Abstract:
Hospitalized patients frequently have disordered and poor-quality sleep due to a variety of both intrinsic and extrinsic factors. These include frequent nighttime intrusions, insomnia related to pain and unfamiliar environments, dark conditions during the day with loss of natural light, and disruption of natural sleep cycle due to illness. Sleep wake disturbances can result in deleterious consequence on physical, emotional and cognitive status, which may impact patient satisfaction, clinical recovery, and hospital length of stay. Despite this, clinicians frequently fail to document sleep disturbances and are generally unaware of best practices to improve sleep quality in the hospital. The purpose of this review is to discuss sleep disturbances in hospitalized patients with a focus on causes of sleep disturbance, effect of poor quality sleep, high risk populations, considerations for surveillance and prevention, as well as pharmacologic and non-pharmacologic options for treatment.

Keywords: Hospitalized patients, sleep wake dysfunction, sleep disorders, circadian rhythm, sleep apnea
Introduction:

Sleep is a homeostatic process that contributes to maintenance of health, cognition and mood stability.\textsuperscript{1,2} Normal sleep in an adult generally is about 7-9 hours per night and consists of 4-6, 90-120 minute cycles between non-rapid eye movement (REM) and REM sleep.\textsuperscript{3} Sleep wake dysfunction (SWD) refers to the disruption of the normal sleep wake relationship that can lead to the development of a transient or chronic sleep wake disorder (SD). This can be a result of reduced number of hours of sleep, poor quality sleep or inappropriate timing or stabilization between wake and sleep. When present, SWD can contribute to development and progression of co-morbid disease.

Approximately 10\% of adults have a chronic SD that results in clinically significant symptoms\textsuperscript{4}, with up to 50\% of adults experiencing transient episodes of sleep wake dysfunction. Similarly, in pediatrics 20-30\% of children are affected by a sleep disorder\textsuperscript{5} and up to 80\% of children with chronic conditions have a co-morbid sleep disorder\textsuperscript{6-8}. The risk of development of a chronic sleep wake disorder increases with age\textsuperscript{9}. Patients with chronic medical disease are higher risk for experiencing co-morbid sleep wake disorders\textsuperscript{10}. In fact, acute hospitalization for medical illness is a high-risk period for development or exacerbation of SWD, which can result in deleterious consequences\textsuperscript{11}.

Hospitalized patients frequently report sleep quality while inpatient to be similar to the report of sleep quality of individuals who suffer from chronic SD.\textsuperscript{2} For instance, insufficient sleep, with an average of 5 hours of sleep per night, with multiple night time awakenings had been found in adult patients in a neurologic ward.\textsuperscript{1} There is a suggestion that the higher the acuity of illness the greater the impact on sleep. For example, pediatric patients in intensive care unit can experience up to a 54 percent reduction in sleep hours, while children in the general pediatric unit have been reported to have a 20-25 percent sleep loss.\textsuperscript{12} A closer examination of the causes of poor sleep, identification of high risk populations and the consequence of impaired sleep complemented with a review of surveillance
techniques and management strategies for SWD may assist in improving early recognition and treatment of sleep disorders in hospitalized patients.

**Sleep Wake Dysfunction in Hospitalized Patients**

The most common acquired SD in hospitalized patients are insomnia and circadian rhythm disorders\textsuperscript{13-16}. However, sleep disordered breathing (SDB), restless leg syndrome (RLS), and hypersomnia disorders can also be present and may be pre-existing or acquired, depending on medical co-morbidity\textsuperscript{11,17}. If there is pre-existing SD, this may become exacerbated by hospitalization and may predispose to development of additional SWD.

There are both intrinsic and extrinsic factors that contribute to development of SWD during hospitalization\textsuperscript{3,18-20}. Intrinsic factors vary by patient, but can include primary medical illness, delirium, psychiatric co-morbidity (anxiety, depression, post-traumatic stress), pre-existing SD and physical pain or discomfort\textsuperscript{1,2,21,22}. Pain and discomfort are generally the most frequently cited causes of SWD during hospitalization\textsuperscript{1}.

Extrinsic factors that contribute to the development of SWD can be environmental noise, bright lights and irregular exposure to lighting, an unfamiliar environment with loss of normal bedtime routine, as well as repetitive clinical interventions, such as testing, clinical examinations and vitals, as well as medication administration\textsuperscript{23}. Environmental noise can be due to equipment/alarms, medical staff, or hospital roommates. Roommates are commonly reported as the most disturbing factor for sleep\textsuperscript{1}. A study evaluating acceptable environmental noise levels found that daytime noise of 59 decibel A (dBA) and nighttime noise of 50.5 dBA did not result in SWD\textsuperscript{24}. However, median noise during the day was found to be 63 dBA and 61 dBA at night\textsuperscript{24}. Noise levels in the ICU have been documented at an average peak of 150-200 dB with evening peaks >80 dB between 12 AM and 6 AM, contributing to about 30% of patient awakenings\textsuperscript{25}. 
Bright lighting and lighting irregularities may represent a more easily modifiable extrinsic factor for hospitalized patients. The strongest environmental cue for human circadian rhythm is the light dark cycle. Therefore, both irregular light exposure and bright light exposure during inappropriate circadian hours can result in circadian sleep dysfunction. Circadian misalignment has been demonstrated to be deleterious in multiple disease processes resulting in worsened disease severity, impaired treatment response and even decreased survivorship.

**Effects of SWD in Hospitalized Patients**

Sleep wake disorders can result in deleterious consequence on physical, emotional and cognitive status, which may contribute to impaired recovery, prolonged length of stay, reduced subjective wellness and poor patient perception of hospitalized care. SWD and sleep deprivation have numerous deleterious effects (Figure 1), including autonomic dysfunction, impairment of the hypothalamic-pituitary-adrenal axis, and immunologic dysregulation. Among hospitalized patients, reduced sleep duration and impaired sleep efficiency were independently associated with greater likelihood for impaired fasting glucose and hyperglycemia.
Figure 1: Consequences of Sleep Wake Dysfunction and Sleep Deprivation"1,2,9,29-33
Poor quality sleep increases likelihood for development of delirium, anxiety and mood disorders\textsuperscript{34-36}. Delirium and sleep deprivation have shared characteristics, including impaired attention, fluctuating mental status, disorganized thinking and altered level of consciousness\textsuperscript{35}. Delirium occurs in up to 50% of hospitalized elderly patients, with strong associations in those greater than 80 and more common in men\textsuperscript{28,35}. Delirium increases length of stay, likelihood for institutionalization post discharge sevenfold and risk for 6-month mortality when compared to those without delirium\textsuperscript{28}.

The presence of pre-existing or newly developed SWD can significantly impact clinical outcomes. The most well studied co-morbid sleep disorder in hospitalized patients has probably been obstructive sleep apnea (OSA)\textsuperscript{17,37-39}. Surgical patients with OSA are more likely to experience postoperative hypoxemia and require ICU transfers with longer hospital stays\textsuperscript{17}. Similarly, pregnant women with co-morbid OSA, have increased post-partum risk for maternal morbidity, cardiovascular morbidity, and in-hospital death\textsuperscript{17}.

Circadian rhythm disturbances are gaining attention as a cause of SWD that negatively contributes to outcome measures in hospitalized patients\textsuperscript{15,16,32}. The circadian rhythm does not only influence sleep wake patterns, but also dictates physiological and cellular functions that allows for adaption to cyclic environmental changes\textsuperscript{40}. Evidence suggests the relationship between circadian function and disease is quite complex and multidirectional\textsuperscript{15,16,26,32,40-43}. There is loss of normal diurnal variation in melatonin secretion in critically ill patients\textsuperscript{43}, likely contributing to circadian misalignment. Patients hospitalized in the ICU have a loss of the normal rhythmic 24-hr physiologic profiles, including blood pressure, heart rate, body temperature, spontaneous motor activity, and the levels of melatonin and cortisol\textsuperscript{44}. In addition, there is suggestion that there is a circadian effect on survival, which has been suggested to be related to circadian variability of immune responses\textsuperscript{42}

**High Risk Populations for SWD**
There are multiple factors that may influence the development of SWD during hospitalization (Table 1). Duration of slow wave sleep (SWS), total REM sleep and arousal thresholds decrease with age, culminating into reduced total sleep times with increased sleep fragmentation in individuals greater than 60 years old\textsuperscript{45,46}. In addition, to the natural sleep changes that occur with age, advancing age is generally related to development of comorbid medical conditions. It is not uncommon for elderly patients to describe sleep complaints due to the presence or complications of these comorbidities\textsuperscript{47}.

Comorbidities commonly associated with sleep disordered breathing and obstructive sleep apnea (OSA) include heart failure, coronary artery disease (CAD), and stroke, among others\textsuperscript{55-61}. It is critical to identify OSA and sleep disordered breathing in these particular at risk populations because untreated OSA is an independent risk factor for initial and recurrent stroke, promotes CAD, and nearly triples the risk of mortality in patients with CAD\textsuperscript{59-62}. Diabetes is another condition associated with sleep changes, and it has been shown to correlate with lighter sleep with increased percent of time spent in stage 1 and 2 of sleep.\textsuperscript{45} COPD has also been shown to correlate with poor quality of sleep due to increased sleep latency, decreased total sleep time, and increased arousal.\textsuperscript{63} Parkinson’s disease correlates with sleep fragmentation and REM behavior disorder (RBD), which can be particularly challenging to address in a hospital setting.\textsuperscript{64} Additionally, many conditions are associated with insomnia, the most extensively studied of which include cancer, untreated or poorly treated nocturnal pain, psychiatric conditions such as depression and anxiety, heart disease, and neurologic disease.\textsuperscript{23,47,54,65,66}

Women have a slight predominance in occurrence of insomnia, as well as periodic limb movement disorder (PLMD) and restless leg syndrome (RLS).\textsuperscript{52,53} They are also statistically more likely to present to medical attention for sleep complaints and are therefore more likely to be prescribed hypnotic medications.\textsuperscript{51} Men on the other hand have a higher occurrence of OSA than women, and tend to have lighter sleep with greater time spent in stage 1 and stage 2 sleep compared to women. They also have a slight predominance for narcolepsy, and older men (age>50) have a slight predominance for REM behavior disorder compared to women.\textsuperscript{55,53} Sleep changes associated with older age include lighter sleep and decreased sleep efficiency with greater time spent in stage 1 and 2 sleep.\textsuperscript{45} Older age was also associated with greater occurrence of nocturnal myoclonus, RLS, and sleep disordered breathing.\textsuperscript{46}

In addition to age, sex, and co-morbid conditions, many medications also are associated with SWD. Stimulant medications are associated with insomnia and circadian rhythm disorders.\textsuperscript{65}
Benzodiazepines and opioids decrease the percent of time spent in later stages of sleep, and thereby reduce sleep efficiency.\textsuperscript{67,68} Antidepressants also reduce the time spent in REM sleep and increase REM onset latency, however this typically normalizes with long term treatment. An exception to this includes MAOIs which can cause REM sleep to be absent for months.\textsuperscript{69}

**Physician Surveillance of SWD**

Despite the high prevalence of chronic sleep disorders in the general population and the knowledge that acute hospitalization is a high risk for development or exacerbation of a SWD, physicians frequently fail to address and document SWD in the hospital. One study performed on the general medical ward of a Veteran’s Affairs hospital found that although 23% of patients admitted had a significant sleep symptom there was no medical record during their admission documenting sleep symptoms.\textsuperscript{70} Another study performed on a general medical floor at a non-profit academic hospital found that sleep histories were documented on only 9% of hospital charts, despite 68% of patients having conditions associated with obstructive sleep apnea (hypertension, obesity, stroke, and prior myocardial infarction).\textsuperscript{71}

Standardized screening (Table 2) should be performed at admission to improve recognition of those with pre-existing sleep disorders and may help capture individuals who are higher risk for development of SWD during hospitalization. Re-evaluation during hospitalization may allow identification of those with secondary development of SWD and provide opportunity for intervention. Proactive methods to prevent development of SWD in hospitalized patients may include implementation of a sleep wake protocols that considers patient risk factors, hospital environment and timing of interventions coupled with reinforcement of regular sleep scheduling, sleep hygiene and pharmacologic interventions as needed\textsuperscript{41,26}. Research evaluating the efficacy and impact of these preventative strategies is limited.

Management of SWD in Hospitalized Patients

*Non-Pharmacologic Interventions*

Non-pharmacologic interventions include strategic lighting, noise reduction techniques, and sleep rounds with sleep protocols featuring various implementations to aid with relaxation. A study on daytime light exposure and sleep found that exposure to at least 3000 lx between the hours of 10:00 and 15:00 was likely to improve quality and duration of sleep in elderly patients.77 Supportive care directed at improved relaxation, such as use of warm blankets, warm milk, a white noise machine, hypoallergenic lotion, or a room spritzer, has been shown to improve perceptions of noise levels and reduce sleep latency in hospitalized patients.1 Use of three part sleep protocol, not only resulted in improved patient’s self-reported sleep quality, but also significantly reduced use of sedative hypnotic drugs from 54% to 31%.21

While elderly and acutely ill patients are at risk for SWD while hospitalized, they are also more prone to serious adverse effects of sedative hypnotic drugs, including falls, delirium, and respiratory depression22. Additionally, sedative hypnotics have not consistently been proven to correlate with improved sleep quality.2,22 In many cases, it is therefore preferable to try non-pharmacologic interventions first line when treating SWD in these populations.

*Pharmacologic Interventions*

Sedative-hypnotic drug use is common, both in the general population and among hospitalized patients. Approximately 35% of patients are prescribed a home hypnotic for sleep2, and 45-70% of patients are prescribed a hypnotic during their hospitalization.22 Additionally, approximately 30% of patients are prescribed a new hypnotic in the hospital without any record of pre-admission use.2 The majority of SHDs used included benzodiazepines or zopiclone, but it is not uncommon for antidepressants, antipsychotics, antiemetics, and narcotics to be used for their sedating properties.2
Although the intention of sedative hypnotics is to improve sleep, use of these medications has not consistently proven to correlate with improved sleep quality, but instead has been associated with adverse cognitive outcomes and falls.²

Discussion

An improved understanding of the various factors that can influence sleep during hospitalization allows providers to better evaluate and treat sleep problems more systematically, but also creates an opportunity for systems to adapt preventative and surveillance practices. Sleep wake dysfunction is a multifactorial problem in hospitalized patients, resulting from a combination of the hospital environment, psychological stress, the patient’s medical illness and treatments. Patients can be stratified by these features that may increase likelihood for development sleep difficulties during hospitalization (TABLE 1).

Implementing standardized screening for SD at admission and possibly during admission may help identify those with pre-existing sleep disorders and those who may have developed SWD during hospitalization. Treatment of SWD should be provided with both pharmacologic and non-pharmacologic options considered. Non-pharmacologic options are typically safer and have been shown to be beneficial. Proactive methods to prevent development of SWD in hospitalized patients may be considered. Further research is needed to evaluate efficacy in preventing SWD, as well as impact on length of stay, patient’s perception, morbidity and mortality.
