Abstract: The diagnostics of natural landscapes geoecological state in the course of the permafrost zone economic development should be based on the assessment of the destructive cryogenic processes formation. It is expedient to consider it in terms of landscapes resistance to cryogenic processes increase. The choice of lithocryogenic stability parameters is substantiated. These are: permafrost distribution over the area, its annual mean temperature and ice content, protective properties of the vegetation and etc. Cryogenic processes activation is estimated with regard to their area, development rate and attenuation, natural landscapes damage, hazard for engineering facilities operation. The assessment procedure, and the way of improving expert numerical scores are shown. At Geography Faculty of Lomonosov Moscow State University, the authors have developed a number of the approved methods of making evaluation maps of different scales applying the methods of landscape indication, modern methods of space images decoding, methods of expert scores, the method statistical calculations and methods of spatial GIS-analysis. The technique of Atlas geo-information mapping on the landscape basis has been introduced in seven atlases at scales from 1:3 000 000 to 1:20 000 000. These maps are widely used in design and survey organizations and in education.

Keywords: geoecological situations, permafrost zone, cryolithozone, cryogenic processes, landscapes stability, geoinformation mapping.

1. Introduction

The diagnostics of geoecological situations in the cryolithozone demands the analysis of the following main parameters of the permafrost: the distribution area, the annual mean temperature and ice content degree. The permafrost area shapes the geography of geoecological hazards emergence (north - south; west - east). The annual mean temperature influences the stability of permafrost and cryogenic landscapes. The lower the temperature, the less the geoecological hazard, other things being equal. The development hazard is directly proportional to the ice content degree of permafrost. With its increase, the geoecological consequences of the economic development grow.

While assessing geoecological situations in the north territories, the following parameters are important: the permafrost distribution on area and profile, its annual mean temperature and thickness, the cryogenic structure of the upper part of the permafrost, cryogenic forms of the relief, the layer of seasonal thawing and freezing. Of importance is the position of permafrost limits as boundaries of permafrost quality changes, its unstable states.
2. Materials and Methods

2.1 Basic mapping materials

As sources for making small-scale maps for the cryolithozone territory, four permafrost maps should be used. These are: Geocryological Map of the USSR (scale 1: 2.5 million (1997)) [1], Geocryological Map of the USSR (scale 1: 5 million (1970)) [2], Circum Arctic Map of Permafrost and Ground Ice conditions (scale 1: 10 million (1997)) [3], Cryolithological Map of the USSR (scale 1: 4 million (1985)) [4]. The most comprehensive source of detailed characteristics of permafrost conditions all over Russia is the Geocryological Map of the USSR (scale of 1: 2.5 million) [1]. From this map we used the data on the permafrost temperature and its thickness, lithological composition, genesis, cryogenic structure and ice content of permafrost that were coordinated with a landscape map.

For displaying the natural background in which various geocological situations are being formed, it is necessary to analyze a number of small-scale permafrost maps, made on a uniform landscape basis, on a geosystems grid of various ranks. In geographical atlases of the recent two decades [5-11], the landscape map (scale 1:1 500 000 000 (fig. 1)),

![Figure 1. Landscape map of the Permafrost zone in Russia](image)

i.e. the generalized Landscape Map (scale 1:4 000 000) for the territory of Russia edited by A.G. Isachenko [12] was the main landscape information source. In legend to this map (fig. 2), the landscape zone types are shown in horizontal ranks. Vertical columns correspond to landscape kinds, i.e. to genetic types of a relief and lithological differences of rocks. The tabular legend facilitates the selection of landscapes characteristics separate components on the lithogenic basis, relief, vegetation in zone and sector aspects that are necessary for permafrost situation understanding.
Let us consider two basic maps of the section "Permafrost" published in the Ecological Atlas of Russia [5]. These are maps of scale 1:20 000 000: "Permafrost of Russia" and "Seasonal freezing and thawing".

On the Permafrost map of Russia (fig. 2), four main types of permafrost distribution are shown: continuous, discontinuous, massive-island and island.

Within each type, the territories with different values of annual mean temperature of permafrost are allocated due to the distribution area. The temperature on plains and plateaus increases first of all from the north to the south. In mountainous landscapes the temperatures are lower, than on the adjacent plains. The greatest variety of temperatures is in the continuous permafrost zone: from –11°C to –3°C.
In the discontinuous permafrost zone, it is difficult to differentiate the permafrost temperature field within the map scale. This type of permafrost is most widespread in mountains and uplands of the south and east of the Russian cryolithozone. Massive-island and island permafrost types are characterized by the temperatures not below –1 °C, and the thawed areas have temperature 1-2° C here. The map shows three main permafrost types due to the ice content degree. Thus, the low-icy permafrost (<20%) is mainly observed in the cryogenic eluvium of the highlands and plateaus, in the upper part of the fractured rocks and the sands. The mid-icy permafrost (20-40%) is represented by sandy and loamy differences within denudation plains. The highly icy permafrost (>40%) is most often observed within low accumulative plains with loamy and sandy ground. The signs indicate the areas of monomineral ice massifs distribution, such as polygonal-vein ice massifs, the kernels of frost heave mounds and ice beds [13,14].

The second important map, necessary for geoeological research, is the Seasonal Freezing and Thawing Map (fig. 3). For its making not only the Landscape Map by A.G. Isachenko [12], but also the Geoecologic Map of the USSR, scale 1: 2 500 000 [1] were used to the full extent along with the results of regional research of seasonal freezing and thawing from publications, funds data, the authors’ personal archive.

It is worth mentioning that the layer of seasonal freezing and/or thawing (so-called "active layer") is the first permafrost horizon from the surface, in which ecologically hazardous cryogenic processes take place. The change of its thickness is integrated in the manifestation of cryogenic processes and serves as an indicator of their activation. During engineering research and calculations, this parameter has paramount importance and, along with ground temperature, their ice content (or humidity), is used for ensuring reliability of buildings, facilities, communications operation/maintenance during the solution of specific engineering-geological objectives.

The peculiarity of the map Seasonal Freezing and Thawing is in the fact that within the borders of the cryolithozone of Russia not only seasonal permafrost thawing is evaluated, but seasonal freezing in taliks too. The area of the latter increases with the approach to the southern permafrost limit. Taliks are almost absent in the continuous permafrost, and in the south of cryolithozone permafrost occupies no more than 5-10% of the area. Therefore, in the discontinuous permafrost within the same landscape, small-scale maps display both depths: of seasonal thawing and of seasonal freezing.

Figure 3. Legend and map fragment Seasonal freezing and thawing
The allocation of two large fields of the seasonal freezing and thawing distribution is the basis for the creation of the legend (fig. 3) and graphic design of a map. The scale is carried out for each of them. The influence of a relief is shown by creating separate scales for their different constituents: plains, mountains, river valleys. The whole depth range of seasonal freezing and thawing is subdivided into three types: small (up to 0.5 m) where the majority of factors interfere with the processes of seasonal freezing and thawing; average (to 1.0-1.5m) with relative compensation of the factors fostering and interfering the process; deep (more than 1.5 m) where the most part of factors fosters the process. The degree of the geocological hazard increases from the deep active layer to the shallow one, as in this direction the hazard of damaging natural environment under anthropogenic impacts increases [15].

The diagnostics of geocological situations is based on geographical features of active layer depths distribution. In continuous permafrost zone, only the depth of seasonal thawing is mapped, which in general is subject to latitudinal and altitudinal zonation. The thawing of less than 0.5 m is shaped by severe climatic conditions of the Arctic and is observed in the polar deserts of the Arctic Ocean islands and on the loaches of ridges of the Northeast of Russia. The thawing from 0.5 to 1.0 m is characteristic of peats and peaty soils of the lake and marsh landscapes elsewhere. The average thawing due to the depth (intervals of 1.0-1.5 m and 1.5-2.0 m) is found in the associated soils of tundra and forest-tundra landscapes within the European North, Western Siberia peninsulas, in the north of the Taimyr Lowland, the seaside lowlands of the Northeast of Russia. The deep, more than 2 meters, thawing is localized in the sandy landscapes created by ancient sea, alluvial, and lake-glacial sediments. In the mountains, according to the landscape zonation and reduction of absolute heights, the depth of thawing increases.

2.2 Methodology of estimating research and mapping

The geosystems stability is one of the fundamental concepts of physical geography and geocology. The cryogenic landscapes resistance to surface damage is understood as the ability to resist to anthropogenic activation of cryogenic processes that may lead to irreversible deterioration of the environmental situation and unacceptable deformations of engineering structures [16]. Cryogenic processes is the key indicator of northern landscapes reaction to external influences [17].

The mechanical damage arising during the engineering facilities functioning and mining are widespread in the cryolithzone. It is also necessary to refer the typical anthropogenic influence of the North, as overgrazing of reindeer pastures, as well as deforestation and burning. All these violations intensify the development of thermokarst, solifluction, deflation, foster the expansion of the boggy areas.

The concept of geo-ecological research is based on the leading factors identification of the landscapes lithocryogenic state, that influence the landscape stability decrease and, as a result, cryogenic processes activation [16]. Thus, for making the Map of landscape stability of Western Siberia cryolithzone, scale 1: 4 000 000 [18], six factors influencing directly the potential activation of cryogenic processes, connected with phase transitions of water, were selected: dissected relief; ground composition; permafrost temperature; ice content (humidity) of the ground; the degree of vegetation recoverability; relative change in the active layer. In the works [15,17, 18] their choice is explained.

The evaluation procedure includes:
- selecting the main factors that influence landscapes resistance to loadings (cryogenic processes activation);
- drawing up the table of factors ranging;
- assigning numerical scores to each landscape in accordance with the table;
- ranking of all landscapes due to vulnerability to the economic development, taking into account the calculated indexes;
- evaluative mapping.

With this technique, the so-called engineering permafrost (lithocryogenic) stability maps are made on a landscape basis. Depending on the regional specifics and the scale of the research, the number and spectrum of the estimated factors may varies. For example, for Central Yakutia it is necessary to consider a number of bioclimatic factors [19], crown density of a forest stand, etc. [15]. Owing to the developed traditions in geocological estimations, expert scores are widely used for the comparative characteristic of the objects. They are simply summed up or arithmetic mean values (rarely -the geometric mean values) are calculated. The
calculation-statistical method of multifactorial landscape biotic and lithocryogenic basis properties correlation analysis can also be used.

At first, the integral impact of all landscape stability factors was estimated by total score [17]. Summing points may be used in the regional survey research, though it has serious limitations due to the fact that points lack dimensionality [20]. But it is easily solved if the points are appointed against the background of a uniform interval 100 cent scale [15,21].

**The Intensity of the Cryogenic Processes**

![Diagram](image)

Figure 4. The ratio of the estimated factor scales, affecting the intensity of cryogenic processes manifestation (Western Siberia)

In this case, the values of six indicators in cents due to which not the sum, but the geometric mean, that can be called hazard coefficient \(C_0\), is calculated, correspond to each landscape. The less the value of \(C_0\), the more steady the landscape should be considered. Thus, for splitting all landscapes into clusters due to stability, two techniques were tested: simple points summing and calculating the geometric mean value in cents.

Graphic figure 4 shows that of the greatest vulnerability for the economic development in this region (in terms of destructive exogenous processes manifestation) are the landscapes with the values of six factors in the right part of the figure. These are plain slightly dissected landscapes with the annual mean ground temperature from 0\(^\circ\) to – 1 \(^\circ\)C, made of peat, with more than 50% of ice content degree, with low recoverability of vegetation (projective covering of less than 20%) in which the thickness of seasonal freezing-thawing layer may increase more than twice in case of mechanical damage of their surface.

Applying the landscape basis and the database with particular values, each factor can be displayed as a separate thematic layer (ice content degree, ground temperature, etc.) and further to use overlaying. It is rather complicated and is not always justified. To simplify mapping, the express assessment of diverse factors with integrated indexes calculation is carried out: permafrost stability coefficient - \(PSC\), coefficient ecological hazard coefficient \(EHC\), hazard coefficient \(C_0\) and others [13]. In large-scale research, it is expedient to use the multiple-factor correlation analysis of the estimated factors which, first, allows us to estimate the importance of a particular factor and, secondly, brings closer the quality standard to the quantitative one.
2.3 Evaluation of geocological situations at local level

For the assessment of the formation of various geocological situations, the table matrix (fig. 5) is developed, on the horizontal axis there are groups of stability according to gradation of the calculated indices, and on the vertical axis there are load categories [22, 23].

![Figure 5: Evaluation of Geocological Situations Shaping](image)

The categories of anthropogenic loading are ranged due to the types and sorts of mechanical damage, residual deer capacity, vegetation recovery rate, a share of the damaged lands, etc. The type of a possible situation is determined by the score in each cell of a matrix. As a result, all cells unite in four groups, forming the types of geocological situations according to regulatory documents of the Ministry of Natural Resources and Environmental Protection of the Russian Federation on nature conservation: from rather satisfactory to crisis [15, 23].

Each situation is characterized by a set of exogenous processes of different intensity. Thus, typical processes of a crisis stage in the forest-tundra of Western Siberia are: in peatlands – vein ices thawing out, deep thermokarst on polygonal-wedge ices, peat block subsidence, intensive thermal erosion in cracks, ice thawing out in frost mounds and their turning into lakes. In bogs with low-center polygons - progressive swamping, thermokarst, seasonal and long-term frost heave. Frost cracking - thermal erosion - is activated in cracks, and intensive deflation is developed with the formation of deflation basins in tundras on icy and ice-rich dusty sands with topsoil cover removed [22].

For making the maps of geocological situations (fig. 6) the map of landscapes permafrost stability is compared to the map of anthropogenic loading via overlaying [22].
The duration of geoecological situations existence (and, therefore, the degree of cryogenic processes activation) depends on the stages of territory development. The scheme (fig. 7) shows that rather satisfactory and intense situations last from 3-5 to 10 years in accordance with the time when survey and construction works are taking place. Critical and crisis situations arise during the deposit operation. Further destruction of the natural complex and activation of the processes occur within the first 5-10 years of commercial production of hydrocarbons. Then, there comes their gradual attenuation both for the natural reasons, and because of the taken engineering and meliorative measures [24].
2.4 Factors of cryogenic processes activation

The main complex of ecologically dangerous cryogenic processes is comprised of two groups: the periods which are becoming more active in summer and in winter respectively [23]. It is important for diagnostics of geoecological situations as in summertime the vegetation ground cover is mainly investigated, in winter snow cover is considered. The first group of the processes is formed in the summer as a result of permafrost thawing. These are thermokarst, thermoerosion, thermoabrasion and solifluction, which under the increase of soil humidity moves into mass dislodging. The second group of the processes consists of in the autumn-winter period when water turns into ice, further cooling of soil takes place, so frost heave and frost cracking are observed. These processes combinations allow us to diagnose the emerging geoecological situations, to estimate the degree of their hazard both for the environment, and for anthropogenic facilities.

The assessment of the processes activation degree is based on the analysis of the following factors (Fig.8): cryogenic structure (or ice content) and temperature regime of the ground in the upper part to the depth, corresponding to the layer of annual heat transfer. Out of the “non-permafrost” components of nature the leading place belongs to vegetation and geological-geomorphological conditions [15].
The vegetation damage is a universal type of the heat exchange change on the surface and in this meaning it is most often “a trigger” for cryogenic processes activation. Its role is double: under natural conditions it is one of the main stabilizers of permafrost conditions, performing the heat-insulating and fixing functions (a protective role of vegetation). After anthropogenic damage, the rate of vegetation cover restoration impacts permafrost processes attenuation [15,25].

The predictive evaluations of their damaged areas, the rates of their development and attenuation along with the remediative, meliorative, environmental and engineering activities are used to stop these processes. The gradation of particular characteristics of the processes is based on quantitative or qualitative (points) indicators for carrying out their numerical comparison. A total score of these indicators is the extent of their activation in the territories under development. Indicators ranging should be brought in a number of tables, some of them are given below (Fig. 9-12).

The paramount indicator is the area of cryogenic processes damage which is estimated on five categories: from less than 5% (1 point) to more than 75% (9 points) of the territory under development.

The second important indicator is the processes development rate (Fig.9). It is clear, that the lower the rate, the less geocological danger of economic development is.

Figure 8. The main factors intensifying the cryogenic processes activation
The permafrost processes, except for area distribution and the speed of development, influence the shape of a landscape in general, that can be estimated only qualitatively (Fig. 10). The first place in the transformation of natural landscapes into the inconvenient areas of land is won by thermoerosion because of the deep surface fragmentation, then the solifluction goes, turning landscapes into the impassable sites because of the pluvoor ground.

The assessment of the work safety degree at engineering facilities (including accident rate) is shown in Figur 11.
Almost all processes which are listed in this table, except frost cracking and kurum formation, predetermine high accident rate of engineering facilities under considerable anthropogenic impacts[26].

The integrated assessment of geoeconomic situations has to include the attenuation rate of dangerous processes along with the efficiency of environmental activities for the protection against them owing to making competent engineering, remediation, etc. decisions (Fig. 12).

Figure 12. Cryogenic processes attenuation rate and availability of engineering protection protection

The natural attenuation can be connected with the consumption of their main resource, i.e. ice, along with the low negative temperatures, rapid vegetation restoration, relief alignments [25].

2.5 The assessment and mapping of geoeconomic situations at regional level

At the overview-regional scale of research, the evaluation and mapping of ecological situations are based on the identification of territories in accordance to permafrost, climatic, landscape conditions of processes activation and anthropogenic loading degree. The potential danger of cryogenic processes manifestation in the territory of Russia cryolithozone is defined by the extent of their activation and a combination of the most typical processes within various natural complexes [15, 25].

On the colour small-scale map of the permafrost zone of Russia (fig. 13), five groups of potential processes activation are allocated: from weak to very strong. The assessment of the extent of permafrost processes activation varies for plain and mountainous territories. On the plains, the whole area of a landscape is estimated. For highlands, the activation of the processes is considered separately within a mountainous terrain and in valleys [5,6,7,15].
The distribution of various combinations of the main cryogenic processes is presented on the map (fig. 14). These combination groups are united in 11 groups according to the zonal and regional varieties of the permafrost, landscape and climatic conditions. They are characterized by different variations of eight most ecologically and technologically dangerous and typical cryogenic processes. In the legend to this map, the first six groups characterize the processes peculiar for plain landscapes, and the groups from the 7th to 11th are for mountains, foothills, including the river valleys dividing these territories [15].

Figure 13. The map of cryogenic processes activation
GIS-analysis of these groups of processes (fig. 15.) leads to the following conclusions.

The first group occupies a quarter of the permafrost zone (fig. 16) where the combination of mountainous and valley processes take place, i.e. thermokarst, thermooesional, frost heave, icing formation, solifluction, kurums, that are spread in a mountainous-highland belt of Central Siberia, the Far East, Baikal and the Transbaikal ridges [14,27]. It corresponds to the fact that highlands occupy the most part of the permafrost zone. The development of these territories is highly localized, though there are a lot of problems with the construction, but they rather rarely occur. The territories of the first group have small environmental hazard.
Figure 16. The first group of processes combinations

The second group (fig. 17) includes three groups of processes combinations which occupy the greatest part of the permafrost zone - 39% (fig. 15). These are highlands too, but different in morphology. There are highlands and loaches of the northern low mountains where the slope processes and icing in the valleys are typical. The development is insignificant here, the problems of construction are very rare. The territories of the second group of processes have moderate environmental hazard.
Figure 17. The second group of processes combinations

The third group (fig. 18) is comprised of the processes each of which occupies less than 10%, but their total area is 36% of the Russian cryolithozone (fig. 15).
Figure 18. The third group of processes combinations

Their diagnostics is the most difficult, as this group is the most numerous in the number of combinations entering it (numbers from 1 to 7). In terms of geomorphology, they are plains and mountain hollows. It is here that there is an active mastering of the territory not only due to the mineral wealth, but also to rather convenient conditions for development. Respectively, the activation of cryogenic processes manifests itself to the utmost. They occupy the largest areas, their rates are large, the combinations are various, the threats to engineering facilities are also diverse [27].

Discussion

Thus, the diagnostics of geocological situations in the permafrost zone in the overview-regional research is based on the assessment of the anthropogenic cryogenic processes activation of through studying the area affected by them, their rate of development, natural landscapes damage, threats to the functioning of engineering structures.

At the overview scales of the research, the most significant permafrost factors are:
- the area of the permafrost distribution in % from continuous to island;
- the annual mean temperature of the permafrost from below – 11 °C up to 0 °C with separate scale for plains and mountains;
- the ice content of the permafrost with the intervals for weakly, mid- and strongly icy types, including monomineral ice.

The hazard severity of the situations increases with the growth of the area and the ice content degree of the permafrost, their approach to 0 °C.

The basis for the diagnostics and mapping of geocological situations are landscapes, and the instrument of diagnostics is the thawing depth. The latter is chosen by us as the most sensitive indicator of the situations change in space and time.

At the local level of the research, the range of estimative factors is wider. It is the ice content degree and temperature of the permafrost, the depth of seasonal thawing or freezing, the relief, the heat-insulating
properties of the vegetation and the rate of its self-recovery, the bioclimatic indicators etc. During the process of evaluative mapping of the permafrost contents, various techniques are used: methods of statistical calculations, indicative signs, maps-indicators, scientific hypotheses, extrapolations, etc. The ecological indicators are generally defined on the basis of expert estimates and rely on the long-term experience of regional research. On the basis of the analysis of the chosen factors, the integrated indicator of their cumulative influence is calculated. It can be either the simple sum of factor points or their geometric mean, or the calculated coefficient developed in the multiple regression equation. For the determination of points dimension it is proposed to use a cent scale. The graphic-analytical method of assigning scores against the background of the interval 100-cent scale allows us to commensurate numerical scores on difficult-to-match scales, as well as to supplement traditional points with an estimate of their own weight. The latter technique of the calculation of the total score, undoubtedly, will interest the reader.

**Conclusions**

The ecological component of the majority of geocryologic research consists in the assessment of the cryogenic processes manifestation of observed in nature. The paper reveals the experience of carrying out diagnostics and mapping of the permafrost-ecological state based on the identification of the areas of anthropogenically provoked cryogenic processes, ranging the extent of their activation and the combinations of the most typical processes within various landscapes. Scientific and methodological approaches of this evaluation find application in engineering geocryology, at predesign stages of the research, in the nature protection institutions for the elaboration of the competent strategy of the cryolithozone development.

The paper reveals the experience of permafrost-landscape mapping in different scales of research: from atlas to large-scale. The atlas maps, designed on a common landscape basis, have universal value, allowing us to arrange, analyze and generalize the information about the permafrost zone landscapes. Their content, the chosen indicators, classifications, gradation of values are developed taking into account the possibility of their further application for geocological estimates, for taking administrative decisions. They are actively used in the educational process as visual aids.
