Abstract

Recent research has revealed surprisingly important connections between animals’ microbiome and social behaviour. Social interactions can affect the composition and function of the microbiome; conversely, the microbiome affects social communication by influencing the hosts’ central nervous system and peripheral chemical communication. These discoveries set the stage for novel research venues focusing on the evolution and physiology of animal social behaviour in relation to microbial transmission strategies. Here, we discuss the emerging roles of teleost fish model candidates and their key potential for advancing research fields linked to sociality and microbial regulation. We argue that fish models, such as the zebrafish, sticklebacks, guppies and cleaner-client dyads, will provide valuable insights into the roles of microbiome in shaping social behaviour and vice versa, while also being of direct relevance to the food and ornamental fish trades.

Keywords: behaviour/sociality; cleaner fish; gut-brain axis; poecilids; sticklebacks; zebrafish

Table of contents:

4. Concluding remarks

1. The gut-brain axis and its importance for health, stress physiology and behaviour

The microbiota-gut-brain axis (MGB axis) has a pivotal role in health, stress physiology and behaviour (Foster, Rinaman, & Cryan, 2017). The interaction between the gut microbiome and the brain is now well established, at least in mammals, and involves multiple pathways, including immune signaling or neurotransmission through bacteria-derived metabolites (such as serotonin, histamine and catecholamine regulators; Sandhu et al., 2017). Host genetics, but also the external environment, are key determinants of microbiome composition from birth (e.g. Yang et al., 2016; Gilbert, 2014; Bonder et al., 2016; Cong et al., 2016). In humans, this includes neonatal hospital conditions, antibiotic use, birth delivery mode, breastfeeding vs bottle feeding, and early life stress (e.g. see Yang et al., 2016). This intimacy between the microbiome and its host has given rise to the concept of the ‘holobiont’, and to the theory that microbial colonization of the foetus and newborn follows co-evolutionary patterns (Gilbert, 2014). After three years of age, the microbial composition in healthy individuals should be relatively stable (but see Desbonnet, Clarke, Shahanan, Dinan, & Cryan, 2014), with the gut harbouring a diverse community, dominated by benign bacteria (Guarner & Malagelada, 2003; Walker, 2013). Concomitantly with early establishment of the gut microbiome are key neurodevelopmental landmarks critical for establishing normal motor,
cognitive and emotional function (Cong et al., 2016; Borre et al., 2014). Synaptogenesis, which onsets post-birth, is one of these crucial steps in early neurodevelopment (reviewed by Borre et al., 2014). The interaction between the microbiome, neurodevelopment and the central nervous system, the gut-brain axis is beginning to be understood, and is based on the observation that stress can increase intestinal permeability, allowing bacteria to translocate through the intestinal mucosa to access immune cells and neurons in the enteric nervous system (Gareau, Silva & Perdue, 2008; Teitelbaum, Gareau, Jury, Yang & Perdue, 2008; Tognini, 2017). The appearance of depressive episodes, related to dysregulations of the hypothalamus-pituitary-adrenal (HPA) axis (Barden, 2004), appear to have a close relationship with gut microbiome colonization. For instance, germ-free (GF) rats, that lack commensal gut bacteria – and, consequently, have a poorly developed immune system – are more reactive to stress when subject-ed to restraint or to novel environments (Sudo et al., 2004; Clarke et al., 2013). Indeed, neonatal stress leads to long-term changes in the diversity and composition of the gut microbiome (García-Ródenas et al., 2006; O’Mahony et al., 2009), which could con-tribute to long-term changes in stress reactivity and in the stress-related behaviour ob-served in these rats. Treatment with probiotics (mainly Lactobacillus spp.) through the initial stress stage normalizes basal corticosterone levels, which are elevated after maternal separation (Gareau et al., 2008). Likewise, pre-treatment of rats with Lactobacillus farciminis reduces the intestinal permeability that results from restraint stress, as well as the associated hyperactivity of the HPA axis (AitBelgnaoui et al., 2012) and potential stimulation of the MGB axis. In addition to these findings relating microbiome and HPA axis function, there is direct evidence that the microbiome can influence central nervous system activity through the activation of stress-related neurons; for ex-ample, orally administered bacteria induce c-Fos
expression in afferent vagal neurons (Lyte, Li, Opitz, Gaykema, & Goehler, 2006) and in paraventricular hypothalamic neurons in GF rats (Sudo et al., 2004) in the absence of systemic immune responses, suggesting that commensal and pathogenic bacteria in the gastrointestinal tract release signals to the central stress circuits. Moreover, electrophysiological experiments demonstrated that vagal nerve endings in the gut are less excitable in GF rodents (McVey Neufeld, Mao, Bienenstock, Foster, & Kunze, 2013), or more excitable after probiotic administration (Kunze et al., 2009), suggesting changes in enteric neuronal responses due to variations in commensal microbiome.

The reciprocal relationship between the microbiome and social life of hosts arose as a surprising topic, emphasizing the impact of microbial communities on animal social communication and signaling. Microbial transfer between socially interacting partners is common and was recently reviewed by Archie and Tung (2015) and Vuong et al. (2017). The general consensus is that commensal bacteria can affect social behaviour, potentially to maximize their transmission and colonization of new hosts (e.g. Archie & Tung, 2015), akin to host manipulation by macroparasites (e.g. Poulin, 2013). It is undisputable that bacteria can manipulate behaviour through the production of metabolites, which mediate chemical communication between interacting host partners (e.g. Ezenwa & Williams, 2014). Commensal bacteria are responsible for the production of odours that allow sexual and reproductive state recognition (Theis et al., 2013) and can be determinants in mate choice (Sharon et al., 2010). Additionally, commensal bacteria may be key drivers in the cost-benefit calculus of group network interactions (e.g. Archie & Tung, 2015; Tung et al., 2015) and while in some cases social microbe transmission can benefit the host by promoting disease resistance (Endt et al., 2010; Stecher et al., 2010; Koch & Schmid-Hempel, 2011), in others bacterial transfer might facilitate pathogen transmission (Garrett, Gordon, & Glimcher, 2010;
Elinav, Strowig, Henao-Mejia, & Flavell, 2011). Although research on microbial influence on animal social behaviour is vibrant and emergent, with much being discovered every year, most mechanistic pathways (neurophysiological for example) are unclear or unknown (see Vuong, Yano, Fung, & Hsiao, 2017). Furthermore, the focus of such studies has been mammalian models (reviewed by Pascoe, Hauffe, Marchesi, & Perkins, 2017). Here, we discuss the emerging roles of fish model candidates and their potential for advancing research fields linked to microbial regulation.

2. From human to fish: widening microbiome-based behavioural neuroscience

2.1. Fish microbiome: what we know

The most comprehensive review of teleost microbiome research collated 46 studies spanning 2006 to early 2014 that focused on the microbiomes of different mucosa in fish (see Table 1 of Llewellyn, Boutin, Hoseinifar, & Derome, 2014). These studies were mostly culture and/or 16S Sanger sequencing-based, focusing on hosts with high fishery, aquaculture or ornamental value. Most were purely descriptive or assessed the effects of diet (e.g. food substitution or supplements with prebiotics or probiotics) or host factors (ontogenetic, genetic or species-specific) on gut microbiota. Since 2014 the number of fish microbiome studies has more than doubled (see for example Tarnecki et al. (2017) for a review on fish gut microbiome studies). The focus of these new studies continues to address the effects of diet supplements on gut microbiota (e.g. Ray et al., 2017; Wang et al., 2016), but increased effort has been placed in determining which ecological factors are determinants of microbiome composition. For example, the effects of abiotic factors (e.g. salinity [e.g. Schmidt, Gomez-Chiarri, Roy, Smith & Amaral-Zettler, 2015], pH [e.g. Sylvain et al., 2016], season [e.g. Zarkasi et al., 2015]...
and geography (e.g. Wilkins, Rogivue, Schutz, Fumagalli, & Wedekind, 2015)) on fish microbiome composition are starting to be unraveled, including those driven by pollutants and habitat degradation (e.g. Narrowe et al., 2015). Disentangling the links between microbiome and fish health is a hot topic, particularly given the growth of aquaculture industry. In this respect, the impact of pathogens, antibiotics and probiotics on microbiome composition has been subject of several studies (e.g. Llewellyn et al., 2017, Reid et al., 2017; Li et al., 2016; Hennersdorf et al., 2016; Carlson, Leonard, Hyde, Petrosino, & Primm, 2017; Gonçalves & Gallardo-Escarate, 2017).

2.2. A fishy absence: the gut-brain axis in fish

As our understanding of fish host-microbiota interactions increases, so it becomes obvious that more research is necessary, particularly on the interdependence between the microbiota and fish behavioural responses. This contrasts with the rise in popularity of fish behavioural neuroscience, where several fish species are widely used as models to study social cognition and behaviour (Oliveira, 2013; Soares, Cardoso, Carvalho, & Maximino, 2018). While there is no doubt a significant bias towards using birds and mammals to study animal social behaviour and cognition, fish possess much more than just a predictable mixture of unlearned predispositions (Brown, 2015). Fish display sophisticated behaviours and complex social networks, such as Machiavellian strategies of deception and reconciliation (Bshary, Wickler, & Fricke, 2002), the ability to monitor the behaviour of others and their own reputation, to cooperate and to adjust their investment levels in accordance to context and even to use social tools to achieve direct goals (Brown & Laland, 2003; Soares, 2017; Soares et al., 2018). This complexity mirrors some homologous components of fish’ neural representations with that of higher vertebrates (Oliveira, 2013). However, much remains to be discovered.
about the similarities and dissimilarities of behaviour and brain processes between fish and mammals.

3. **The usefulness of fish models to study microbiome-behaviour interactions**

Given that fish display a complex array of social behaviours, from lone individuals to complex group behaviour based on reciprocity, we should expect a variety of effects on (and of) the microbiome. Nonetheless, an important gap in the literature is the virtual absence of gut-brain axis studies on fish species. We argue that fish models, such as the zebrafish, sticklebacks, guppies, cleaner-client dyads among others (Box 1), can help provide valuable insights into the roles of microbiome in shaping social behaviour and vice versa.

3.1 **Zebrafish**

The zebrafish is a key model organism in developmental biology and genetics and is increasingly used in behavioural neuroscience (Norton & Bally-Cuif, 2010; Kalueff, Stewart, & Gerlai, 2014; Stewart, Braubach, Spitsbergen, Gerlai & Kalueff, 2014). A wide array of tools, from behavioural assays to neurogenetic and neurogenomic tools (Rinkwitz, Mourrain, & Becker, 2011; Gerlai, 2014) have been developed for zebrafish, including specific assays for anxiety- and fear-like behaviour, as well as for stress responses (Jesuthasan & Mathuru, 2008; Maximino et al., 2010; Clark, Boczek, & Ekker, 2011; Stewart et al., 2014). There is mounting evidence for a species-specific “core” gut microbiota in zebrafish, as animals reared for generations in the laboratory show similar components in relation to animals captured in the wild (Roeslers et al., 2011).

The core microbiome of the zebrafish gut is known from many experimental studies. As described for other vertebrates, zebrafish exhibit ontogenetic shifts in mi-
Crobiome composition (Falcinelli et al., 2015; Roeselers et al., 2011; Hall, Tolonen, & Xavier, 2017; Shin, Whon, & Bae, 2015). Recently, the effects of probiotics on zebrafish, namely on their behaviour, have been assessed. Adult zebrafish treated with the probiotic Lactobacillus rhamnosus IMC 501 for 28 days showed increases in the abundance of taxa belonging to Phylum Firmicutes in the gut (Borrelli et al., 2016). Treatment of zebrafish larvae with L. rhamnosus IMC 501 from 0 to 8 days post-fertilization decreased the relative abundance of Proteobacteria and increased Firmicutes. Borrelli et al. (2016) found similar increases in Firmicutes after 28 days of treatment in adult animals. Importantly, adult zebrafish treated with L. rhamnosus IMC 501 displayed less shoaling and increased bdnf mRNA in the brain, with upregulation of genes involved in the serotonergic system in the brain (tph1a, tph1b, tph2, htr1aa, slc6a4a, and mao) and gut (tph1a) (Borrelli et al., 2016). The reductions in shoaling could represent an anxiolytic-like effect; however, Schneider et al. (2016) did not find alterations in anxiety-like behaviour after 15 days of treatment with L. rhamnosus GG – although this probiotic prevented the anxiolytic-like effect of chronic ethanol treatment. These discrepancies could also be due to differences in treatment duration (28 vs. 15 days). Consistent with this hypothesis, Davis et al. (2016) found that treatment with Lactobacillus plantarum for 30 days decreased anxiety-like behaviour in the novel tank test, an effect that was accompanied by increased slc6a4a (serotonin transporter) expression in the brain (but no alterations in the GABAergic, neuropeptide Y, or oxytocin-like pathways). L. plantarum did not alter gut microbiota diversity, but Mycoplasmataceae, Stenotrophomonas, Catenibacterium, unclassified Lactobacillaceae, and Achromobacter were enriched in Lactobacillus-treated animals. Interestingly, when L. plantarum-treated animals were exposed to a chronic unpredictable stress paradigm, serum cortisol and leukogram alterations were not altered, but the probiotic protected
against the gut dysbiosis induced by stress. Interpreting these findings is hard, as the authors did not report any behavioural alterations in stressed animals. For now results based on probiotic treatment should be treated with caution, but suggest that, at least in zebrafish, the microbiome is associated with defensive (anxiety-like) behaviour, and therefore could indirectly mediate sociality by altering the anti-predatory component of social behaviour or by decreasing the neophobia associated with social novelty.

3.2. Poeciliids

The guppy (*Poecilia reticulata*) and indeed a range of other poeciliid fish are widely studied tropical fish species (Evans, Pilastro, & Schlupp, 2011), renowned models of ecology and evolution. The Trinidadian guppy system in particular has been used to study the complex role of gene flow on adaptation and fitness in a natural setting.

Naturally isolated populations provide natural (replicated) study systems that have been used intensively to assess the impact of different environmental factors, and predation and parasitism pressure on host morphology, genotype and behaviour (e.g. Endler, 1995; Magurran, 2005; Reznick, Shaw, Rodd, & Shaw, 1977; Reznick & Ricklefs, 2009). While these wild guppies have been used to study micro-evolutionary speciation in both field and laboratory studies, the ease with which they can be maintained and bred in captivity has meant they are also one of the most common fish in the worldwide ornamental trade. Their popularity relates to the availability of many different domestic colour and ornament varieties and hybrids (locally known as rainbowfish or millionsfish to reflect their colour and abundance). As the trade continues to expand, new strains are being selectively bred as these small viviparous fish have a fast generation time and are relatively tolerant of poor water quality. This has provided the basis for numerous studies on the genetics, immunology, particularly the MHC-genes
Phillips et al., 2018) as well as the ecology and behaviour (Croft et al., 2011) of this model species.

Using the ‘natural Trinidad laboratory’ of replicated distinct up- and downstream populations across four rivers, Sullam et al. (2015) were the first to assess the guppy microbiome, and they did so in relation to host adaptation. They found clear microbiome differences in the guts of wild-caught and laboratory bred fish, and from field specimens revealed that gut microbiome communities varied temporally, across streams and between ecotypes in a stream-specific manner. But this study also high-lighted the myriad of other biotic and abiotic factors that could be driving microbiome divergence (Sullam et al., 2015).

Although still largely unexplored, there is some parallel between the response of poecillid and mammal microbiome to antibiotic use. In mammals, antibiotics can disrupt microbiome communities resulting in decreased microbiome-mediated disease resistance (otherwise known as ‘colonisation resistance’) so although there may be a short-term gain from treatment in the long-term health, and even survival, can be compromised (Adleberth, Cerquetti, Poilane, Wold, & Collignon, 2000; Fons, Gomez, & Karjalainen, 2000). Likewise, in poecillids (e.g. mosquitofish, Carlson, Hyde, Petrosino, Manage, & Primm, 2015) antibiotics can disrupt the host microbiome and impact health. ‘Probiotic rescue’ is being tested as a solution to this problem. Schmidt et al. (2017) found that probiotics (Phaeobacter inhibens S4Sm and Bacillus pumilus RI06-95Sm) can reduce antibiotic-associated mortality in Poecilia sphenops.

Studies assessing the social behaviour of guppies revealed how different life-history trajectories shape sociality (e.g., Dugatkin, 1988; Farr, 1975) and the importance of cooperation in the establishment of these social groups (Dugatkin & Alfieri, 1991). If the gut microbiome does influence its host behaviour and if there is a probability of
transmission between conspecifics, we should then expect, similar to what was found for zebrafish, social interactions and prosocial behaviour to be associated with microbiome composition.

### 3.3 Sticklebacks

The three-spined stickleback (*Gasterosteus aculeatus*) is the temperate equivalent of the guppy, being a small freshwater fish that is robust and easy to maintain and breed in large numbers in both the laboratory and field. But this fish is not just a leading model in ecology and evolutionary research; following publication of its genome (Jones et al., 2012) it arguably has reached supermodel status. Following glacial retreat in the northern hemisphere 12,000 years ago, repeated evolution from ancestral oceanic to derived freshwater forms resulted in many beneficial genetic variants surviving in thousands of distinct natural populations (Bell & Foster, 1994). Unlike laboratory genetic screening, which identifies mutants causing abnormal development, physiology or behaviour, these natural variants highlight biological innovations. Consequently, a large community of researchers utilises stickleback variants to understand adaptive speciation, behaviour, development, immunology (e.g. Cresko, McGuigan, Phillips, & Postlethwait, 2007; Huntingford, Ostlund-Nilsson, & Mayer, 2006; Scharsack, Kalbe, Harrod, & Rauch, 2007), and a range of projects are in progress assessing the microbiome of sticklebacks across a range of different environments. To date, such research has been largely confined to correlative approaches: QTL mapping, divergence mapping, and association studies.

Stickleback microbiome research has only just got off the starting block, but we already know that diet has a sex-specific effect on the gut microbiota (Bolnick et al.,...
2014b), and perhaps surprisingly individuals with more generalised diets have less diverse microbiota than dietary specialists (Bolnick et al., 2014c). Of key importance is host genotype compared to transient environmental factors (Smith, Snowberg, Caporaso, Knight, & Bolnick, 2015), but systems-based approaches in the future are likely to reveal the true complexity of these interactions. Oceanic (ancestral) sticklebacks mount a strong immune response to residential microbiota compared to freshwater variants as revealed by the use of the stickleback as a newly developed gnotobiotic vertebrate model (Milligan-Myhre et al., 2016). Alongside zebrafish, sticklebacks could provide a powerful tool for mapping the natural genetic basis of the variation in immune response to microbes (Small, Milligan-Myhre, Bassham, Guillemin, & Cresko, 2017), and thus provide important clues regarding the role of intrinsic factors in microbiome composition. In the next few years, improved genome annotation will facilitate identification of candidate genes and experimental gene manipulation will provide the tools to validate suspected candidate genes. Importantly, recent research has already shown that specific Major Histocompatibility Complex alleles and diversity are related to the composition and diversity of gut bacteria in sticklebacks (Bolnick et al., 2014a), as has previously been discerned for macroparasites (Matthews, Harmon, M’Gonigle, Marchinko, & Schaschl, 2010; Eizaguirre, Lenz, Kalbe, & Milinski, 2012).

### 3.4. Cleaner fish

Cleaning mutualisms are interspecific associations where cleaners remove ectoparasites and infected tissue from the body surface, mouth and gill chambers of their client fish (Côte, 2000). These interactions have been extensively studied, particularly in tropical regions, where obligate cleaner fish (cleaners that depend exclusively on client-gleaned
material throughout their life cycle) occupy territories (known as cleaning stations) that are visited by fish species (often referred to as clients). Cleaner-client fish dyads are perfect candidate models to study the role of microbiome in mutualistic behaviour and physiology as both partners come in close physical contact during interactions, allowing direct microbe transmission (skin-to-skin) while potentially also modulating the gut microbiome of cleaners, which feed actively of clients’ mucus, parasites and hyperparasites.

In recent years, a priority has been identification of neurohormonal candidates that may modulate behavioural changes in marine cleaning mutualisms, allowing us to relate social cognition to the underlying mechanistic and neural mechanisms (Soares, 2017). These studies have highlighted the importance of neuromodulators such as nonapeptide arginine-vasotocin (AVT), which has substantial motivational and learning effects on cleaners (Soares, Bshary, Mendonça, Grutter, & Oliveira, 2012a; Cardoso et al., 2015a, Cardoso, Paitio, Oliveira, Bshary, & Soares, 2012b). Monoamines such as serotonin and dopamine (DA) also have a crucial impact, with serotonin increases being responsible for changes in motivation to engage mutualistically (Paula, Messias, Grutter, Bshary, & Soares, 2015), while disruption in dopamine transmission leads the cleaner to anticipate a lower probability of feeding or, alternatively, a higher likelihood of being punished by being chased or the client leaving (Messias, Paula, Grutter, Bshary, & Soares, 2016a). The effects of pharmacological stimulation of the DAergic system were most evident during the learning process, in which individual learning abilities of cleaners were tested in laboratory conditions (Messias, Santos, Pinto, & Soares, 2016b). The involvement of the dopaminergic system on cleaners’ decision-making changed depending on context and the predictive condition of reward (for instance when time delays occur, Soares, Cardoso, Malato, & Messias, 2017a), or with
familiarity/novelty (Soares, Santos, & Messias, 2017b). Moreover, the role of social stress on cleaning performance has been studied. Indeed, one of the most notable behaviours by these animals is the cleaning and entering of predators’ mouths, a behaviour that has been interpreted as altruistic on behalf of the clients that may simply eat the cleaner (Trivers, 1971). This seemingly fearless behaviour became a paradoxical feature of cleaners’ proactivity and ‘gutsy’ cooperative behaviour, but also of putative anxiety and stress control, particularly when cleaners were found to show a preference for predatory over herbivorous clients, despite no obvious increase in ectoparasitic crustaceans in these hosts (Soares, Cardoso, & Côté, 2007). The main hypothesis raised to explain this behaviour is that cleaners need to be more proactive and spend more time inspecting predators (therefore glean more parasites and other material), in response to an increase in cortisol levels of energetic expenditure and putative decrease of immune reactivity (Soares, Bshary, Cardoso, Côté, Oliveira, 2012b). The role of stress mechanisms mediating the cleaners’ cooperative levels were further tested, as these mechanisms were discovered to be involved in cleaners’ decisions, as the exogenous effects of cortisol rises were found to propitiate cleaners’ behavioural switch from cooperation to cheating (e.g. more stress led to more cheating; Soares, Cardoso, Grutter, Oliveira, & Bshary, 2014).

Our current understanding of cleaner fishes’ social behaviour and proximate mechanisms prompts us to hypothesise that the cleaners and clients’ microbial composition may have a direct role in determining the costs and benefits of these complex behavioural trade-offs. But at this point it is impossible to know which behaviours are influenced by cleaners’ microbiota, especially given the diversity of social challenges cleaner must face.

4. Concluding remarks
The use of fish in microbiome-related research is expanding (Llewellyn et al., 2014), although currently the research is mostly ecological or diet focused on farmed or commercially valuable fish species (Box 2). The advantages of fish use in basic and applied neurobehavioural research include: rapid generation time and fertility (typically external fertilization), small size, genetic diversity, amenability to genetic manipulation, and finally intermediate physiological and behavioural complexity in relation to other model organisms (Friedrich, Genoud, Wanner, Ahrens, & Hughes 2013; Friedrich, Jacobson, & Zhu, 2010, Kalueff et al., 2012, 2014; Maximino et al., 2015; Nor-ton & Bally-Cuif, 2010; Rinkwitz et al., 2011; Stewart et al., 2015; Soares et al., 2018).

Moreover, complex neuroscientific tools and sophisticated behavioural paradigms have been developed for the zebrafish model. On the other hand, fish use in behavioural studies covers a multitude of species. A combination of the laboratory tools available for zebrafish and the ecological and ethological perspectives gleaned from other fish species is ideal (Hall, Serrano, Rodd, & Tropepe, 2014).

A key difference between fish and other terrestrial models for microbiome studies is the fact that living in aquatic conditions may increase the level of microbiota contamination from surrounding water. However, many studies have compared the surrounding water microbiome with that of the fish, and while for larvae colonization from water microbiota seems to occur, for adult fish the observed differences are enough to discard this hypothesis. At this point, the major drawback of our suggested systems is an overall lack of core information. So far microbiome research in fish disregards behavioural and physiological responses. Nevertheless, the potential of using fish models is endless considering their diversity, and the fact we may build from extensive knowledge regarding behavioural ecology (guppies, sticklebacks), physiology and genetics (cleaners and zebrafish) and animal production of certain key species. This
opens the door for a wealth of research: for example, do most fish species share common behavioural and physiological end-points arising from modulation by microbiota?

The multidimensionality of fish diverse behavioural systems sets the stage for future interdisciplinary research that should start with a strong ecological (field-derived) approach, being followed by lab-based cognitive and pharmacological experimentation. The implications of such integrated approaches may be of translational relevance to human behavioural deficits and psychiatric disorders, especially regarding the influence of social conditions to microbiome functionality (see Box 2).

Box list

**Box 1. A move to therapy? The use of model fish species to unravel the effects of microbiome into human social behavioural disorders**

Animal-focused research is pivotal to the advancement of scientific knowledge, but fish use in translational medical research has mostly focused on zebrafish. In neurosciences and behaviour, both larval and adult zebrafish have contributed to our understanding of the genetic control of brain processes, and the effects of pharmacological manipulations. In fact, the similarities between mammalian and zebrafish paradigms are a clear demonstration of the evolutionarily conserved nature of behaviour and physiological modulation across species (Kalueff et al., 2014). We expect fish to share an increasing role when it comes to microbiome-based research and, most specially, in contributing
empirically to the influence of skin and gut microbiome on the onset and development of several human behavioural disorders.

The study of the microbiome of model fish organisms could generate interesting insights into conserved and derived features of host-microbiome interactions and their impact on behaviour. Importantly, while the study of fish models is likely to be useful in the study of the evolutionary biology of host-microbiome interactions, the availability of behavioural assays for anxiety in both adult and larval zebrafish offers potential biomedical applications. The development of models for stress-induced dysbiosis, novel developments regarding the zebrafish inflammasome (Angosto & Mulero, 2014), and the interactions between these mechanisms pave the way for innovative models for psychiatric disorders. In addition, fish are emerging models of social behaviour and associated pathological alterations. Sociality is a fundamental dimension of human interactions and altered social behaviour is a symptom of many psychiatric disorders. In fish, due to the widespread influence of ecological and ecophysiological research, the focus has been largely aggressive behaviour – a symptom of acute psychotic states, drug abuse and mood disorders. A recent review highlighted that the broader array of social behaviour and cognition – from social motivation, social anxiety and social avoidance through social cognition, reproductive behaviour, and altruism and cooperation – represent important endpoints which could be used as models of specific disordered domains of psychiatric conditions related to mood disorders and social anxiety (Soares et al., 2018). Understanding how the microbiome interacts with these factors could open avenues for investigation on probiotics and other live biotherapeutics on psychiatric disorders (Marchesi et al., 2015; O’Toole, Marchesi, & Hill, 2017).
Box 2. The social life of farmed fish: the search for new boundaries of social learning and stress response

Fish farming is crucial for maintaining global protein sources for rising human consumption and for providing animals that can restock exploited or/and degraded habitats or for create new fishing areas (Fernö, Huse, Jakobsen, & Kristiansen, 2006). When these hatchery-reared fish, however, are released into the wild they tend to have low survival partially due to behavioural deficits, although other causes (and consequences) are still under debate (Young, 2013; NASCO, 2017). Overall, available information indicates that this is a product of rearing environment, which limits fish exposure to natural stimuli and has profound consequences in fish learning and decision-making skills. In summarizing the differences (and implications) between natural and farmed fish, we identify the following:

1. Behavioural shifts. i) Foraging: fish reared in restricted conditions are less able to adjust to novel situations, which may occur when reared fish are released into the wild, needing to identify and catch live prey; ii) Aggression and reproduction: implications of rapid growth and high density.

1. Spatial dynamics. Farmed fish live in high density groups, but because these constantly changing, the establishment of clear individual and collective behaviour may thus be limited. While exposure to a greater number of conspecifics could be a source of extra information and learning, in practice the ability to recognize and associate with conspecifics may also decrease with group size for some species (Griffiths & Magurran, 1997; Ward, Holbrook, Krause, & Hart, 2005). Additionally, artificial grouping of similar sized animals may also modulate behaviour.
1. Coping and anti-predator responses. The monocultural and relatively sterile conditions of aquaculture tend to produce fish unable to appropriately cope with novel and complex (natural) environments. The lack of previous exposure to predators, limits individual recognition which may become fatal (Brown & Warburton, 1999).

2. Parasite resistance. Stressful conditions can lead to immunocompromised fish that are more prone to infection and directly transmitted pathogens can spread rapidly amongst high density hosts.

3. Poorer development and physiological state (ontogeny), due to differences in nutrition, exercise and putative chronic stress levels of tank reared fish. Indeed, a combination of factors during the development of these fish, such as high levels of stress exposure and absence of appropriate socio-environmental stimulation may lead to limited neural and sensory development (Fernö et al., 2006).

In addition, many farmed fish are genetically selected which is likely to change their physical characteristics, usually targeting rapid growth but this may also change key behavioural traits. The implications of fish domestication in terms of behavioural and physiological variation urgently warrants further research.

**Acknowledgements**

MCS and RX are currently supported by FCT under the Programa Operacional Potencial Humano – Quadro de Referência Estratégico Nacional funds from the European Social Fund and Portuguese Ministério da Educação e Ciência (MCS: SFRH/BPD/109433/2015; RX: IF/00359/2015). Research on cooperative fish was mostly supported by the Portuguese Foundation for Science and Technology-FCT (grant PTDC/MAR/105276/2008) and by the European Regional Development Fund.
(ERDF) through COMPETE program and by National Funds through FCT - Foundation for Science and Technology (project PTDC/MAR-BIO/0902/2014- POCI-01-0145-FEDER-016550; and project POCI-01-0145-FEDER-027995). JC and RX were partially funded by the Welsh Government and Higher Education Funding Council for Wales (HEFCW) AquaWales Project through the Sêr Cymru National Research Network for Low Carbon Energy and Environment (NRN-LCEE). CM and MGLM are currently supported by CNPq/Brazil under Edital Universal 2016 (CM: 400726/2016-5; MGLM: 423735/2016-0). The authors have no conflicting interests.
