Abstract: Easter Island (Rapa Nui) deforestation has traditionally been viewed as a single event, synchronous in time and space across the island and caused by Polynesian settlers. However, recent studies have challenged this idea introducing the concept of spatio-temporal heterogeneity and suggesting a role for climate change. This paper presents a continuous paleovegetation record of the last millennium (~960 to ~1710 CE), based on palynological analysis of a peat core from Lake Kao. During this time interval, deforestation was gradual, with three main pulses at ~1070 CE, ~1410 CE and ~1600 CE, likely driven by drought, anthropogenic practices (mostly fire) or the coupling of both. Some forest regeneration trends have been documented after the first and the second deforestation pulses. Forests were totally removed by 1600 CE, coinciding with the full permanent human settlement of the Kao area. Comparison with other continuous palynological records available for the last millennium (Aroi marsh and Lake Raraku), confirms that forest clearing was heterogeneous in time and space, rather than synchronous island-wide.

Keywords: charcoal, climate change, deforestation, drought, fire, human disturbance, last millennium, non-pollen palynomorphs, pollen analysis, Rapa Nui

1. Introduction

The deforestation of Easter Island (Rapa Nui) was considered for a long time as an abrupt and island-wide event due to the overexploitation of natural resources by the first Polynesian settlers, who were assumed to have caused their own cultural collapse after their arrival on the island between 800 CE and 1200 CE [1, 2]. However, recent paleoecological investigations have challenged this view by suggesting that deforestation was gradual and heterogeneous in time and space across the island, and that the ancient Rapanui civilization was resilient to deforestation [3]. It has been proposed that this discrepancy was due to the occurrence of a millennial-scale sedimentary gap in the first palynological studies [4, 5], which hid the landscape changes of the last millennia [6]. New coring campaigns developed during the last decade, with emphasis on the more recent times, have yielded continuous (gap-free) and chronologically coherent paleovegetation records (without age inversions) for Lake Raraku and the Aroi marsh (Fig. 1), two of the three Easter island sedimentary basins suitable for paleoecological research [7, 8]. The other sedimentary basin that would be useful for this purpose, Lake Kao (or Kau), remained problematical due to gaps and frequent age inversions that prevented the development of reliable age-depth models [9-11]. A single continuous and chronologically coherent record exists for Lake Kao covering the last millennium [12] but pollen analyses of this sequence have not yet been published. Here we present the pollen analysis of another continuous sequence from Lake Kao encompassing the last millennium [3]. Results are considered preliminary as resolution can be increased and some low abundance pollen and spore types still lack identification. However,
deforestation trends are already clearly visible and can be compared with other gap-free and
cronologically reliable records of similar resolution from Raruku and Aroi.

2. Coring site and methods

Lake Kao (~1250 m diameter and ~10 m depth) is the largest permanent freshwater body of
Easter Island and is located within the Kao volcanic crater, in the southwestern corner of the island, at
110 m elevation (Fig. 1). The surface of this lake is a mosaic of open waters and peat-forming floating
mats dominated by Scirpus californicus (Cyperaceae) and Polygonum acuminatum (Polygonaceae). A
220-cm depth peat core (KA008-03) was retrieved from this floating mat with a Russian corer, at the
northern side of the lake (27° 10’ 57.526” S - 109° 26’ 7.591”) (Fig. 1). Nine samples were taken for
radiocarbon dating, which was performed at the Radiochronology Lab of the Université Laval (Canada).
The age-depth model was carried out using the smooth-spline option in the Clam 2.2 software [13].

Samples for pollen analysis were processed at the ICTJA Laboratory of paleoecology with standard
palynological methods, including KOH, Na2P2O7, HCL and HF digestions, acetolysis and mounting in
glycerin-jelly [14]. Lycopodium tablets were added before treatment. Counting procedures followed ref.
[15]. The diagram was plotted with psimpoll 4.27 and pollen zones were obtained using the OSIC
(Octimal Splitting by Information Content) method [16]. The interpretation of these zones was based on
previous knowledge about pollen-vegetation relationships on Easter Island, with the addition of some
indicator non-pollen palynomorphs (NPPs) that were not analyzed in former investigations. Among
these NPPs, the most important are fungal spores from genera such as Sporormiella, Byssothecium,
Gelasinospora and Glomus. Sporormiella is a coprophilous fungus growing in the dung of domestic
vertebrates and is thus commonly used as an indicator of human presence [17]. Byssothecium is a
saprobe or weak parasite on woody and other plant remain substrates, whereas Gelasinospora prefers
dry conditions with charred material [18]. Glomus, a mycorrhizal fungus living in forest soils is
commonly considered as an indicator of increased erosion rates [19]. Microcharcoal particle
concentration, expressed in particles >5 μm/g, was used as a proxy for fire.

3. Results and interpretation

Radiocarbon ages are shown in Table 1 and the best-fit age-depth model is displayed in Fig. 2.
According to this model, the sequence encompasses roughly the last millennium, except the last 2-3
centuries (1022 cal yr BP to 237 cal yr BP or 928 CE to 1713 CE). The sampling resolution is multidecadal
(~36 y/sample). The average model error is 5.3% (range: 4.0% to 11.5%). Average accumulation rates are
3.6 mm/y (range: 2.1 mm/y to 4.6 mm/y), with lower values in the uppermost part of the sequence,
higher values in the intermediate part and medium values in the basal part. The pollen diagram was
subdivided into four pollen zones (Fig. 3), from I to IV, which are described in chronological order.

Pollen Zone I (289-255 cm; 993-881 cal yr BP; 957-1069 CE). This zone is co-dominated by palms and
grasses, suggesting an open palm woodland with Triumfetta (Tiliaceae) shrubs in the understory. Ferns
started to be abundant at the end of the zone. Indicator NPPs were still absent, with only scattered
occurrences of Sporormiella and Byssothecium. Charcoal is present but in very low amounts. The whole
picture suggests a dispersed human presence with a very low ecological impact.

Pollen Zone II (255-175 cm; 881-544 cal yr BP; 1069-1406 CE). This zone begins with a rapid and
significant palm forest decline, with a minimum at about 1100 CE, that turned the Kao vegetation into a
grassland with scattered palm trees. This conspicuous shift occurred in the middle of a Medieval climatic
drought that desiccated the shallower Lake Raraku [7] and is not associated with a coeval increase in
indicators of human presence (Sporormiella, charcoal), which suggests that climate may have been the
main driver for the forest decline. A fire peak occurred at 1150-1200 CE but this did not seem to affect
the trend of forest regeneration, possibly favored by a wetter climate [7]. This regeneration culminated
at about 1350 CE, when a new forest retraction took place, this time coeval with small increases of
Sporormiella and fire, suggesting more intense human activity than in former times.
**Pollen Zone III** (175-127 cm; 544-340 cal yr BP; 1406-1610 CE). At the beginning of this zone, palm pollen almost disappeared and the landscape became almost entirely herbaceous. Indicators of human presence (*Sporormiella*, charcoal) slightly increased and fungi associated with dead wood and charred plant material (*Byssothecium*, *Gelasinospora*) followed a similar trend, supporting anthropogenic forest clearing and the corresponding accumulation of degraded and burned wood and other plant materials. Minimum forest values at about 1470 CE coincided with an increase of erosion indicators (*Glomus*). A new forest regeneration trend can be observed, culminating at the end of the zone, although this is less intense than in the former pollen zone. A significant increase in fire indicators and coprophilous fungi (*Soporumcella*) at the end of the zone (from about 1550 CE onwards) suggest that forest regeneration was interrupted by human occupation of the Kao catchment. The onset of another drought during the Little Ice Age (LIA) [7] would have contributed to fire exacerbation.

**Pollen Zone IV** (127-83 cm; 340-239 cal yr BP; 1610-1711 CE). The Kao area was already devoid of forests, which were replaced by extensive grassland meadows, with the addition of an unknown Apiaceae. Human settlement increased abruptly, as indicated by the dramatic increase of fires, coprophilous fungi (*Sporormiella*) and saprophytic fungi (*Byssothecium* and *Gelasinospora*). This coincided with the maximum development of a LIA drought recorded at Lake Raraku [7], which suggests that climate could also have had a role by favoring biomass flammability and fire expansion. Archaeological evidence indicates that the ceremonial village of Orongo, situated on the SW of the Kao crater (Fig. 1) was founded by 1600 CE [20], which is consistent with an eventual permanent human occupation of the Kao catchment and the development of intensive terrace cultivation practices on the shores of the lake [11].

### 4. Preliminary conclusions

Based on the above results, some preliminary conclusions may be advanced pending further high-resolution studies. However, the main trends of deforestation and landscape shift are not expected to undergo significant changes.

- During the last millennium (~960 CE onwards), the Lake Kao catchment was progressively deforested, with the total disappearance of forests by 1600 CE.
- Forest clearing was gradual but spiked with three major acceleration pulses at ~1070 CE, ~1410 CE and ~1600 CE.
- Forest regeneration was observed after the ~1070 CE pulse and, to a minor extent, after the ~1410 CE acceleration.
- Using the pollen percentage as a proxy for forest cover, the general deforestation trend progressed at a rate of -10 forest pollen %/century, whereas accelerations occurred at rates of -30 to -50 %/century.
- Both climatic (drought) and anthropogenic (mostly fire) drivers, as well as their coupled action, seem to have had a role in the acceleration of forest clearance.
- Total deforestation coincided with the permanent human settlement of the lake catchment, coinciding with the foundation of the ceremonial village of Orongo, around 1600 CE.

### 5. Discussion

The Kao deforestation timing and rates were different from those observed in Lake Raraku and the Aroi marsh (Table 2), confirming that forest clearing was heterogeneous in time and space across the island, contradicting the earlier hypothesis of a single, abrupt and island-wide event. The Kao deforestation timing is also consistent with the hypothesis of intra-island population migration and reorganization as a consequence of the coupled action of the LIA drought and anthropogenic deforestation [3]. According to archaeological evidence, Lake Raraku and its surroundings was the center of the ancient Rapanui civilization, based on the cult of the megalithic anthropomorphic statues known as moai, which were
carved from the tuff that forms the Raraku crater. At some point, a cultural revolution took place and the main center of Rapanui moved to Orongo, on the edge of the Kao crater. This then became the center of a new cult (the Birdman cult) involving a profound social, religious and political reorganization [20]. The earlier date proposed for this cultural shift is 1600 CE, when Orongo was founded. According to the intra-island migration hypothesis [3, 21], the desiccation of Lake Raraku between 1570 CE and 1720 CE, together with the full forest removal of this catchment, had occurred by 1530 CE, and would have turned the site into a badland unable to support human life and the activities required for the Moai cult. By then, Lake Kao was likely the only permanent freshwater source on the island and, hence, the most suitable site to sustain human life. Therefore, a migration of the cultural center from Raraku to Kao seems a plausible explanation and is supported by the chronological coincidence between the foundation of Orongo (1600 CE), as shown by archaeological evidence [20], and the full human occupation of the Kao catchment, as documented in this paleoecological study. Further paleoecological research based on biomarkers, as indicators of climate change and human presence and activities, is in progress.
