Abstract

During weekly monitoring of a compensatory habitat reintroduction for an endangered frog species, a group of a dozen adult diving beetles (Coleoptera: Dytiscidae) were encountered attacking and quickly dismembering and consuming a tadpole. A single adult diving beetle was also discovered burrowing its head deep inside and consuming a tadpole approximately three to four times its size. Although Dytiscidae are known to occasionally consume vertebrates such as tadpoles, adults are typically considered scavengers, and this communal predatory behavior and feeding method have not been previously documented. Besides these interesting novel behaviors, these observations may have implications for amphibian conservation since management efforts are not typically concerned with naturally occurring ubiquitous threats such as those from small invertebrate predators, as it is rarely been observed in nature. However, this may be perhaps due their ability to consume prey rapidly, especially if working in packs. Although amphibian conservation plans always expect some losses from natural predation, diving beetles may seriously affect conservation efforts such as captive breeding and reintroductions with populations already on the threshold of extinction and where every individual critical to success.

Keywords. compensatory habitat, frog, invertebrate, predation, reintroduction, tadpoles

Introduction

In-situ and ex-situ conservation programs, including reintroductions to formerly occupied sites and translocations to compensatory habitats, have emerged as key management tools to mitigate the global decline of amphibians (Biega et al. 2017; Harding et al. 2016; Heatwole et al. 2018; Zippel et al. 2011). However, the success rate of such mitigation strategies has been fairly low, with few projects resulting in self-sustaining populations (Germano et al. 2009; Germano et al. 2015). Even those few initiatives that have been successful have required very large release numbers or a decade or more of intervention (Germano and Bishop 2009). Although studies have proposed many strategies to improve survival in managed populations (i.e., increased salinity to combat chytrid (Clulow et al. 2018) or removal of invasive predatory fish (Klop-Toker et al. 2018; Vredenburg 2004)), recent outcomes have been mixed (Harding et al. 2016). One possible reason for this may be because most conservation efforts are typically concerned with managing 'unnatural' threats such as habitat loss, disease, and invasive species; with little attention given

to naturally occurring threats which may also severely affect managed species, particularly small and fragile populations where survival of every individual is critical.

The role of invertebrate predation in shaping vertebrate communities is often underestimated or overlooked entirely (Nordberg et al. 2018) which has resulted in the lack of their recognition in conservation planning. This is evident with predaceous diving beetles (Coleoptera: Dytiscidae) which are often the top predator in aquatic freshwater habitats around the world (Culler et al. 2014; Wellborn et al. 1996), yet are understudied as both an aquatic insect group and aquatic predator (Yee 2014). Although many aspects of their ecology and life history remaining relatively unknown, diving beetles are considered generalist predators and can cause trophic cascades due to their high feeding rates on zooplankton, aquatic invertebrates, and relatively small vertebrates (Cobbaert et al. 2010; Culler et al. 2014). The larvae are exclusively carnivorous and are commonly known as water tigers due to their voracious appetite, advanced chemical senses for detecting prey, and variety of hunting strategies, which can shift from sit-and-wait to active hunting based on habitat complexity (Michel et al. 2009; Yee 2010, 2014). They also possess large hollow curved mandibles which are used to pierce and inject digestive enzymes into their prey, before subsequently sucking and ingesting the liquefied mixture (Kehl 2014). This feeding behavior allows larvae to consume much larger prey, such as tadpoles (Pearman 1995; Tejedo 1993), fish (Culler et al. 2014), and even snakes (Drummond et al. 1981). Dytiscidae larvae are such effective predators that some tadpole undergo dytiscid-induced behavioral changes such as altered activity levels (Tejedo 1993), avoidance of areas where larvae are present (e.g., avoid aquatic vegetation to prevent ambush attacks) (Rubbo et al. 2006; Smith et al. 2009), as well as a truncation of hatching time or decrease in tadpole size (Pearman 1995).

Although adult diving beetles are also known to occasionally predate on tadpoles (Cabrera-Guzmán et al. 2012) and fish (Culler et al. 2014; Melisi et al. 2016), they are mostly considered scavengers as they are perceived as less efficient and clumsy at capturing active prey, especially larger prey, due to their smaller body size and chewing parts that are more gape-limited compared to the larvae (Culler et al. 2014). However, recent evidence suggests that adults not only have the capability to predate on larger vertebrates but that their predatory behavior can have drastic effects on populations of endangered species (Bittel 2019). For example, conservation efforts to save the critically endangered Devils Hole pupfish saw limited success, until it was discovered that adult diving beetles were consuming fish twice their size and significantly hindering recruitment in the managed population (Bittel 2019; Heil 2018). Once most of the beetles were actively removed, researchers who were recovering zero to one egg per month were now finding up to 100 a week (Heil 2018). Although the predation capacity of adult beetles remains understudied, findings such as this allude to their potential impact on vertebrate populations within aquatic systems.

Predation of tadpoles by adult diving beetles was witnessed on 27 of January 2014 at 22:00 during nocturnal monitoring of a compensatory habitat reintroduction program of the green and golden bell frog (*Litoria aurea*) (for details see Valdez et al. (2017)). A group of a dozen adult diving beetles (unidentified, but likely to be the three-punctured diving beetle (*Cybister tripunctatus*)) were encountered engulfing, attacking, and quickly dismembering a striped marsh frog (*Limnodynastes peronii*) tadpole (Figure 1), all in nearly a minute (Video 1: https://archive.org/details/2014012722.15.21). In a different area of the same pond, a single adult diving beetle was discovered consuming an *L. peronii* tadpole that was approximately three to four times its size (Figure 2; Video 2: https://archive.org/details/2014012722.16.53). In contrast to the typical feeding method recorded for adults, which are generally thought to tear their prey item into small pieces, this individual beetle had its head burrowed deep inside the tadpole in a manner similar to the feeding method of larvae, which pierce their prey and suck out its liquefied remains. To my knowledge, this communal predatory behavior and feeding method have not been previously described among diving beetles.

Besides the novelty of these behaviors, it was concerning how vicious and quickly the adult diving beetles consumed their much larger tadpole prey, especially considering that predation occurred within a managed compensatory habitat enclosed by predator-proof mesh designed to protect the managed sympatric species from large vertebrate predators. Although diving beetles were not observed predating on tadpoles of the reintroduced *L. aurea* species, it is possible that this interaction could at least partly explain the few remaining adults and lack of recruitment after only three years, despite being one of, if not the largest, amphibian reintroductions in Australia with 10,000 tadpoles originally released (Valdez et al. 2017). During the first year of weekly monitoring when tadpoles were first released, over 80 percent were found in ponds containing no beetles, with the largest densities consistently occurring in ponds with zero or a negligible number of beetles. Furthermore, although only a quarter of the naturally occurring ponds in the neighboring landscape were free of diving beetles they contained nearly half of all extant *L. aurea* tadpoles (Valdez et al. 2015). These findings suggest that the presence of adult diving beetles could have impacted the survival of *L. aurea* tadpoles to some extent before they had a chance to metamorphose out of the aquatic environment after reintroduction, thereby hampering the success of conservation efforts.

These observations may have implications for future amphibian conservation, given that current management efforts are typically not concerned with naturally occurring ubiquitous threats such as those from invertebrate predators. It is possible that predation by diving beetles has been ignored until now as it has rarely been observed in nature, perhaps due their ability to consume prey rapidly, especially when working in packs. Although amphibian conservation plans always expect some losses from natural predation, diving beetles may seriously hamper conservation efforts, particularly for populations already

on the threshold of extinction where every individual is critical to prevent further declines. This is because diving beetles are known to have a voracious appetite, with experiments showing adults consuming at least nine tadpoles per day (Cabrera-Guzmán et al. 2012) and larvae consuming dozens in a day (Kruse 1983). The impact diving beetle presence may have on conservation efforts may be exacerbated in compensatory and restored habitats, since they are among the first macroinvertebrate predators to colonize new freshwater habitats (Bilton 2014). Another potential problem is that they have similar dispersal patterns to that of many amphibian species, dispersing from permanent to temporary ponds during the warmer breeding periods (Bilton 2014; Davy-Bowker 2002), with some diving beetles even depositing their eggs within amphibian egg clutches (J. Gould, pers. comm.). As temperatures continue to rise as a result of climate change, the impact diving beetles have on amphibian populations could become even more relevant to the success of conservation efforts, particularly if greater predation (Rall et al. 2010) and dispersal (Bilton 2014; Miguélez et al. 2008) rates result in poorer pre-metamorphic survival of more populations of endangered amphibians already on the edge.

With up to 53% of amphibian species threatened with extinction (IUCN 2018), all possible threats which may negatively impact conservation success must be identified. While invertebrate predation on vertebrates is largely ignored and underestimated, recent evidence suggests it may be more common and impacts on vertebrate populations may be further researching than previously thought (Nordberg et al. 2018; Rudolf von May et al. 2019). Despite representing the top predator and the most diverse or abundant Coleoptera taxon in most freshwater aquatic systems, many aspects of the ecology of predaceous diving beetles remain unknown (Yee 2014). However, the evidence presented here suggests that diving beetles may be significant predators of tadpoles even those much larger species, and their effect on amphibian populations, specifically tadpoles, should not be ignored. Further research should be conducted to quantify their impact on amphibian populations, breeding, and the success of amphibian conservation plans.
