Abstract: The effect of filling velocity on positive macrosegregations in large size steel ingots was studied. Macrosegregation and macro-/micro-structure were characterized on the hot-tops and a portion of the upper section of two ingots. The measurements revealed that segregation features in the two ingots varied as a function of the alloying elements, and that the severity of positive macrosegregation in the casting body was reduced when the filling rate was increased. It was also found that at the higher filling rate, grain morphologies in the first solidified zones of the ingot changed from columnar to equiaxe, and secondary dendrite arm spacing (SDAS) became slightly smaller in the intermediate and final solidified zones. The experimental findings were analyzed in the framework of diffusion and convection controlled solidification, as well as liquid metal flow theories. The solute dependence of segregation features was related to the difference in solid-liquid partition coefficient and diffusion capability of each element in the liquid iron. Calculation of Reynolds numbers (Re) during the filling process, for both ingots, showed that higher filling velocity caused more instable movement of the liquid metal in the initial solidification stage, resulting in the modification of grain morphology, as well as accelerated solidification rate.

Keywords: medium-carbon low-alloy steel; large size ingot; hot-top; filling rate; positive macrosegregation

1. Introduction

Ingot casting is the only method for the production of large size mono-block high-strength steels used in energy and transportation industries. Various forms of casting defects, however, may stem from the liquid metal filling stage, and then remain during the solidification process. Among them, macrosegregation, defined as chemical heterogeneity on the scale of the entire ingot, is one of the most important ones, particularly in high alloyed steels. Such compositional variation over large distances results in local changes in mechanical properties, which may lead to reduced ingot quality and sometimes even to ingot rejection [1,2]. While the severity of macrosegregation could be significantly reduced in small to medium size ingots through subsequent homogenization and forging operations; the situation is more complex when it comes to large size ingots. Therefore, a better understanding of macrosegregation mechanisms, with the aim to control its extent in heavy castings, is an important scientific challenge with direct industrial implications. This is particularly true when it comes to high value added products, such as large size casting of high strength steels used for turbine shaft applications.
Macrosegregation pattern in heavy low-alloy steel ingots is often characterized by intense positive segregation in the upper part, negative segregation at the bottom, A- and V-type segregates in the body [3]. The pioneering work of Flemings and co-workers, developed in the 1960s [4,5], set the theoretical bases for studying the mechanisms of macrosegregation. Since then, intensive researches have been underway and some critical process parameters have been identified and used as 'countermeasures' to produce sound ingots with improved quality and limited macrosegregation [6-9]. Specially, stringent control of the superheat [7], accelerating the solidification process in the mold [8], and improving ingot dimensions and configurations [9] have been investigated experimentally and numerically by researchers.

In recent years, the influence of filling process parameters has been studied by several researchers. Lee et al. [10] numerically studied the velocity, stress and temperature fields of pure metal during mold filling and solidification process, showing the important effect of filling process on fluid flow and heat transfer at the early stages of casting process. Im et al. [11] modeled the effects of wall temperature and filling flow on solidification, and pointed out that the residual flow due to the filling stage had an important effect on flow characteristics and the liquid metal solidified slower in higher flow situation. Ravindran et al. [12] presented a model to investigate the effect of mold filling on cold shuts formation and the metal front migration, and incorporated inter-dendritic flow models to simulate the effect of solidification on the filling pattern and temperature field. Yadav et al. [13] modeled the filling and solidification of Pb–15wt%Sn alloy in a small side-cooled cavity (50×60mm²), and investigated melt super heat and filling velocity on the evolution of mushy region and macrosegregation. It was found that residual flow due to filling effects significantly affected the shape of the mushy zone, delayed the development of solutal convection, resulting in less intense macrosegregation near the cold wall and a farther distance of A-segregates from the cold wall.

Kermanpur et al. [14] simulated a 6-ton Cr–Mo low alloy steel to study the effect of bottom pouring rate and mold dimensions on solidification behavior and crack susceptibility during subsequent hot forging. Results showed that pouring the melt at a constant rate with a lower mold slenderness ratio would improve the riser efficiency and thereby possibly reduce crack susceptibility during subsequent hot forging. However, the effect of filling velocity on macrosegregation in large size steel ingots has not yet been reported, either numerically or experimentally.

In the present work, the effect of filling rate on positive macrosegregation patterns in two large size cast ingots was studied. Various experimental techniques were used to examine the chemical composition, macro and microstructure evolution of the hot-top and a portion of the upper section of the ingot. The results were analyzed in the framework of diffusion and convection controlled solidification, as well as liquid metal flow theories. The obtained results are expected to contribute to a better understanding of macrosegregation mechanisms in large size ingots. The results could also be used as an input data in numerical simulation codes which still suffer from lack of accurate determination of material characteristics [15].

2. Materials and Experimental process

Two 40 metric tons (MT) cylindrical shape steel ingots, 250cm in height and 150cm in mean diameter, were cast in big-end-up cast iron molds using identical conditions, except for the filling rate. The hot-top, as an extension of the ingot with 70cm in height, was made in the mold lined inside with insulating tiles. During the production process, molten steel with the nominal composition listed in Table 1 was first produced by melting scrap material in an electric arc furnace, and then teemed into a ladle before ladle refining and vacuum degassing in an argon atmosphere. Then it was smoothly bottom poured into the mold at 1570°C until the mold was filled to the top of the insulating tiles. Two filling times were used: the first ingot named LFR, with a filling rate of about 0.0018m/s (30min for the 40MT ingot), and the second one, HFR, with a filling rate of about 0.0024m/s (22min). The liquidus temperature for the current material was determined to be 1495°C using the thermodynamic software Thermo-Calc® [16]. Based on this value, the initial superheat (the excess temperature above the melting point) for both ingots was determined to be 75°C.

After solidification, a block comprised of the hot-top and 30cm thick section of the ingot’s main body was transversely cut off for the investigation. Then, two plates (130×70×1.5cm³) were sliced on each side of the axial plane. One slice was sectioned at regularly-spaced intervals into over 250 samples (6.5×4.5×1.5cm³). All the faces in the centerline plane along the longitudinal axis were grounded, and then chemically mapped using the Thermo Scientific ARLTM 4460 mass spectrometer. The axial face of the other slice was prepared by grinding and macroetched in a 50% HCl solution at 50°C to reveal macrosegregation patterns. Some selected regions were metallographically prepared and etched in Oberhoffer’s etchant, and then optically observed using a binocular microscope.

It should be noted that hot-tops are commonly used in ingot casting industry in order to provide a reservoir of molten steel for feeding the shrinkage zone as the ingot solidifies [1]. They are generally cut off from the ingot body after solidification. However, there is a growing interest in reserving at least part of the hot-top for further use [17]. Thus, in the present study, positive segregation in the hot-top was also characterized along with the upper section of the casting body to evaluate and validate such possibility. It is clear that, if successful, the findings can result in significant material and energy saving in ingot casting industry.

The chemical composition of each specimen was obtained by averaging out 3 random spectrometer measurements and calculated using the relation [18]:

$$R_i = \frac{(\omega_i - \omega_{0,i})}{\omega_{0,i}}$$

Here, $R_i$ is the segregation ratio for solute element $i$, $\omega_i$ is the solute’s local concentration and $\omega_{0,i}$ is its nominal concentration value. A positive $R_i$ value corresponds to positive segregation, and conversely, a negative $R_i$ to negative segregation. Segregation ratio patterns of different elements in the longitudinal section of the entire block were then reconstructed using MATLAB® [19] by filling the areas between the isolines using constant colors corresponding to the local segregation intensities.

3. Results and Discussions

3.1. General macrosegregation patterns

The chemical distribution patterns of the principal alloying elements on the axial plane in the two ingots are shown in Figure 1. The observed section is illustrated in grey in the upper right corner in the figure. The patterns on the left are for LFR and those on the right for HFR. Regions with no segregation ($R_i = 0$) are colored with light blue, negative segregation ($R_i < 0$) with dark blue and the hot-top/casting body separation position is marked with a black dashed line. It can be seen that all the solute segregation ratio maps appear symmetric about the ingot central axis, even though minor differences are present. A gradient in solute concentration is observed over the ingot’s radius from the periphery to the center and from the lower to the upper region. This indicates that the slow rise in concentration of solute in the solid was the result of bulk liquid becoming progressively concentrated in solute elements.
Figure 1. Segregation ratio patterns in the two ingots (LFR and HFR) for the three analyzed solutes: 
(a) (b) C; (c) (d) Mn; (e) (f) Cr.

A weak difference from nominal composition (negative segregation) is observed in the region next to the surface layer of the hot-tops. This difference could be attributed to the increased local solidification time due to the presence of the refractory lining in the hot-top wall. The presence of the refractory lining decreases the cooling rate, as compared to the mold wall, and therefore reduces the segregation in these regions [18]. Besides, some concentration islands are observed, which can be associated with possible segregation channels.

It is also noted in Figure 1 that segregation features in the two ingots were found to vary as a function of alloying elements. Carbon is the element with the highest segregation ratio. The most intense positive segregation ratio of carbon, manganese and chromium in both ingots was found to be sequenced in decreasing order, and reached 1.316, 0.225 and 0.212, respectively. The above sequence is consistent with the descending order of the solid-liquid partition coefficient \( k \) (the ratio of the solute content in the solid \( C_S \) compared to the solute content in the liquid \( C_L \) in equilibrium, \( k = C_S/C_L \)) of each solute. This coefficient was determined for each element based on linearized binary phase diagrams with respect to iron calculated using Thermo-Calc® [16] and the results are shown in Figure 2a. The smaller the partition coefficient of a solute element, the more solute the solid will reject into the liquid during solidification, and the more intense the resulting segregation will be [20]. Although the \( k \) value of manganese lies between carbon and chromium, as seen in Figure 2a, its slightly lower diffusion coefficient in the liquid iron (as displayed in Figure 2b [21]) results in similar positive segregation pattern to chromium. In addition, as shown in Figure 1, the most intense segregations of all the solutes (the red color in the maps) in LFR were observed at the top center of
the hot-top, in contrast to the lower locations of positive segregates of manganese and chromium in HFR.

Figure 2. (a) Partition coefficients of different alloying elements determined based on linearized binary phase diagrams with respect to iron; (b) Evolution of diffusion coefficients of solutes in liquid iron as a function of temperature.

3.2. Effect of filling rate on segregation severity

Frequency distribution of segregation ratios were examined in the hot-top and the upper section of the casting body for the two investigated ingots. The results are plotted in histograms in Figure 3. It can be seen in Figure 3a that in the hot-top of ingot HFR, the intensity of positive segregation of all the analyzed elements is more pronounced (histograms with $R_i > 0$), especially in higher segregation regions ($R_i > 0.1$); solute concentrations close to the nominal composition are less (histograms in the region $R_i = 0$). In contrast, in the upper section of the casting body of ingot HFR (Figure 3b), the positive segregation is less intense (histograms with $R_i > 0$) and more solutes are present with concentrations near the nominal composition ($R_i = 0$).

Figure 3. Frequency distribution of segregation ratios: (a) In the hot-top; (b) In the upper section of ingot body.

The above-mentioned tendency, more severe segregation in the hot-top of HFR and less severe segregation in the casting body of HFR, was more remarkable when the evolution of carbon and manganese was examined along the central axis, as shown in Figure 4a and 4b. The axial concentration examination of chromium presented less severe segregation in both the casting body and the hot-top of HFR, as shown in Figure 4c. Besides, it can be seen that in both ingots, the axial concentrations of carbon present a stepped monotonic increase from the cutting section to the top center of the hot-top. In contrast, positive segregation of manganese and chromium were found to
increase progressively in a fluctuating way. The fluctuation was more distinct in HFR. The most intense positive segregation regions of manganese and chromium in HFR were found to lie about 5cm below the corresponding regions in the low filling rate case, LFR.

![Graphs showing segregation ratio profiles along the ingot central axis of the two ingots: (a) Carbon; (b) Manganese; (c) Chromium.](image)

Figure 4. Segregation ratio profiles along the ingot central axis of the two ingots: (a) Carbon; (b) Manganese; (c) Chromium.

An examination of the concentration distribution along the cutting line of the two ingots (i.e. 30cm below the hot-top/casting body interface), as shown in Figure 5, revealed that the concentration profiles of all the three solutes in the casting body of HFR are below the LFR case and closer to the nominal composition ($R_i = 0$), presenting less severe segregation.

The above results indicate that the filling velocity has a clear influence on the resultant macrosegregation, at least in the studied zones, of large size ingots. The obtained results confirm the observations of Yadav et al. [13] in small size ingots, despite the fact that in large size ingots the filling time is very small compared to the total solidification time.
3.2. Effect of filling rate on fluid flow and solidification time

Considering the large size of the ingots, the solid percentage formed at the end of filling is not expected to induce changes in the melt density, temperature and viscosity. Thus, the influence of filling velocity on the flows of the liquid steel during the filling stage (considered as isothermal flow of a single phase material) was analyzed using the dimensionless Reynolds number (Re) \[22,23\]. The proposed approach is similar to the ones used by Marx et al. \[22\] and Wu et al. \[24\] for physical modelling of liquid melt flow in steel ingots:

\[
Re = \frac{\rho v d}{\mu}
\]

In the above equation, \(\rho\) represents the density of the fluid (kg/m\(^3\)), \(v\) the fluid flow velocity (m/s), \(d\) the characteristic length (m) and \(\mu\) the dynamic viscosity of the fluid (Pa-s).

The density and the dynamic viscosity of the investigated steel at the filling temperature, 1570°C, were determined using Thermo-Calc® \[16\] and JMatPro® \[25\], respectively. The mean filling speed was taken as the characteristic velocity and the average diameter of the cylinder mold cavity as characteristic length. After calculation with all the determined parameters, Reynolds numbers of 3208 for LFR and 4375 for HFR during the pouring process were obtained. The higher value of Re_{HFR} indicates that more flow instabilities and movements were produced inside the mold under HFR condition. This flow instability is expected to result in some residual flow up to the initial stage of solidification under HFR condition.

Macroetch analysis of the zones near the surface of the ingot (first solidified zones), as reported in Figure 6, revealed columnar grains in the casting body of LFR (Figure 6a) and equiaxed grains in...
the same position of HFR (Figure 6b). The examined region is encircles in red in the upper right corner of Figure 6. A schematic views of the grain morphologies are also provided for clarification (due to the large size of the blocks and the grains, it is difficult to capture high quality images with uniform light and shade in one single picture). Campbell [26] found that a dampened fluid flow promotes columnar growth, while an unsteady liquid movement promotes the development of equiaxed grain structure [27]. The presence of the equiaxed grain morphology in the first solidified zone in HFR is probably indicative of the presence of higher liquid instabilities at the start of solidification, as also predicted by Reynolds number calculations.

![Grain morphologies](image)

**Figure 6.** Grain morphologies in the bordering zones (the chill walls are on the left) of (a) LFR; (b) HFR.

Several researchers have examined the mutual influences of residual flow and solidification on the thermal and solutal behaviors of the ingot. Zhao et al. [28] and Zhu et al. [29] reported that the presence of residual flow can homogenize the temperature and solute field in the bulk liquid at the early stages of solidification, while Wang et al. [30,31] and Aboutalebi [32] related it to a decrease of temperature gradient in the pool of liquid. The lower temperature gradient can prolong the thermal convection time in the cavity, and delay the development of solutal convection [33], because of better mixing of solute ahead of the liquidus front and thus decreased density gradients [34]. Others reported that delayed solutal convection can significantly affect the distribution of solutes [35-37], and hence affect the evolution of macrosegregation pattern during the intermediate and final stages of solidification. Therefore, more intense movement of the liquid metal in the initial solidification stage, caused by higher filling velocity, is probably the source for the observed reduced solute segregation in the casting body in the HFR ingot as compared to LFR.

In addition, secondary dendrite arm spacing (SDAS) measurements along the cutting section of the LFR ingot revealed SDAS values as large as 536μm in the 1/2 radius position from the center and 474μm in the ingot center. The two observed regions solidified in the intermediate or final stage of the solidification process. The SDAS values were also in the same range for the HFR ingot but slightly smaller (530μm and 470μm, respectively, in the corresponding regions), as presented in Figure 10. Lower SDAS values are generally correlated with shorter solidification times [26]. Furthermore, as reported by Vives et al. [35], higher filling rates result in increased dissipation rate of the melt superheat with the mold and accelerated solidification rate due to the higher strength of convection. Therefore, the findings of the shorter solidification time arisen from higher filling velocity can result in less time available for solutes to transport, and could be another source for the lower segregation intensity in the casting body of HFR. It should be noted that further experimental work on measuring the SDAS values in different locations of the ingots will contribute to confirm and better quantify the differences in the SDAS values for each condition.

The shorter solidification time and the lower diffusion coefficient of the solutes are probably the main sources for the observed lower location (~5cm) of the positive manganese and chromium concentration cores in HFR (as reported in Figures 1 and 4). Besides, no sufficient diffusion time could be the origin for the observed higher fluctuations in the concentrations of manganese and chromium in the radial and axial distributions in HFR (as seen in Figures 4 and 5). The reduced segregation in the casting body of HFR, produced under fast filling conditions, is probably the root cause for the
higher segregation intensity observed in the hot-top of HFR. Indeed, a lower segregation level in the casting body results in more partitioning of solutes into the melt and their accumulation towards the end of solidification in the upper part of the hot-top [4]. The axial less severe segregation of chromium in both the casting body and the hot-top of HFR could be due to the less available time for the diffusion of the solute.

4. Conclusions

The effect of filling rate on positive macrosegregation characteristics in large size steel ingots was studied based on the analysis of the hot-top and a small portion of the main ingot body. It was found that accelerating the filling process alleviates solute segregation in the upper section of the casting body. The beneficial effects could be due to a combination of the more intense movement of the liquid metal caused by higher kinetic energy of the liquid metal in the initial solidification stage and shorter solidification time that reduces the available time for the segregation to build up.
