Abstract: Although transplantation procedures have been developed for patients with end-stage hepatic insufficiency or other diseases, allograft rejection still threatens patient health and lifespan. Over the last few decades, the emergence of immunosuppressive agents, such as calcineurin inhibitors (CNIs) and mammalian target of rapamycin (mTOR) inhibitors, has strikingly increased graft survival. Unfortunately, immunosuppressive agent-related neurotoxicity is commonly occurred in clinical situations, with the majority of neurotoxicity cases caused by CNIs. The possible mechanisms whereby CNIs cause neurotoxicity include: increasing the permeability or injury of the blood-brain barrier, alterations of mitochondrial function, and alterations in electrophysiological state. Other immunosuppressants can also induce neuropsychiatric complications. For example, mTOR inhibitors induce seizures; mycophenolate mofetil induces depression and headache; methotrexate affects the central nervous system; mouse monoclonal immunoglobulin G2 antibody against cluster of differentiation 3 also induces headache; and patients using corticosteroids usually experience cognitive alteration. Therapeutic drug monitoring, individual therapy based on pharmacogenetics, and early recognition of symptoms have greatly reduced neurotoxic events. Once neurotoxicity occurs, a reduction in the drug dosage, switching to other immunosuppressants, using drugs to treat the neuropsychiatric manifestation, or blood purification therapy have proven to be effective against neurotoxicity. In this review, we summarize the recent topics on the mechanisms of neurotoxicity of immunosuppressive drugs. In addition, some information about neuroprotective effects of several immunosuppressants are also discussed.

Keywords: alloimmune response; immunosuppressants; calcineurin inhibitors; corticosteroids; mTOR inhibitors; neuro toxicity; neuroprotective effects

1. Introduction

The first kidney transplant, performed by Murray et al. in 1954 [1], heralded a new age for patients with terminal hepatic insufficiency, end-stage renal diseases, and other severe diseases. However, the one-year survival rate of transplant patients was only 35% in the 1960s and 1970s and did not significantly increase until the development of ciclosporin A (cyclosporine, CsA) and tacrolimus (FK506) [2]. Strikingly, the rapid development of drugs to induce and maintain immunosuppression, such as antibodies and anti-metabolic drugs, has helped to increase graft and one-year patient survival to more than 90% in recent years [3]. Based on pharmacological mechanisms, immunosuppressive agents can be divided into six categories, including calcineurin inhibitors (CNIs), mammalian target of rapamycin (mTOR) inhibitors, cell cycle inhibitors, corticosteroids, monoclonal and polyclonal antibodies, and other newly developed drugs [4].

Although many benefits have been realized, postoperative complications remain unsolved and they influence the quality of life and long-term survival rates of transplant patients [5]. Among all of the postoperative complications, neurological problems are frequent, both in the immediate operation period and for many years after transplantation and they are associated with a poor
prognosis and significant morbidity [6,7]. For example, van de Beek and colleagues [8] reported that
the rate of perioperative neurological complications were associated with one-year mortality and
rose from 19% to 30% in the past 10 years in a retrospective cohort study. Furthermore, the risk of
neurological complications was shown to be 81% in patients over 18 years. Common complications
seen with all types of transplantation include alterations of consciousness, seizures, encephalopathy,
and cerebrovascular events [9-12]. The etiologies of neurological complications are diverse,
including immunosuppressant-related neurotoxicity [13,14], infections [15], metabolic disorders,
hemorrhage [9], and primitive disease prior to the transplant. Neurotoxicity induced by
immunosuppressive agents has remained as a severe problem in the clinical situations because of
worsening the patients’ quality of life. For example, CNIs may induce mild symptoms, such as
tremor or severe symptoms, such as seizures, central pontine myelinolysis (CPM), and cortical
blindness. Treatment with mouse monoclonal immunoglobulin G2 antibody to cluster of
differentiation 3 (muromonab-CD3, trade name: Orthoclone OKT3®) is associated with headache
and aseptic meningitis. These clinical features and risk factors are well understood, however, the
specific mechanisms of immunosuppressant-related neurotoxicity and its predictive factors are still
obscure.

Over the last few decades, several attempts have been made to shed light on the pathogenesis of
immunosuppressant-related neurotoxicity and to recognize the heralding symptoms. In this article,
we focus on the clinical features, risk factors, pathological mechanisms, and management of
neurotoxicity induced by immunosuppressive agents.

2. The alloimmune response

Once cells or tissues or an organ are transplanted between a donor and a genetically
non-identical recipient (allograft transplantation), many cells, including T cells, B cells, and
macrophages are activated and participate in immune events that can initiate an alloimmune
response, and finally, induce allograft rejection. As shown in Figure 1a, allorecognition is initiated by
two pathways: 1) activated T cells with direct alloreactivity interact with major histocompatibility
complex (MHC) molecule-peptide complexes on donor antigen presenting cells (APCs) and induce
donor cell apoptosis through cellular rejection [16] and 2) donor peptides bound to self-derived
MHC molecule peptide complexes processing by recipient APCs are recognized by recipient T cells
and then cause allograft destruction [17].
Figure 1. T cells, B cells, and macrophages initiate alloimmune responses and induce allograft rejection after transplantation. (a) Allorecognition can be initiated by direct or indirect pathways; (b) Three signals participate in the activation of T cells; (c) Two signal processes are involved in the activation of B cells. APC, antigen-presenting cell; BCR, B-cell receptor; DSA, donor specific antibody; IKK, inhibitor of NF-κB kinase; IL-2, interleukin-2; NO, nitric oxide; MAP, mitogen-activated protein; MHC, major histocompatibility complex; PI-3K, phosphatidylinositol 3-kinase; TCR, T-cell receptor; Tfh, T follicular helper; TNF-α, tumour necrosis factor alpha.

2.1. T-cell activation

T cells can be activated by three types of signals (Figure 1b). Firstly, the T-cell receptor-CD3 (TCR-CD3) complex on CD4+ T cells, which delivers cognate antigens and forms T-cell receptor-major histocompatibility-allopeptide complexes that activate a series of biochemical reactions. Secondly, T cells that have received an initial signal activation are activated by the interaction between CD80 or CD86 on APCs and CD28 molecule on T cells, finally generating a co-stimulatory signal, thereby initiating immunological activation. Several signalling pathways, including the calcineurin pathway, the Ras/mitogen activated protein (MAP) kinase pathway, and the nuclear factor kappa B (NFκB), inhibitor of NFκB kinase (IKK) pathway have been reported to participate in these two activation processes. The third type of activation signal involves the binding of interleukin-2 (IL-2) with the gamma chain of its receptor to initiate T cell proliferation, DNA synthesis, and cell division through the activation of mTOR pathways [18].

2.2. B-cell activation

Two signal processes account for the activation of B cells [19], as described in detail in Figure 1c. The first activation signal occurs when macrophages in the subcapsular sinus capture the cognate antigens and then these antigens on macrophages bind with the surface B cell receptors (BCRs) of naïve B cells, forming an immunological synapse [20]. Signaling BCR microclusters are involved in
the process of moving antigens into endosomal compartments of B cells and the expression of a series of factors that play an important role in regulating downstream signaling pathways, including calcineurin and mTOR pathways [19,21]. The antigens are then processed enzymatically, internalized, and ultimately selected to present on the surface of the B cell associated with MHC II molecules [22].

Naive B cells are activated with the help of follicular helper T (Tfh) cells, which initiate cell co-stimulation interactions that produce cytokines [23-25]. The activated B cells migrate into the germinal center where some of them differentiate into memory B cells or plasmablasts. Plasmablasts further differentiate into long-lived plasma cells on bone marrow, which can secrete high-affinity donor-specific antibodies that participate in antibody-mediated rejection [26,27].

3. Classification of immunosuppressants

The functions of T and B lymphocytes in the process of rejection have become gradually understood and the immunosuppressive regime has been optimized as a result of many experimental and clinical studies. Immunosuppressants are classified according to their mechanisms of action, as shown in Table 1 [3,4,18,28-34]. CNIs inhibit the activity of a calcium-dependent phosphatase named calcineurin, thereby impeding the transduction of nuclear factor of activated T cells (NFAT) and the production of cytokines, such as IL-2, tumour necrosis factor-alpha (TNF-α), and interferon-gamma (IFN-γ). mTOR inhibitors suppress the translation of mRNA-encoding proteins, T cell proliferation, and cytokine production. Antimetabolites inhibit the synthesis of purine by diverse mechanisms, such as inhibiting inosine-5′-monophosphate dehydrogenase (IMPDH) or incorporating into newly synthesized DNA to block purine synthesis enzymes. Corticosteroids, in combination with CNIs and antimetabolites, are used as the cornerstones of immunosuppressive regimens. Their immunosuppressive mechanism is diverse and may relate to interference with intracellular transcription factors and the signalling pathways of several surface receptors. Monoclonal and polyclonal antibodies may interact with cell surface antigens, such as CD3, CD20, and CD25. Immunosuppressants currently being developed include antibodies, FK778, janus kinase (JAK) inhibitors, fingolimod, and blinatumomab. Among these immunosuppressive agents, those that can cause neuropsychiatric complications are CNIs; mTOR inhibitors; mycophenolate mofetil; corticosteroids; and some monoclonal antibodies, such as OKT3, belatacept, and blinatumomab.

Usage in induction and acute rejection treatment is still under study; has similar immunosuppressive effect compared to ATG, but less side effects. Pre-treatment of diphenhydramine and acetaminophen can decrease side effects. The usage for immunosuppressants has been only reported in case reports and observational studies, has limited efficacy and high cost.

4. Clinical features induced by different immunosuppressants

4.1. CNIs

Neurotoxicity induced by CNIs occurs at three distinct time points after transplantation: early, intermediate, and late. Most patients who use tacrolimus intravenously develop neurotoxicity on the first day after transplantation [35]. Patients who develop neurotoxicity in the intermediate or late stage demonstrate only short or intermediate survival times [36].

The neurological complications of CNIs are various and can involve both the central nervous system (CNS) and the peripheral nervous system [37]. Mild neurological manifestations related to CNI toxicity are common and include tremor, insomnia, nightmares, sleep disturbances, headache, vertigo, mood disturbance, and paraesthesia (e.g. electric shock–like pain and severe itching) [38,39]. Serious adverse neurological effects have been relatively rarely observed and include seizures, speech disorders, cortical blindness, coma, encephalopathy, central pontine/extrapontine myelinolysis, and neuromuscular complications [14]. Tacrolimus treatment has a significantly higher incidence of neurological syndromes than CsA treatment in solid organ transplantation recipients [40,41].

Tremor is the most pronounced neurological complication associated with CNI toxicity and a fine tremor of the upper limbs can help diagnose neurological complications at early stages [13]. Tremor is significantly more common in patients treated with tacrolimus than those treated with CsA. In a more recent trial, less than 20% of patients treated with CsA experienced tremors, while tacrolimus-related neurotoxic events occurred in up to 40% of patients [42]. In general, tremors involved both upper and lower limbs, with some patients even experiencing tremors in the head/facial muscles. Tremors exclusively involving the trunk, lower limbs, or the craniofacial area are rare in the clinic [42]. Considering that the main goal of immunosuppressive therapy is to increase the survival rates of transplant recipients and tremors appear to be isolated, with cerebellar or neuropathic involvement, this symptom tends to be ignored when its severity is not significant and does not influence the patient’s quality of life.

Seizures are common in transplant recipients undergoing CNI therapy, occurring in up to 27% of organ transplant patients [43]. Although seizures frequently occur with posterior reversible encephalopathy syndrome (PRES), new onset of seizures are not indicative of a poor prognosis, because most patients do well and do not require long-term antiepileptic therapy [44]. In patients with seizures, generalized tonic-clonic type and occipital lobe seizures are usually observed [45]. Simple or complex partial seizures represent a localized process that may be reflected by focal electro-encephalogram (EEG) abnormalities, whereas seizures that occur secondary to PRES frequently show short single grand mal episodes with variable theta/delta slowing [44]. Seizures associated with CNI neurotoxicity frequently originate from occipital regions [46]. PRES is a serious complication associated with immunosuppressive therapy after transplantation [47]. It is a neurotoxicity characterized by headache; confusion; nausea and vomiting; altered mental status; visual disturbances; intracranial haemorrhage; altered sensorium; and occasionally, focal neurological deficit [45,48-51]. In most cases, immunosuppression-associated leukoencephalopathy occurs within the first three months after transplantation and it is usually associated with intravenous treatment methods [52]. PRES appears to be significantly more common in hematopoietic or liver transplantation than other transplantations [53].

Cranial computed tomography (CT) finding is insensitive to detect PRES and often shows no abnormalities, while magnetic resonance imaging (MRI) has been proven to be most sensitive imaging test. Vasogenic oedema, which is a symptom of PRES, can be easily identified. Radiologists can reliably differentiate these changes from cytotoxic oedema using diffusion weighted image (DWI) and apparent diffusion coefficient (ADC) maps. Moreover, the extent of abnormal T2-weighted signal intensities and DWI signal intensities correlate well with prognosis [47]. PRES predominantly affects the posterior cerebrum and the cerebral white matter, causing focal reversible vasogenic oedematous changes in specific posterior regions of the parietal and occipital lobes, which
can lead to irreversible cytotoxic oedema in some cases [44,54]. Grey and white matter lesions can be observed by MRI on fluid attenuated IR (FLAIR) and T2-weighted sequences, and deeper structures such as the basal ganglia, brain stem, and deep white matter tracts may be also affected [44,55]. Cytotoxic oedema and haemorrhage are uncommon findings in these patients [44]. Typically, the characteristic of PRES is bilateral symmetric patterns of oedema, usually including diffuse white matter hyperintensity with a parieto-occipital predilection [56,57]. If PRES is not diagnosed at an early stage, cerebral ischaemia and massive infarction may result in an increase in morbidity and mortality [47]. Hypertension is another important symptom of PRES and therefore, when immunosuppressants need to be continued in the clinic, blood pressure should be effectively monitored and controlled.

CPM is one of the most detrimental neurological complications after organ transplantation and the mortality due to this neurotoxicity is more than 50% [58]. The incidence of CPM is more common in liver transplantation and in patients treated with CsA than in those treated with tacrolimus [59-61]. MRI features include hyperintense lesions in the centre of the pons on T2 images. Rapamycin is recommended as a replace for CNIs, because it is rarely associated with CPM. However, rapamycin is unstable and requires frequent monitoring of blood concentrations when used in clinical practice.

The number of case reports related to catatonic symptoms and akinetic mutism induced by CNI administration after organ transplantation has increased in recent years [62,63]. Even when used to treat psoriasis, CNIs have been shown to exacerbate the symptoms of paranoid schizophrenia, then disappear a few days after the discontinuation of CNI treatment [64].

In addition to CNIs, other immunosuppressants may also manifest neuropsychiatric complications, although neurotoxicity reports are rarer for these drugs than for CNIs [37]. Mycophenolate mofetil rarely induces depression and headache, but seizures were frequently observed in several reports concerning neurological complications during rapamycin therapy. The main neurological complication of muromonab-CD3 treatment is headache, whereas patients treated with corticosteroids may experience anxiety, insomnia, mood disorders, psychotic episodes, and cognitive symptoms [65,66].

4.2. Antimetabolites

Methotrexate (MTX) can induce CNS toxicity that presents in the form of encephalopathy, myelopathy, or meningitis [67]. Neurological symptoms are caused by MTX are usually classified into acute, subacute, or chronic neurotoxicity. Patients who experience subacute neurotoxicity usually recover completely and spontaneously within a week and therefore, subsequent MTX treatment is safe for most patients [68]. Neurological symptoms induced by mycophenolate mofetil are rare and mild, manifesting as depression and headache.

4.3. Corticosteroids

Neurological side effects occur in approximately 3–4% of patients who use corticosteroids [69]. Corticosteroid-induced neuropsychiatric symptoms include mood changes, behavioural disorders, and cognitive symptoms that typically manifest during the first few weeks of therapy [66]. Peripheral toxicity occurs after long-term use, usually in the form of neuromyopathy, with muscular weakness, affecting the proximal and lower extremities [70]. Steroid dementia syndrome appears to be rare [71] and these symptoms may not recover completely even after the cessation of treatment [72]. Epidural lipomatosis can also induce radiculopathy due to spinal compression [73].

To improve neurological symptoms, adjustment or discontinuation of corticosteroids may improve some of these adverse effects. If the psychiatric symptoms are serious, short regimens of low-dose psychotropic agents are often required (e.g. haloperidol, olanzapine, quetiapine, or risperidone).

4.4. Monoclonal antibodies
Polyclonal and monoclonal antibodies are usually used to induce immunosuppression and the treat of graft rejection [72]. With the exception of OKT3 and belatacept, biologic agents show low incidences of adverse neurological effects. The neurotoxicities induced by OKT3 range from headache and fever to confusion, aseptic meningitis, cerebral oedema, encephalopathy, seizures, hemiparesis, nuchal rigidity, and myoclonic activity [37,74]. Furthermore, treatment with CsA after OKT3 results in an additive or synergistic adverse effect on neurological complications [75]. In general, pathological changes can be detected by a head MRI and neurological abnormalities resolve after the cessation of OKT3 treatment [75,76]. However, cytokine release syndrome in patients treated with OKT3 is so serious that it limits the usage of this agent. Blinatumomab, a novel recombinant murine protein, is used for the treatment of Philadelphia chromosome-negative, relapsed or refractory precursor acute lymphoblastic leukaemia. There are a variety of neurological symptoms induced by blinatumomab treatment, such as somnolence, confusion, dizziness, tremor, seizure, encephalopathy, speech disorders, and loss of consciousness, which appear to be more common in patients over 65 years of age [77].

Conditions that increase the neurotoxicity of immunosuppressant agents include pre-existing mental disorders [78]; hypertension [79]; electrolyte disorders, including hyper- and hypotremia and hypomagnesemia [37]; dysmetabolic alterations, such as hyperglycaemia [37]; infections that impair the function of the blood-brain barrier (BBB); hypocholesterolaemia, which increases the uptake of immunosuppressant drugs in the brain [80]; polymorphisms of the ATP-binding cassette transporter B1 (ABCB1) gene and cytochrome pigment (CYP) gene, which decrease immunosuppressant efflux or elimination [81,82]; drug interactions [82,83]; a prolonged surgical period [84]; and low liver function or acute liver failure [85].

5. Mechanisms of neurotoxicity induced by different immunosuppressants

5.1 CNIs

The biochemical basis of CNI-induced neurotoxicity remains unclear. It appears that high blood concentrations of the drugs are correlated with neurological symptoms, but they can also occur in patients with concentrations within the therapeutic range [13,14,86]. Although both CNIs are used as immunosuppressants are lipophilic, with CsA being more lipophilic than tacrolimus, they do not easily pass through the BBB [87,88]. One possible hypothesis is that tacrolimus and CsA increase the permeability of the BBB by inducing apoptosis and nitric oxide (NO) production and inhibiting P-glycoprotein (P-gp) function, which leads to further accumulation of drugs in the brain, extravasation of proteins and fluid into the interstitium, and impaired BBB function. An investigation of the effects of tacrolimus and CsA on mouse brain capillary endothelial cells (MBEC4) found that drug-treated cells experienced 1) loss of junctions with neighbouring cells and detachment from the substratum, 2) chromatin condensation and fragmentation, and 3) DNA fragmentation [89]. The two drugs induced dose-independent apoptosis of the brain capillary endothelial cells, with similar effects between CsA and tacrolimus [89]. Dohgu et al. [90] reported that CsA increases NO production in brain endothelial and astroglial cells, which then participates in the impairment of BBB function. The expression of P-glycoprotein decreases with high concentrations of CNIs, leading to inhibition of the efflux process and enhancement of permeability. This may partly explain the mechanism of CNI-induced encephalopathy [91]. It should be mentioned that the drug concentrations in above studies were quite high compared to clinical doses and further investigation is required to determine whether normal brain capillary endothelial cells are impaired. In fact, a recent study using an in vitro BBB model, consisting of a co-culture of bovine brain capillary endothelial cells (ECs) and neonatal rat glial cells, showed that repeated exposure to 1 μM CsA, found in human plasma, had no toxic effect on BBB integrity [92]. This result was confirmed by a kinetics study, in which intracellular CsA uptake and permeability across the BBB were minimal [93]. It is also important to stress that, despite no cell damage, some key neurotransmitters, factors metabolically linked to neurotransmitters, or energy metabolism related
An alternative hypothesis is that alterations in mitochondrial function induced by CNIs contribute to neurotoxicity. A study in human umbilical endothelial cells showed that tacrolimus significantly compromised respiratory chain (RC)-complexes II and III and the mitochondrial marker enzyme, citrate synthase (CS), thus indicating partially impaired mitochondrial function [95]. Furthermore, a similar analysis found that tacrolimus decreases oxygen consumption in human cell lines and causes a slight reduction in the synthesis of mitochondrial DNA-encoded proteins [96]. These studies suggest that the direct inhibition of the electron transport chain by CNIs, rather than effects on mitochondrial density or electron transport chain (ETC) quantity, are responsible for impaired mitochondrial function. This conclusion is contrary to an early study reporting that tacrolimus inhibits both complex III, where reactive oxygen species (ROS) are generated and complex V, where adenosine triphosphate (ATP) is depleted by ATPase activation [97]. Two studies in glioma cells and glial cells demonstrated that tacrolimus can increase the production of ROS and decrease antioxidant status [98,99], indicating that mitochondrial function may be impaired by tacrolimus treatment.

There is also evidence that the complex of CNIs and immunophilins may be associated with neurotoxicity. Calcineurin is expressed in several areas of the brain, including the cerebral cortex, striatum, substantia nigra, cerebellum, and hippocampus, where it regulates the dephosphorylation of Ca2+ channels, the activity of the N-methyl-D-aspartate (NMDA) receptor, the ryanodine receptor, and the inositol trisphosphate (IP3) receptor and even memory and synaptic plasticity [100-102]. These neurotoxic effects may depend on immune dysregulation in the nervous system, due to the pharmacologic effects of the CNI-immunophilin complex [91,103,104]. The maximal inhibitory effect of tacrolimus on calcineurin is approximately 60% (while CsA is more effective at inhibiting calcineurin) [105], but tacrolimus has no pharmacological effect in FK506-binding protein (FKBP) 1A (FKBP12)-null mice [106]. These findings suggest that the FK506-FKBP complex has some unknown molecular mechanisms besides its calcineurin inhibitory effect. It is noteworthy that the level of FKBP12 expression is 10–50-fold higher in the brain than in the immune system [107,108]. Tacrolimus-induced toxicity is consistent in organs with high FKBP levels, such as the brain and kidneys. Moreover, once tacrolimus enters the brain, it is eliminated slowly by binding to FKBP [109]. In an in vitro model, CsA inhibits calcineurin in the brain, even at concentrations as low as 200 nM, in a relatively short time frame and this inhibitory effect is sustained during drug administration [93]. With the exception of calcineurin inhibition by the tacrolimus-FKBP complex, the exact mechanism of neurotoxicity is not completely elucidated. Research on calcineurin inhibition-induced depressive-like behaviour in a prefrontal cortex model raises the possibility that blockade of the mTOR signaling pathway accounts for the neurologic disorders [110]. In support of this, another study showed that receptor-associated FKBP12 participated in the intracellular mTOR activation pathway, which is well known for its critical roles in the integration of neuronal activity and synaptic inputs in multiple physiological and pathological processes [111,112]. These experimental findings are in agreement with a clinical study showing that tacrolimus induces a higher incidence of neurotoxicity than CsA [113,114].

Vasoconstriction or vascular injury [115] may also be involved in the mechanism of CNI-induced neurotoxicity. Tacrolimus may be associated with the blood vessel contraction. Moreover, some investigators have suggested that, in addition to vasoconstriction caused by tacrolimus, the high infiltration pressure of the tacrolimus dissolution liquid may also affect neurotoxicity. However, although this hypothesis is interesting, it does not explain the phenomenon where patients experience CNI-induced neurologic disorders, even though their blood pressure is maintained within the normal range throughout hospitalization [63,116].

Other proposed mechanisms of CNI-induced neurotoxicity include a possible modulation of excitability properties, causing nerve membrane depolarization [117] and alterations in electrical activity [94,118]; suppression of brain-derived neurotrophic factor (BDNF) and its receptor, tyrosine...
kinase receptor B (TrkB), mRNA and protein expression in the hippocampus and midbrain [119]; and significant intracellular CNI uptake, thus increasing the toxicity of other drugs administered at the same time [93]. Metabolites of CNIs may also be neurotoxic, even though they are usually not assessed in clinical practice.

### 5.2 Antimetabolites

Several biochemical pathways including a decreased S-adenosylmethionine/S-Adenosylhomocysteine (SAM/SAH) ratio, elevated levels of homocysteine, and elevated levels of adenosine and direct toxic effects on neurons and astrocytes may be the causes of MTX-related neurotoxicity [68].

### 5.3 Corticosteroids

Corticosteroids are often used in combination with other immunosuppressive agents. They cause neurological complications through two mechanisms that involve direct and indirect toxic effects on CNS biochemistry and electrophysiology. These include glutamate excess and neurotoxic effects on neurons and astrocytes may be the causes of MTX-related neurotoxicity.

### 5.4 Monoclonal antibodies

The mechanisms of muromonab-CD3- and belatacept-related neurotoxicity have rarely been reported. It has been postulated that cerebral complications are related to the OKT3-mediated release of cytokines [75]. This hypothesis may explain the cases of aseptic meningitis, but it cannot explain why neurological symptoms persist after cytokine levels return to baseline. Other studies have suggested that circulating lymphocytes and cells of the nervous system share some of the same surface antigens, such that OKT3 combines with cell surface antigens to facilitate OKT3 antibodies crossing the BBB [76]. Cytokine release syndrome induced by blinatumomab may be responsible for some of the adverse neurological effects, but further studies are warranted to clarify the precise mechanism of blinatumomab-induced neurotoxicity [77].

### 6. Management

Immunosuppressants, particularly CNIs, can induce neurotoxicity in solid organ transplantation cases. The management of blood concentrations of the drugs by therapeutic drug monitoring, individual therapy based on pharmacogenetics, and the early recognition of symptoms using electrophysiological and imaging strategies, may help avoid neurotoxicity [82,121,122]. However, even with these measures in place, the incidence of neurotoxic symptoms remains high (3–32 %) [79,123,124]. Once neurotoxicity occurs, reducing in the drug’s dosage, switching from tacrolimus to CsA or vice versa, or using an alternative immunosuppressant agent, such as mycophenolate mofetil, have proven to be effective approaches to reverse this neurotoxicity [63,125,126]. A study comparing the effects of tacrolimus and rapamycin on bioelectrical activity and evoked field excitatory postsynaptic potential (fEPSP) in the CA1 area of hippocampal tissues has also suggested that rapamycin could replace to CNIs in the event of seizures [127]. However, in some cases, switching between tacrolimus and CsA has not been effective at improving neurotoxicity. Moreover, considering that switching immunosuppressants may elevate the risk of graft rejection in some patients and reducing the CNI dosage does not always improve the symptoms, continued administration of CNIs in combination with drugs that treat the neuropsychiatric manifestations may be the best approach. For example, olanzapine coupled with the continued use of tacrolimus has been shown to resolve manic episodes [128]. Olanzapine has also been considered for the treatment of catatonic mutism after liver transplantation [129]. Benzodiazepines can improve catatonia, especially akinetic–hypokinetic catatonic syndromes [40,130]. The neurotoxicity associated with CNIs is strongly correlated with the intracerebral...
concentration of the drugs [131]. Sakamoto et al. showed that continuous administration of tacrolimus is more advantageous than intermittent administration to reduce neurotoxicity in rats [132]. In addition, tacrolimus-induced neurotoxicity and nephrotoxicity can be ameliorated, while maintaining its immunosuppressive effects, by treating rats in the dark phase [133]. According to a case report, red-blood cell exchange improved the clinical status of a 60-year-old woman with severe neurological impairment due to tacrolimus overexposure. Hence, red-blood cell exchange may be an effective therapy to reduce tacrolimus neurotoxicity [134]. This blood purification therapy has also been shown to be effective in ifosfamide-induced severe concurrent neurotoxicity and nephrotoxicity [135].

7. Neuroprotective effects

7.1 CNIs

The immunosuppressants, tacrolimus and CsA, have neuroprotective effects in animal models of focal and global cerebral ischemia [136-138], portacaval anastomosis and hyperammonaemia [139], intracerebroventricular streptozotocin-induced neurotoxicity [140], and temporal lobe epilepsy (the turnover of tacrolimus is much faster in rats than in humans) [141].

When wild-type mice are treated with tacrolimus for one week, their neocortices show longer total dendritic arbors and more complex branching further away from the cell body, compared to untreated animals [142]. There is some experimental data to indicate that the neuroprotective effects induced by tacrolimus and CsA may be related to calcineurin inhibition; NFκB activation [143]; downregulation of proinflammatory/cytotoxic cytokines [144]; decreased NO synthetase-mediated NO production [136,139,145]; inhibition of Ca2+ release by the endoplasmic reticulum (ER) (tacrolimus) [146]; inhibition of Ca2+ release by both the ER and mitochondria, as well as mitochondrial permeability transition (mPT) (CsA) [147]; deceased apoptosis and c-jun protein expression in neurons[148]; calcineurin-independent mechanisms [149]; activation of pro-survival pathways by BDNF and its receptor, tropomyosin receptor kinase A (TrkA) [150]; and excitotoxic neuronal death [151].

However, although the neuroprotective functions of tacrolimus have been demonstrated in various nerve injury models, this has been challenged by models of inherited peripheral myelinopathies treated with tacrolimus. For example, tacrolimus exacerbates neurological abnormalities, including demyelination and dysmyelination-associated axon loss in inherited de/dysmyelination mice, while the peripheral nerves of wild-type mice do not show any neurotoxic symptoms after treatment with tacrolimus [152].

Interestingly, a recent study found that tacrolimus and CsA treatment had no better long-term effects than treatment with vehicle alone (cremophor and ethanol mixture). Moreover, the drug-treated group showed even more significant decreases in brain weight. Therefore, Setkowicz and Guzik [153] concluded that the neuroprotective effects observed in rat brains injured mechanically at early developmental stages may result from the influence of the vehicle alone. Further studies and more investigations are needed to clarify the potential neuroprotective effects and mechanism of CNIs.

7.2 mTOR inhibitors

mTOR is associated with the pathogenesis of neurological, cognitive, and psychiatric disorders, such as epilepsy, stroke, traumatic brain injury, parkinsonism, spinal cord injury, and Alzheimer’s disease [154]. In a mouse model of epilepsy induced by knocking-out the protein phosphatase and tensin homolog (PTEN), mTOR activity increases in neurons. Therefore, reducing mTOR activity may effectively suppress epileptogenesis and alleviate this disease [155]. The role of mTOR in cerebral ischemia has also been reported in some rodent experiments. Some studies have shown that mTOR pathway has neurotoxic effects, while others have reported the opposite finding that the
mTOR pathway has neuroprotective effects. Some reports have suggested that suppressing the pharmacological effects of the mTOR pathway can regulate autophagy and result in neuroprotection, whereas other reports have suggested that the neurotoxicity of mTOR inhibitors is related to the promotion of autophagic processes, long-term activation of Akt, and activation of S6 kinase 1 (S6K1) occurring in brain cells after a stroke [154,156-158]. The study by Chen and co-workers [159] may explain the paradoxical effects of the mTOR inhibitor, rapamycin. In that study, rapamycin was shown to cause a paradoxical, but transient, increase in mTOR pathway activation in a kainite injection model and in normal rats, by increasing the phosphorylation of S6. These results suggest that the effects of rapamycin on mTOR are related to the type or period of stimuli and the dose administered [160].

8. Conclusions

Neurological disorders are common after solid organ transplantation. The reasons for these neurotoxicities are multifactorial, ranging from the effects of immunosuppressive agents to pre-transplantation disease. In this article, we mainly discuss the neurological complications resulting from immunosuppressive therapy in five topics, including the process of alloimmune responses, the classification of immunosuppressive agents, their clinical features, their mechanisms, and their clinical management. Interestingly, some studies have also shown that these immunosuppressive agents may have neuroprotective effects. However, two recent studies have reported contradictory findings, suggesting that further studies are required to clarify these potential neuroprotective effects of immunosuppressive agents.
