, \) and \(1\). Then \( h \) defines a separoid relation and the closed elements form a lattice isomorphic to \( M_n \) for some integer \( n \). The function \( h \) is entropic on \( M_n \) so \( h \) is also entropic on the original lattice.

**Lemma 1.** If \( h \) is submodular and increasing on \( \cap\)-irreducible elements then \( h \) is increasing.

**Proof.** Assume that \( h \) is submodular and increasing on \( \cap\)-irreducible elements. We have to prove that if \( X \supseteq Z \) then \( h(X) \geq h(Z) \). In order to obtain a contradiction assume that \( Z \) is a maximal element such that there exist an element \( X \) such \( X \supseteq Z \) but \( h(X) < h(Z) \). We may assume that \( X \) cover \( Z \). Since \( h \) is increasing at \( \cap\)-irreducible elements \( Z \) cannot be \( \cap\)-irreducible. Therefore there exists a maximal element \( b \) such that \( Y \supseteq Z \) but \( Y \nsubseteq X \). Since \( X \) cover \( Z \) we have \( X \cap Y = Z \). According to the assumptions \( h(X) + h(Y) \geq h(X \cup Y) + h(X \cap Y) \) and \( h(X \cup Y) \geq h(Y) \) because \( Z \) is a maximal element that violates that \( h \) is increasing. Therefore \( h(X) \geq h(X \cap Y) = h(Z) \).

**Theorem 7.** Any lattice with 7 or fewer elements is a Shannon lattice.

**Proof.** Up to isomorphism there only exist finitely many lattices with 7 elements or less. These are listed in the appendix. Each of these lattices has finitely many extreme polymatroid functions. These extreme polymatroid functions can be found by hand or by using the R program with package rcdd. All the extreme polymatroid functions on these lattices can be represented by a trivial lattice, or by 2, or by \( M_5 \), or by \( M_6 \), or by \( M_7 \). All these lattices are representable and thereby they are Shannon lattices.

The number of lattices grow quite fast with the number of elements and the number of elements is not the best way of comparing lattices.

![Figure 2. The Matuš lattice with a non-entropic polymatroid function.](image-url)
The Boolean lattice with four atoms is the smallest non-Shannon Boolean algebra. Nevertheless there are smaller non-Shannon lattices. Figure 2 illustrates the Matúš lattice\(^5\), which is a lattice with just 11 elements that violates Inequality (1). This corresponds to the fact that the lattice in Figure 2 is not equivalent to a lattice of subgroups of a finite group. The lattices that are equivalent to lattices of subgroups of finite groups have been characterized [29], but the characterization is too complicated to describe here. Using the ideas from [30] one can prove that the Matúš lattice in Figure 2 has infinitely many non-Shannon inequalities. Therefore any lattice that contains the Matúš lattice as a \(\cap\)-semilattice also has infinitely many non-Shannon inequalities. We conjecture that if a lattice does not contain the Matúš lattice as a \(\cap\)-semilattice then it is a Shannon lattice.

The result of Matúš has recently found a parallel in matroid theory. An infinite set of inequalities is needed in order to characterize presentable matroids [31–33].

5. The skeleton of a lattice

In this section we will develop a cutting-and-gluing technique that can be used to handle many lattices, but it is especially useful for planar lattices. We present the notion of tolerance. Further details about this concept can be found in the literature [5,34]

**Definition 4.** A symmetric and reflexive relation \(\Theta\) on a lattice is called a tolerance relation if 
\[
(X_1 \cap X_2) \Theta (Y_1 \cap Y_2)
\]
and
\[
(X_1 \uplus X_2) \Theta (Y_1 \uplus Y_2)
\]

If \(\Theta\) is a tolerance relation then for any \(X\) the set \(\{Y \in \mathcal{L} \mid X \Theta Y\}\) is an interval in the lattice. These intervals are called the blocks of \(\Theta\) and the blocks will be denoted \([X]_{\Theta}\). For a tolerance relation the blocks may be considered as elements of the factor \(\mathcal{L}/\Theta\) and this factor has a natural structure as a lattice. Congruence relations are special cases of tolerance relations, but in general the blocks of a tolerance relation may overlap. We note that if the intersection of two blocks is non-empty then the intersection is a sublattice. If \(X \in \mathcal{L}/\Theta\) then \(\mathcal{L}/X\) will denote the block in \(\mathcal{L}\) determined by \(X\). We defined a glued tolerance relation as a tolerance relation where \(X\) cover \(Y\) in \(\mathcal{L}/\Theta\) implies that \(\mathcal{L}/X \cap \mathcal{L}/Y \neq \emptyset\).

A tolerance relation can be identified with a subset of \(\mathcal{L} \times \mathcal{L}\) so tolerance relations are ordered by subset ordering. The trivial tolerance relation is the one where \(x \Theta y\) holds for all \(x, y \in \mathcal{L}\) and this tolerance relation is the greatest tolerance relation. A glued tolerance relation contain any covering pair and glued tolerance relations are characterized by this property. Therefore the intersection of two glued tolerance relations is a glued tolerance relation. Therefore the set of glued tolerance relations form a lattice. The smallest glued tolerance relation is denoted \(\Sigma(\mathcal{L})\) and is called the skeleton of the lattice.

**Lemma 2.** Let \(\mathcal{L}\) be a lattice with a increasing function \(h\). If the function \(h\) satisfies
\[
h(X) + h(Y) \geq h(X \cap Y) + h(X \uplus Y)
\]
for all \(X, Y\) where \(X \cap Y\) is covered by \(X\) and \(Y\), then the function \(h\) is submodular on \(\mathcal{L}\).

---

\(^5\) The lattice is named in honor of František Matúš who passed away shortly before the submission of this manuscript.
Proof. First we prove that if the function $h$ satisfies

$$h(X) + h(Y) \geq h(X \cap Y) + h(X \cup Y)$$

for all $X, Y$ where $X \cap Y$ is covered by $X$, then the function $h$ is submodular on $\mathcal{L}$.

Let $A$ and $B$ denote two lattice elements. Define sequences $X_1 \subseteq X_2 \subseteq \cdots \subseteq X_n = A$ and $Y_1 \subseteq Y_2 \subseteq \cdots \subseteq Y_n = A \cup B$ by first defining $X_1 = A \cap B$ and $Y_1 = B$. Assume that $X_1$ is an element that covers $A \cap B$ and such that $X_1 \subseteq A$. Let $X_{i+1} \subseteq A$ be a cover of $A \cap Y_i$ and let $Y_{i+1} = X_{i+1} \cup Y_i$. Then

$$h(X_{i+1}) + h(Y_i) \geq h(Y_{i+1}) + h(X_{i+1} \cap Y_i).$$

Adding all these inequalities leads to

$$h(A) + h(B) \geq h(A \cup B) + h(A \cap B) + \sum_{i=0}^{n-1} (h(X_{i+1} \cap Y_i) - h(X_i))$$

and the inequality is obtained because $h$ is increasing to that $h(X_{i+1} \cap Y_i) - h(X_i) \geq 0$ and because $X_{i+1} \cap Y_i \supseteq X_i$ by construction of the sequences.
To see that we just need to check submodularity when $B$ covers $A \cap B$ is proved in the same way.

**Proposition 8.** Let $\mathcal{L}$ be a lattice with a tolerance relations $\Theta$ and let $h : \mathcal{L} \rightarrow \mathbb{R}$ denote some function. Then $h$ is polymatroid if and only if the restriction of $h$ to any block $\mathcal{L}_x$ is polymatroid.

If $h$ is entropic then the restriction to each block is entropic. To characterize the blocks of a lattice has been done for certain classes of lattices but here we shall only mention a single result.

**Theorem 8 ([35]).** The blocks of a modular lattice are the maximal atomistic intervals.

In particular the skeleton of a modular lattice consists of blocks that are geometric lattices.

6. Results for planar lattices

In this section we will restrict our attention to planar lattices. There are several reasons for this restriction. First of all: any poset with a planar Hasse diagram is a lattice if and only if it has a least element and a greatest element [36]. As a consequence any $\cap$-semilattice of a planar lattice is also a planar lattice. Certain cut-and-glue techniques are also very efficient for planar lattices. Finally both planar distributive lattices and planar modular lattices have nice representations that will play a central role in our proofs.

**Theorem 9.** Let $h$ denote a polymatroid function on a planar lattice $\mathcal{L}$. Then $h$ has an entropic representation if and only if the restriction to each block of $\Sigma (\mathcal{L})$ has an entropic representation.

**Proof.** The proof is via induction over the number of elements in the lattice. For a trivial lattice there is nothing to prove. Assume that the theorem has been proved for all lattices with fewer elements than the number of elements of $\mathcal{L}$. Assume that $h$ is a polymatroid. Since the lattice is planar it has a left boundary chain $\emptyset \subseteq L_1 \subseteq L_2 \cdots \subseteq L_m$ and a right boundary chain $\emptyset \subseteq R_1 \subseteq R_2 \cdots \subseteq R_k$ where $L_m = R_k$ is the maximal element of $\mathcal{L}$. Let $R_k$ be the minimal element of the right boundary chain such that $L_1 \subseteq R_k$. We note that $R_k = L_1 \cup R_{k-1}$. Let $L_j$ denote the largest element in the left boundary chain such that $L_j \subseteq R_k$. Then there is a chain from $L_j$ to $R_k$ and we have a glued tolerance relation with two blocks $\mathcal{L}_0 = \{ X \in \mathcal{L} | X \subseteq L_j \}$ and $\mathcal{L}_1 = \{ X \in \mathcal{L} | X \supseteq L_j \}$ and with the two chain lattice 2 as factor lattice. These two blocks are glued together along a chain $L_j = y_1 \subset y_2 \subset \cdots \subset y_t = R_k$ that $\mathcal{L}_1$ and $\mathcal{L}_0$ share. There are two cases. Either $R_k \subset R_n$ or $R_k = R_n$.

Assume that $R_k \subset R_n$. Then the glued tolerance relation is non-trivial. Since $h$ restricted to $\{ X \in \mathcal{L} | X \supseteq L_j \}$ and $\{ X \in \mathcal{L} | X \subseteq R_k \}$ are probabilistically representable we may without loss of generality assume that there exists two groups $G_1$ and $G_0$ such that to $X \in \mathcal{L}$, there is a subgroup $G_i (X) \subseteq G_i$ such that $h (X) = \ln | G_i : G_i (X) |$. We associate the variable $X_{G_1} (X)$ that maps an element $g \in G$ into the left coset $gG_i (X)$.

The goal is to find a joint distribution to a set of variables associated to each $X \in \mathcal{L}$. We note that all variables in $\mathcal{L}_0$ are functions of $r_k$ so if we map $X_{G_1 (r_k)}$ into $X_{G_0 (r_k)}$ all other variables in $\mathcal{L}_2$ are determined. In particular the chain $y_1 \subset y_2 \subset \cdots \subset y_t$ is determined by $r_k \equiv y_t$. The sequences $X_{G_1 (y_j)}$ is mapped into the sequence $X_{G_0 (y_j)}$ recursively starting with mapping $X_{G_1 (y_1)}$ into $X_{G_0 (y_1)}$. This is possible since $X_{G_1 (y_1)}$ and $X_{G_2 (y_1)}$ are uniform distributions on sets of the same size. Now there are equality many values of $X_{G_1 (y_2)}$ and $X_{G_0 (y_2)}$ that maps into the same values of $X_{G_1 (y_1)}$ and $X_{G_0 (y_1)}$ so the the values of $X_{G_1 (y_2)}$ and $X_{G_0 (y_2)}$ can be mapped into each other. We continue like that until all the random variables along the chain $y_1 \subset y_2 \subset \cdots \subset y_t$ have been identified.

If $r_k = r_n$ then we make a similar construction with the role of the left chain and the right chain reversed. If this leads to a non-trivial glued tolerance relation we glue representations together as we did above.
If both the left chain and the right chain lead to trivial glued tolerance relations then \( L_1 \uplus r_1 \) is the maximal element of \( L \) and the whole lattice consists of a single block in \( \Sigma(L) \). In this case the content of the theorem is trivial. \( \square \)

**Theorem 10.** All planar modular lattices are Shannon lattices.

**Proof.** Without loss of generality we may assume that the lattice consist of just one block for the tolerance relation \( \Sigma(L) \). A modular block is atomistic, but if a modular planar lattice is atomistic it is equivalent to the trivial lattice or to the lattice \( 2 \) or to the lattice \( 2 \times 2 \) or to one of the lattices \( M_n \). \( \square \)

Our construction actually tells us more. If the lattice is distributive it is glued together of blocks that are either equivalent to \( 2 \) or to the lattice \( 2 \times 2 \). Therefore the lattice is a sublattice of a product of two chains as illustrated in Figure 5. This result was first proved by Dilworth [37]. Other characterizations of planar distributive lattices can be found in the literature [38]. Since the extreme polymatroid functions on the lattices \( 2 \) and the lattice \( 2 \times 2 \) only take the values 0 and 1 the same is true for any planar distributive lattice.

\[ \text{Figure 5. A product of two chains.} \]

A modular planar lattice will also contain blocks of the type \( M_n \). Therefore a modular planar lattice can be obtained from a distributive planar lattice by adding double irreducible elements [39] as illustrated in Figure 6.

Since \( M_n \) has extreme polymatroid functions that takes the values 0, \( \frac{1}{2} \) and 1 the extreme functions are modular. Gluing such modular functions together leads to extreme polymatroid functions that are modular. Therefore all extreme polymatroid functions on a planar modular lattice can be represented by a planar modular lattice with a modular function. Therefore the independence structure is given by \((X \perp Y | \ Z)\) when \( Z = (X \uplus Z) \cap (Y \uplus Z) \).

The extreme polymatroid functions on a planar modular lattice can be represented as follows. Let \( X_1, X_2, \ldots, X_m, Y_1, Y_2, \ldots, Y_n \) denote independent random variables uniformly distributed over \( \mathbb{Z}_p \) for some large value of \( p \). Let \( Z_{ij} \) denote the random variable

\[ \bigcup_{l \leq i} X_l \uplus \bigcup_{l \leq j} Y_l. \quad (62) \]

and let \( Z_{ijk} \) denote the random variable

\[ \bigcup_{l \leq i} X_l \uplus \bigcup_{l \leq j} Y_l \uplus \left( X_{i+1} + k \cdot Y_{j+1} \right) \quad (63) \]
for $k > 0$. The way to index the variables can be seen in Figure 7. Then the entropy is proportional to the ranking function. A polymatroid function $h$ that has a representation given by an Abelian group satisfies the Ingleton inequalities [40], i.e. Inequalities of the form

$$h(X) + h(Y) + h(X \cup Y \cup V) + h(X \cup Y \cup W) + h(V \cup W) \leq h(X \cup Y) + h(X \cup V) + h(X \cup W) + h(Y \cup V) + h(Y \cup W).$$

(64)

Therefore the Shannon inequalities imply the Ingleton inequalities as long as the polymatroid function is defined on a planar modular lattice. Paajanen [41] has proved that under some conditions the entropy function of a nilpotent $p$-group can be represented by an Abelian group. The core of the proof was that the subgroup lattice of a nilpotent $p$-group is also the subgroup lattice of an Abelian group. Many of these lattices are planar and in these cases the results by Paajanen [41] follow from our results on planar graphs.

Appendix Augmentation

In database theory extensivity (18) is replaced by the following property.

\[ \text{Augmentation} \quad X \rightarrow Y \implies X \cup Z \rightarrow Y \cup Z. \quad (A1) \]

If \( Z = X \) augmentation (A1) reduces to extensivty (18). In a finite lattice extensivity (18) together with the other Armstrong axioms imply augmentation (A1). To see this, first we observe that in a finite lattice extensivity (18), monotonicity (19), and transitivity (20) imply that \( X \rightarrow Y \) is equivalent to \( \text{cl}(X) \supseteq Y \). Monotonicity (16) gives \( \text{cl}(X \cup Z) \supseteq Y \). Using monotonicity (16) and extensivity (15) we also get \( \text{cl}(X \cup Z) \supseteq \text{cl}(Z) \supseteq Z \). Combining these two inequalities gives \( \text{cl}(X \cup Z) \supseteq Y \cup Z \) as desired.

The condition in Theorem 1 that the lattice is finite can be relaxed to the ascending chain condition, because this is essentially what is used to conclude that the chain (22) must stop. The observation that augmentation can be relaxed to extensivity could be used to simplify some algorithms for database normalization.

Appendix Lattices of size 1 to 7

Here we give a complete list of the Hasse diagrams of lattices with 7 or fewer elements.

Appendix B.1 Lattice of size 1

The trivial lattice is the only lattice of size 1.

\[
1
\]

Appendix B.2 Lattice of size 2

The two element chain 2 is the only lattice of size 2.

\[
1 \quad 0
\]

Appendix B.3 Lattices of size 3

The three element chain 3 is only one lattice of size 3 and it is distributive. The extreme polymatroid functions can be represented by the lattice 2.

\[
\]

Appendix B.4 Lattices of size 4

There are two lattices of size 4 and they are both distributive. Their extreme polymatroid functions can be represented by the lattice 2.
Appendix B.5 Lattices of size 5

The lattice $M_5$ is modular but not distributive. It has a new non-trivial polymatroid function as extreme point. The other extreme points can be represented by $M_3$ and the lattice 2.

Appendix B.6 Lattices of size 6

The lattice $M_6$ has a new non-trivial polymatroid extreme point. The other extreme points can be represented by $M_3$ and the lattice 2.
The next five lattices have extreme points that can be represented by $M_5$ or the lattice $2$. The first two lattices are modular but not distributive. The next three are not modular.

The extreme points of the last nine lattices are all represented by the lattice $2$. The first four are not modular.
The last five are distributive.

Appendix B.7 Lattices of size 7

The lattice $M_5$ has a new polymatroid extreme point. The other extreme points can be represented by $M_4$, $M_3$, and the lattice 2.

The next seven lattices have extreme points that can be represented by $M_4$, $M_3$, or the lattice 2. The first two lattices are modular. The last five lattices are not modular.
The following lattices have extreme polymatroid functions that can be represented by $M_3$ or the lattice $2$. The first five lattices are modular.

The next lattices are not modular.
The last 22 lattices of size seven only have trivial extreme points. The first 14 lattices are not modular.
The last eight lattices are distributive.
