*The physics of the human brain has two components – basic physics common to all mammals and the physics of thinking inherent only in man. The development of the mental component of the structural and functional organization of the brain in phylogeny was associated with the chiral factor of the external environment, and in ontogenesis - with the social factor. The sensitivity of the brain to these factors was based on the single-connected nature of its aqueous basis, the mechanism of electromagnetic induction, and the features of the thermodynamics of the brain in a state of night sleep. In order to unify the description of the mechanism of electromagnetic processes in the brain, the concept of a quasiphoton has been introduced, combining all forms of excitation of electronic and molecular-cellular structures of the brain. Equivalent schemes of vibrational contours of neural network elements and macrostructures of the brain are proposed. Estimates of the kinetic parameters (activation energy, velocity) of the physical processes underlying the energy-information exchange of the brain with the external environment are made. Mechanisms of operative (physical) and permanent (chemical) memory of the brain, including a model of nonlocal quantum correlations, are discussed.*

## 1. Conceptual introduction

The main structural and functional element of the brain is the nerve cell. It generates and conducts electrical impulses - action potentials (PD). The motion of charge associated with the PD induces local vortices of the electromagnetic (EM) field, which, in principle, can be defined as EM quanta or quasiphotons (QPH). The metric, the principle and the speed of motion of a QPH will be determined by the electrophysical properties and structural features of the neuron and its surrounding medium. For energy-information support of the mechanism of pulse generation and for the synthesis of metabolites, the cell body, its core and dendrites are responsible. Axons in symbiosis with neuroglia (oligodendrocytes, astrocytes) translate metabolites and impulses, realizing their energy and information through the synthesis and actions of neurotransmitters in synapses. The ability of the nerve cell to provide energy for the reaction of oxidation of glucose, which in the mitochondria is transformed into energy of macroergic bonds of ATP. In neural cells, the energy of ATP is converted into the energy of QPH, into the energy of the chemical bonds of the synthesized substances, into the kinetic energy of metabolites and molecules of the medium

(heat). At the expense of the same energy, axons grow, the development of neural networks and neuroglial connections, which, in particular, are responsible for the mechanical integrity of the cytoskeleton of the brain. The physicochemical properties of water, which form the basis of liquid brain systems (cerebrospinal fluid, blood), are fully responsible for the electrophysics of the brain and for its thermodynamic properties, both at the micro and macro levels of its organization.

Thus, the behavior of the brain as a single physical system is primarily subordinated to the classical laws of electrophysics and the thermodynamics of continuous colloidal media. Within the framework of these laws, the neuron metabolism is carried out, and the brain fulfills its basic functions, controlling homeostasis and timely launching the mechanism of sexual reproduction. The corresponding physics of the brain will be the same for all mammals, so it can be considered the base. This is what allows us to extrapolate the results of animal studies on the human brain. However, only the hominid organism (*homo erectus*) acquired sensitivity to the factor of phylogenesis of geocosmic scale [1], under the influence of which the structures responsible for speech and thinking began to form and develop in the brain in the conditions of the social environment. Anatomical differences in the brain of modern man and monkey are clearly expressed in the structure and volume of the frontal-temporal lobes of the neocortex. A key role in the physics of thinking is played by the structural and functional asymmetry of the cerebral hemispheres, which is absent in animals and has a racial-sexual differentiation in man. The genesis of this asymmetry could be determined by the restructuring of the physics of genital organs, hands, eyesight and hearing at the stage of erectness and in the process of developing skills to conscious labor. Proceeding from these data, the cognitive functions of the brain will be based on the physics of the frontal-temporal lobes of the neocortex and the chirality of the communication of the brain, both interhemispheric and somatic, and with the external medium.

Given the presence in the brain of metastable and dynamic QPHs of various types and energies, one can assume their active participation not only in metabolism, but also in the physics of cognitive functions within the framework of the laws of classical quantum mechanics. The nature of the external universal chiral factor, like the nature of the chiral energy quanta in the brain, need not necessarily coincide with the nature of the QPH, the metric of which, nevertheless, may be spiral. Mechanisms of absorption and actions in the brain of chiral energy quanta (eg, neutrino nature [1]) are closely related to the physics of self-organization and phase transitions in cooperative chiral systems [2, 3].

The main question of brain physics is the modeling of the mechanism of psychophysical isomorphism [4], which, in essence, summarizes the following processes in itself:

- formation of the sense-word (thoughtform) at the level of the atomic-molecular system of the EM-matrix;

- recognition and verbalization by another system of atoms of the content of the thought form.

The space-time separation of two physical systems involved in the formation and recognition of a thought-form presupposes the physical isolation of the thought-form in the form of a bound system of discrete forms of matter isomorphic to the EM-matrix of the thoughtform. The physical isolation of the thought form is a necessary condition for the adequacy of the exchange of information on the mechanism of nonlocal quantum correlations. Ideal, in this sense, the carrier of the thought form can be the simplest forms of matter, preceding the quanta of fields and elementary particles. Then the problem of harmonizing and joining the physics of thinking with the physics of the basic functions of the brain will be reduced to the problem of verbalization of the fundamental dynamic form of matter, capable of becoming a carrier of energy and information due to its movement [5]. The axiomatics of the simplest forms of matter (energy forms) were constructed [6], relying on the laws of dialectics and extrapolating the authentic positions of classical and quantum physics. The universalism of energy forms (EF) allows them to be used for the modeling of thought forms, QPH and precursors of elementary particles. Interactions of the EF with the brain material are mediated by QPH, combining the fractal-resonant principle of the effect of EF [6] with the mechanism of nonlocal quantum correlations [7].

The energy forms and their condensates, in fact, include hypothetical "strings", "quarks", "Abrikosov vortices", "density matrices" and other abstract models of subelementary discrete forms of matter. In [8], in analyzing the thermodynamics of the brain's thinking activity, the gas of hypothetical x-particles (fermions), distributed over the neural network of the cerebral cortex, was proposed as the "working body" of the thinking apparatus. If the attempt to assign x particles to a neutrino is groundless [4, 6], then certain features of the thermodynamics of x particles are acceptable for bioactive EFs and QPH.

Thus, the physics of thinking can be isolated within the framework of the physics of the basic functions of the brain, referring to it the unique ability of the brain substance under normal conditions to resonantly absorb, generate, select, combine and preserve discrete forms of matter

(energy forms and QPH), recognizing in their actions the meaning- words, mental or other mental information. To substantiate the use of energy forms and QPH for the modeling of the physics of thinking, the present work analyzed the structural and functional features of the brain and made estimates of the activation energies (EM quanta) of key physicochemical processes that provide energy-information exchange inside the brain and between the brain and the external environment to which the human body as well. The results of the analysis and estimates were used to carry out extrapolations of known physical laws to the level of physics of energy forms.

## 2. Electromagnetic induction

### 2. 1. Oscillating contour

The kinematics of EF [6] illustrates the phenomenon of electromagnetic induction (EMR), which formally obeys the first Maxwell equation [9]:

$$\text{rot}\mathbf{E} = - \partial\mathbf{B}/\partial t , \quad (1)$$

where  $\mathbf{E}$  and  $\mathbf{B}$  are mutually orthogonal vectors of the intensity of the vortex electric and magnetic fields.

With the help of (1) for a closed loop with current, an equation for the self-induction EDF ( $U$ ) is obtained:

$$U = - L (dJ/dt) = - d\Phi/dt, \quad (2)$$

where  $L$  is the loop inductance;  $J$  is the current, and  $\Phi = LJ$  is the flux linkage of the self-induction of the circuit.

Effects of EMP in various structures and media of a living organism that have their local magnetic ( $\mu$ ) and dielectric ( $\epsilon$ ) characteristics are subject to the second Maxwell equation:

$$\text{rot}\mathbf{H} = \mathbf{j} + \partial\mathbf{D}/\partial t , \quad (3)$$

where

$$\mathbf{D} = \epsilon_0\epsilon \mathbf{E} , \mathbf{B} = \mu_0\mu\mathbf{H}, \quad (4)$$

$\mathbf{j}$  is the bias current, and the electrodynamic constant of vacuum ( $\epsilon_0\mu_0$ ) and the medium are related to the propagation velocities of EM quanta in vacuum ( $C$ ) and medium ( $V$ ) by the relationships [9]:

$$C = (\epsilon_0\mu_0)^{-1/2} , V = C(\epsilon\mu)^{-1/2} = C/n \quad (5)$$

Extrapolation of the EMP phenomenon to the level of EF [6] can be illustrated by the example of an oscillatory circuit (Fig. 1).

Figure 1. Vibrational contour - a) and its transformed forms corresponding to the beginning of oscillations - b) and quarter of the period - c); d) - extrapolation of the state of the contour (c) to the level of the energy form ( $v/g$ -pair) having the momentum  $P$  and the equivalent mass  $m_g$ .

For an ideal circuit, the frequency of the harmonic electromagnetic oscillations is given by the formula:

$$\omega = (LC)^{-1/2} \quad (6)$$

Transformation of the oscillatory circuit by opening the capacitor and compressing the coil is shown in Fig. 1. The state b) corresponds to the antenna circuit, which can, in principle, receive and emit photons of the radio wave band. In this case, the vortex E and B fields fill the entire space. The transformation c) corresponds to the state of the oscillatory circuit, when the energy of the E-field is transferred to the energy of the vortex B field. The configuration of the EM field in state c) can be identified with the EF ( $v/g$ -pair [6]) by relating its momentum  $P$  or the energy of the E-field, with the current pulse before it is twisted in the coil's spiral. Accordingly, the rotational moment of the current or the associated B-field energy will correspond to the moment of the EF pulse or its equivalent mass ( $m_g$ ). With the combination of different  $v/g$ -pairs, field quanta (photons, gravitons) are collected, and when they are condensed by a number equal to Avogadro's number ( $6 \cdot 10^{23}$ ), elementary particles are formed [6].

## 2.2. Electromagnetism of the neuron

It is obvious that EMP plays an essential role in the mechanisms of generation and action of electromagnetic fields of electromagnetic nature in the human nervous system. At the heart of

its communicative and signaling functions lies the ability of nerve cells to generate and conduct electrical impulses. Electrophysics and metabolism of the nervous system and neurons are examined using ECG, EEG, MEG, NMR and positron emission tomography (PET) methods, thermoencephalography, psychopharmacology and direct probing of nerve cells by microelectrodes. Quantum magnetometers (SQUID), in principle, allow one to register the magnetic field of an individual neuron [10, 11]. The phenomena of EMR and resonance, apparently, underlie the mechanism of sensitivity of the nervous system to direct effects of external EM radiation of various ranges. The presence in the nervous system of LC-structures, in principle, allows the "adjustment" of the sensory elements of the nervous system to the frequencies of both internal and external biogenic radiations by the principle of heterodyne coupling.

To explain the electrical properties of the membrane, an equivalent circuit is used, in which the conducting channels for various ions are modeled by the source of the EMF and the ohmic resistance (R), and the insulating properties of the membrane are the capacitance (Fig. 2).

*Figure 2. Equivalent electric model of the nerve membrane: the batteries create a total membrane potential  $U$ , ion conductivity is denoted by resistances  $R$ , capacitance of the membrane is capacitor  $C$  [12].*

The parallel connection of several contours, shown in Fig. 2, simulates the neuron membrane [12]. However, for the neuron model of the central nervous system, which has a myelin sheath, the capacitive characteristics of the membrane are not sufficient. Indeed, in the spiral structure of myelin there are regular channels (notches) (Fig. 3), which, in the context of the equivalent electric model of the membrane (Fig. 2), can play the role of local inductance coils. The number of notches on one myelin fiber segment, the larger the thicker axon cylinder [13].

Figure 3. Ultrastructure of the myelin membrane of the nerve. a is a general view of the notch; b - enlarged image of notch [13].

Fig. 4. Diagram of the cytoplasmic canal (incision) (1) in the myelin sheath (2) of the axon. 3 - axoplasm [13].

The marginal structure of the myelin sheaths in the intercept region of Ranvier forms coils of spirals of paranodal loops of about 1  $\mu\text{m}$  in length, communicating with the axoplasm through special windows. If these structures are regarded as inductors (Fig. 5-7), they will play an important role in the saltatory mechanism of axon conduction.

Figure 5. An electronic photograph of the interception of Ranvier, peripheral nerve [17].

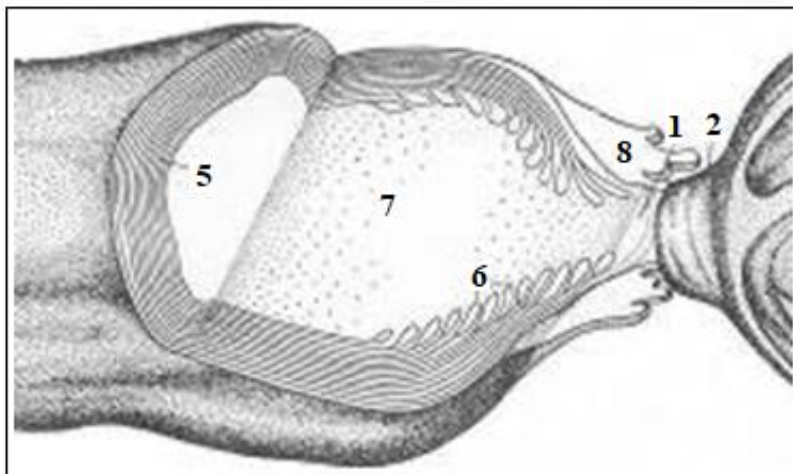

Figure 6. The scheme of the structure of the interception of Ranvier. 1 - intercept slot; 2 - the pulp cone; 5 - compact myelin; 6 - splitting of the main dense lines in the interception area; 7 - axial cylinder (axoplasma); 8 - cytoplasm of the Schwann cell [13].

Figure 7. Scheme of the edge helices of the myelin sheath loop in the Ranvier intercept region. 1 - cytoplasm; 2 - myelin; 3 - axoplasm [13].

Differences in the electrodynamic properties of the axoplasm, membrane, and intercellular fluid, due to the difference in their ionic-molecular composition and structure, must leave their imprint on the mechanism of PD generation. The stimulus that starts the charge exchange of the membrane can be both physical and chemical, and the redistribution of charges can in one way or another balance the transfer of ions through the membrane and their adsorption on its surfaces [14]. With ionic currents of charge exchange of the surface of the axon membrane, impulse displacement currents will be associated in the paranodal loops and in the scroll channels of the notches, which allows them to be likened to magnetic dipoles [9]. The kinetics of ion currents and displacement currents in the axon, membrane, and paranodal loops of the myelin sheath correlates with the kinetics of growth and subsequent relaxation of the membrane potential. Since the phase of the PD growth lasts about 0.1 - 0.2 ms, and the relaxation time of the membrane potential is of the order of 1 ms [15], then the displacement impulse currents corresponding to the phase of increase will be an order of magnitude greater than the relaxation currents. Changing the charge on the inner side of the axon membrane in the Ranvier intercept region generates a polarization wave or bias current in the paranodal region of the myelin segment [16]. The magnitude of this perturbation will decay exponentially with distance [17], and the propagation velocity will not exceed the velocity of motion of the PD in the unmyelized nerve (of the order of 1 m/s). The presence of communication windows of the paranodal loops with axoplasm [16] ensures the transformation of the polarization wave into a circular bias current in the helices of the loops.

Thus, the generation of PDs in the Ranvier interception is associated with the induction and emission of vortex EM quanta, whose metrics are simulated by EM vortices c) and c) in Fig. 1. It is possible that this is the main function of the end coils of the myelin sheaths and incision spirals. The direction of the vector of the flux density of the EM energy (the Poynting vector) will be determined by the sign of the spiral. This chirality factor of the neuron will ensure one-sided distribution of the EM-quantum, and therefore, PD on the myelinated nerve. Upon reaching the EM quantum with the velocity  $V$  (5) of the end coil of the myelin segment, it can play the role of a stimulus for the generation of PD in the next interception of Ranvier. In this model of the saltator conductivity of the neuron, the speed of the spike motion will be limited by the process of current excitation in the end coils, whose time is of the order of  $10^{-6}$  s (1  $\mu$ m: 1 m/s). At the same time, the average transfer rate of PD from one end of the myelin segment to the other at a length of about 100  $\mu$ m and will determine the rate of the saltative mechanism of conductivity  $\sim$  100 m/s.

Using the value of the potential difference corresponding to the PD of a typical neuron ( $U \sim 70$  mV [15]), we estimate the amount of electrical energy that is expended in excitation of the PD in the Ranvier interception in the saltator mechanism of neuron conduction. To do this, imagine the interception in the form of a cylindrical capacitor, the lining of which is formed from the neuron membrane and the length is equal to the length of the interception ( $f$ ). The change in the energy of the capacitor ( $W$ ) can be estimated from the formula:

$$W = (U^2 C)/2. \quad (8)$$

The value of  $C$  for a cylindrical capacitor with the distance between the plates ( $d$ ) and the radius of the inner cylinder ( $R$ ) under the condition  $d \ll R$  is equal to

$$C = (2\pi\epsilon_0\epsilon f)/[\ln(1 + d/R)] \approx (2\pi\epsilon_0\epsilon fR)/d$$

and the quantity

$$W = (U^2 \pi\epsilon_0\epsilon fR)/d \quad (9)$$

We substitute in (9) such values for a nerve with  $R = 5 \mu\text{m}$  [17]:  $U \sim 0,07\text{V}$ ;  $\epsilon_0 = 8.85 \cdot 10^{-12}$  F/m;  $\epsilon \sim 5$ ;  $f \sim 10^{-7}$  m;  $d \sim 10^{-8}$  m, we obtain

$$W \sim 5 \cdot 10^{-17} \text{ J or } 3 \cdot 10^7 \text{ J/mol.} \quad (10)$$

The same value of  $W$  is obtained if we substitute in  $C$  the value  $C = 10^{-2}$  F/m<sup>2</sup> [17] for the same parameters of Ranvier intercept and  $U$ . The value (10) is comparable with the energy released during oxidation of  $\sim 10$  glucose molecules and at the hydrolysis of  $\sim 10^3$  ATP molecules.

It is known [12, 17] that during the hydrolysis of one ATP molecule,  $\sim 3$   $\text{Na}^+$  ions pass through the membrane in exchange for two  $\text{K}^+$  ions, and when the PD is excited, the flux density of  $\text{Na}^+$  ions through the intercept membrane is  $J_{\text{Na}} \sim 4 \cdot 10^3$  ions/ $\mu\text{m}^2$ . Then the number of  $\text{Na}^+$  ions entering into the axon will be equal to  $J_{\text{Na}} (2\pi Rf) \sim 10^4$ , it corresponds to  $\sim 3 \cdot 10^3$  ATP molecules, the total energy of which agrees in order of magnitude with (10). When ATP concentration in axoplasm of axon of squid is  $\sim 1$  mmol per kg of  $\text{H}_2\text{O}$  [12], the total number of ATP molecules in the Ranvier interception cylinder (radius  $5 \mu\text{m}$  and length  $1 \mu\text{m}$ ) will be  $\sim 4 \cdot 10^7$  molecules. Consequently, the value of  $W$  is only 0.01% of the total energy resource of the Ranvier interception.

It is obvious that the energy of the EM quantum that plays the role of the stimulus of the PD generation in the Ranvier interception will be one, two orders of magnitude less than the value of  $W$ . For example, for the upper limit of the energy of the EM quantum one can take the energy

of a photon with a wavelength of 600 nm ( $4 \cdot 10^{-19}$  J), which is sufficient to excite the signal in the retinal cell of the retina [15].

### 2. 3. Neural networks

Submission of neurophysics to the law of EMP can be formalized by introducing an inductor into the equivalent circuit of the nerve membrane with the myelin sheath together with the capacitor (Fig. 8). Such a modification of the equivalent circuit, transforming it into an oscillatory circuit, significantly expands the range of the electrophysical properties of the neuron.

Figure 8. Modified electrical circuit of the nerve membrane.  $R_m$ ,  $U$  - ion channel;  $C$  is the capacity of the membrane;  $L$  - inductance of glial membrane myelin helices;  $R_{in}$  - resistance of axoplasm

In addition, the introduction of inductors into the electrical circuit of the nerve membrane allows us to model the chirality factor of a neuron and to associate it with the mechanism of differentiation of nerve signals to stimulating and inhibitory ones. The combination of the chirality factor with a biochemical factor (synaptic connections) empowers the logical element of neural networks to encode the "yes" and "no" signals (Fig. 9).

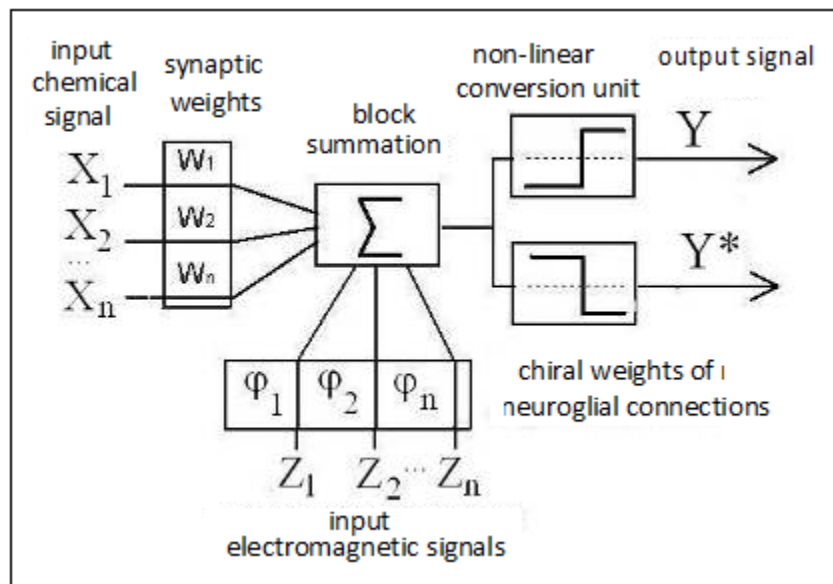

Figure 9. Modified functional scheme of a formal neuron [18].  $X_n$  - biochemical,  $Z_n$  - electrophysical factors of neuron activity;  $Y$  ("yes"),  $Y^*$  ("no") are analogues of the exciting and braking signals.

In addition, EM-quanta or QPH generated in a neural network can be combined into a dynamic quantum system (Bose-gas) and represent the brain as a processor, the elemental base of which is the entirety of the multilevel hierarchy of neuron-neuronal and neuroglial connections. At the same time, the efficiency of the quantum level of the neural network organization will be limited by the value  $V$  (5) and the transmission and processing time of the signal in the scale of the neural network from  $1 \mu\text{m}$  to  $10 \text{ cm}$  will vary in the range from  $10^{-15}$  to  $10^{-10}$  s. The first value is comparable with the lifetime of the singlet electron-excited state of the molecule (optical QPH), and the second with the characteristic lifetime of tetrahedral water clusters.

## 2. 4. Capsulated nervous terminations

### 2.4.1. Fatera Pacini Body

EMP can also be used to explain the mechanism of generation of electrical impulses in encapsulated nerve endings. The most important for brain physicists the representative of this kind of endings is the Fatera-Pacini body (FPB) (Fig. 10). FPB is abundantly present in the subcutaneous layer of the palms and feet, in the female genitalia and in the connective tissues of the internal organs [19].

*Figure 10. Encapsulated ending nerve – the body Fatera-Pacini [19]. Linear dimensions reach 1-2 mm.*

In addition to the sensory function, FPB can obviously accept gravitational and geomagnetic energies and simultaneously play the role of EM-quanta generators. It is suggested [19] that the basis for the mechanism of TP generation in FPB is the biochemical response of FPB to its mechanical deformation. However, the isomorphism of FPBs and complex electromagnetic devices, which have two inductors embedded in the rod, suggest the participation of EMP in the mechanism of PD generation. Deformation of FPB, being associated with changes in its induction or capacitive characteristics, can lead to the excitation of electromagnetic pulses that stimulate the

generation of PD. In this case, a decrease in the values of L and C in accordance with formula (6) should lead to an increase in the frequency of generation of stimuli ( $w$ ), and hence the repetition rate of the PD, which is observed experimentally [19]. We note that in the absence of external deformation of FPB, their background activity as "generators" of quasiphotons can provide a rhythmic deformation of the fiber around the FPB, which corresponds to the pulsation of the circulatory system. It is also possible that the LC-contour in the structure of FPB can move resonantly in the motion of the arms and legs resonantly in the energy of the geomagnetic field.

#### 2.4.2. Eye

The eye can be considered an integral capsular end of a large number of axons of the optic nerve. Its main function is to convert the front of photons of the visible range into a complex spatio-temporal mosaic of PD and QPH. The electrical energy (momentum) of the photon absorbed by the retina stimulates the generation of PD in it and is partially transformed into a pulse of optic nerve adhesion. In this role, about 10% of the photons enter the eye, the remaining 90% are absorbed by the optical media of the eye [19]. When photons are absorbed, both in the retina and in other elements of the eye, the probability of generation of states with intra- and intermolecular charge transfer in the donor-acceptor fragments ( $D^{+\delta}-A^{-\delta}$ ) is high. Such metastable states are called excitons. The kinetics of the process of exciton relaxation in the retina correlates with the kinetics of PD generation. A sufficiently long lifetime and a high photostationary concentration of these states cause the dipole polarization of the retina surface [20]. The movement of retinal charges during eye movement induces vortex magnetic fields (EM vortex), the maximum energy density of which is achieved in the frontal and temporal lobes, as well as in the sinuses of the skull (maxillary, wedge-shaped, frontal) (Fig. 11). It is known [11] that in these areas the functions of attention and self-awareness are localized, that is why the EM-vortexes of the eyes can take a direct part in their activation. With this in mind, suppose that the eyes and their nervous system, along with their sensory function, play a dominant role in the physics of the cognitive functions of the brain. That is why with increased mental work, not even related to reading, the eye muscles become very tired, which provokes the development of a specific pattern of wrinkles around the eyes. Note that with the congenital defeat of the CNS departments responsible for the formation of visual representations of the external world ("central congenital blindness"), the child is doomed to remain an idiot.

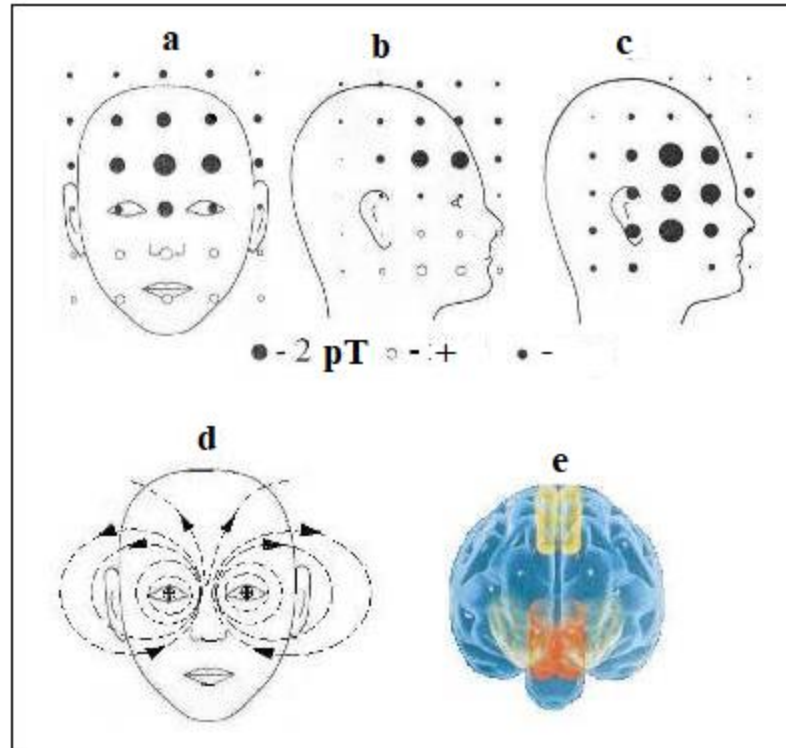

Figure 11. The distribution of magnetic induction for various eye movements (a, b, c) [20, 21] and the scheme of fluxes of magnetic induction in the frontal projection (e). Floor. - the magnetic field is directed inward, ot. - outside the object. The value of the B-field is proportional to the radius of the circle. A), b) - horizontal movement of the eyes from right to left within an angle of  $55^\circ$ ; c) - eye movement from the bottom up.

Fig. 11e shows the areas of the brain (front view) responsible for self-awareness: the medial prefrontal cortex (connects the self-sensations and the memory of oneself) is highlighted in red; yellow - predelinic (activation of retrospective memory of yourself) [11].

The geometry of the vortex B- and D-fields of the eyes is determined by the trajectories of the charges of the retina and muscles during the movement of the eyes in the vertical and horizontal directions. The localization of the maximum value of the B-field with the horizontal movement of the eyes at the midpoint (Fig. 11a) indicates the summation of B-fields at this point from both eyes. This is possible under the condition that the vortex metrics induced to the right and left eyes are mirror symmetric. It is possible that the chirality of the electromagnetic stimulus, and hence the signs of the myelin spirals of the nerves of the right and left eyes are opposite. It can be imagined that EM vortices induce mirror-symmetrical pairs of EFs in the CSF cerebral liquor between the

hemispheres, their fusion, in principle, can produce a QPH and such a mechanism of EM-quantum generation, obviously, underlies the exothermic process of recombination of two dissimilar electric charges. It is obvious that the organizing effect of the eye EM-vortices in the process of formation of the child's self-consciousness determines the formation in the medial prefrontal region of the neuronal cortex of a unique form, called spindle cells [11, 15]. Similar reactions of EF fusion-recombination induced in the right and left hemispheres can also take place in the cerebrospinal fluid of the third and fourth ventricles, taking an active role in their bioenergetics. A simplified diagram of the frontal projection of the D-, B-vortexes of the eyes is shown in Fig. 11e. The cross in the center of the eye indicates the spike of the optic nerve that leaves in the plane of the picture. This scheme also coincides with the distribution of the lines of force of the magnetic dipole, oriented along the line of the nose. This is also consistent with the fact that the porous bones of the walls of the nose, the sphenoid sinus and the latticed bone have a high residual magnetization value [30].

In support of the important role of the eyes in the cognitive physics of the brain, there is a complex relationship between eye energy and the baseline rhythm of brain electrophysics ( $\alpha$ -rhythm):

- only the higher mammals have an  $\alpha$ -rhythm [22] and it is established synchronously with puberty, after which it is not fixed in the frontal lobes [15];
- $\alpha$ -rhythm, like the beta-rhythm, can be localized separately in the right or left hemisphere of the brain [23];
- The  $\alpha$ -rhythm disappears with a loss of consciousness and opening of the eyes, but in the blind it is either poorly expressed or absent [15];
- The frequency of the  $\alpha$ -rhythm ( $\sim 10$  Hz) is correlated with the frequency of a standing EM wave in a spherical resonator that forms the Earth's surface and its ionosphere [24].

The vitreous body of the eye in the background can condense the EM energy of the external environment and, possibly, the energy of the solar neutrino [1, 6], directly feeding this energy to the brain. The evidence supports this assumption:

- rapid eye movement in the phase of paradoxical sleep (phase-BDG) is associated with the intensification of brain physics [15];
- the formation of a specific five-fingered relief on the surface of the eye socket, facing the brain and curving the line of the nose [25];

- muscles of the eyeball spontaneously twitch at a frequency of 20 - 150 Hz (microsaccharides, tremor) [15];
- the layer of ganglion cells of the retina bordering with the vitreous body in the dark and with closed eyes show background activity with a frequency from 1 to ~20 pulses per second [26];
- exposure to closed eyes of mechanical pressure and a pulsed magnetic field initiates a "vision" of white light (phosphenes) [15, 27]
- an increase in the intensity of light leads to an increase in the frequency of generation of PD in the optic nerve [15];
- the crystalline lens and the vitreous of the eye are optically active [28, 29];
- glycolysis of glucose in the vitreous body gives, in addition to ATP, chiral lactic acid [15];
- the characteristic time of hydrodynamics of the eye is ~ 900 s, during this time half of the vitreous fluid is renewed [15].

The ontogeny of the asymmetry of sight, smell, hearing, facial (nose curvature) and genitalia is synchronized with the process of stabilizing the frequency of the  $\alpha$ -rhythm [31] and for 12-13 years repeats the stage of phylogenesis corresponding to the uprightness. Moreover, by the age of two years, when the child begins to walk independently, the genesis of brain asymmetry involves the energy of the TFP stop and the physics of the genital organs, the gender peculiarities of which leave their imprint on the topology and functions of the brain of a man and a woman [32].

### **3. Quasifoton**

#### **3.1. Types of quasiphotons**

To describe the properties of various condensed media, the concept of a quasiparticle is widely used [33]. Since the water content in the brain reaches ~75% [15], it can be considered a highly concentrated colloidal solution. To describe the mechanisms of energy-information processes underlying the physics of the brain, it is convenient to use the concept of a QPH as a generalization of the EM quantum. Thus, a QPH is a carrier of the excess energy of an electromagnetic field localized on an electron or on the electron system of an ordered atomic-molecular structure. The precursor of a QPH is a photon or an EM quantum, in the case of their absorption by the system. Depending on the energy of the photon and the electronic structure of the system, the metric, the lifetime and the fate of the QPH vary widely. The physics of QPH

genetically inherits the laws of atomic-molecular spectroscopy and the properties of excited states of molecules of various types (electronic, vibrational, translational, rotational) [34]. Mixed electron-nuclear configurations of excited states will correspond to rotational and vibrational QPH, and optical QPH to purely electronic excited states. Examples of an optical QPH are an EM stimulus generating a PD, an exciton, or an electronically excited state of a molecule. The vibrational QPH in an elastic coupled structure will be similar to a phonon. A rotational QPH in a system of coupled nuclear or electron spins can be identified with a magnon [33]. QPH can be free and bound, depending on the properties of the medium and the mechanism of interaction of its elements. Thus, the metric-dynamic characteristics of QPH will be determined by the type of chemical bonds and the type of intermolecular interactions that determine the degree of orderliness of the medium.

The energy of QPH of various types will vary over a wide range, the upper limit of which can be regarded as the energy of the QPH stimulating the generation of PD in the interception of Ranvier ( $\sim 10^{-19}$  J). For the lowest energy limit of a QPH, one can take the energy of a vortex EM field generated by the motion of the eyes. The density of a given energy at  $B \sim 4$  nT is of the order:

$$E = B^2 / (2\mu_0\mu) \sim 10^{-23} \text{ J/cm}^3 \text{ or } \sim 0.01 \text{ kJ/mol in cm}^3. \quad (11)$$

The degree of influence of this field on the magnetically susceptible micro and macro structures and the environment of the brain will be determined by the energy density:

$$E = (\mathbf{M} \mathbf{B})/2,$$

where  $M$  is the specific magnetization (the specific density of magnetic moments is  $m$ ), equal to:

$$M = \Sigma m.$$

In the case of ring currents of any nature ( $J$ )  $m = J \Delta S$ , where  $\Delta S$  is the area of the surface covered by the current. Moreover, the polarization effect of the magnetic field can be enhanced by the thermal motion of the medium particles [36].

The energy of the thermal effect from the light stimulation of the rat eyes is comparable with the value (11), which is manifested by an increase in the local temperature of the visual cortex of the brain by  $\sim 0.06$  °C [11]. The energy of the QPH of the thermal energy corresponding to a given quantum is  $\sim 10^{-24}$  J or  $\sim 10^{-3}$  kJ/mol. In the range  $10^{-3}$  -  $10^2$  kJ/mol, the energy of biogenic MW radiation ( $\lambda = 100$  -  $1$  mm,  $E = 10^{-3}$  -  $0.1$  kJ / mol) falls into the range [37]; including the energy of the resonance frequencies of water ( $\lambda \sim 6$  mm,  $E = 0.02$  kJ/mol) [38]. It is known [3] that the activation energy of the processes of associating sugars and quanta of biogenic MW

radiation is one or two orders of magnitude less than the thermal energy and is comparable in order of magnitude with (11). It follows that quasi-photons of rotational type will play a key role in the processes of self-organization of liquid brain media, and the physics of the fronto-temporal lobes, responsible for the cognitive functions of the brain, will be directly related to the electrophysics of the eyes.

### 3.2. Quasiphoton metric

The elementary structural cell of liquid water is a dynamic tetrahedron formed of four water molecules connected by hydrogen bonds. The fifth molecule of water or a molecule or atom commensurate with it can be in the center of a tetrahedron, then it is called a centered tetrahedron (Fig. 13). Thanks to hydrogen bonds, water effectively interacts with dissolved molecules, thereby expanding the range of their physico-chemical properties. This feature of aqueous colloids and gels is especially important for brain physics, since its intercellular volumes are, as a rule, comparable to the sizes of biomolecules, cells and organelles [35].

Because of this, it is necessary to assume a significant effect of the epitaxial effect on processes regulating interneuronal and neuroglial interactions. It is known, for example, that in chemical reactions occurring in an optically active medium or on the surface of quartz, the yield of chiral products increases. The increase in the epitaxial effect of membranes and the walls of various organs, in addition to the mediation of water, is apparently facilitated by bound or adsorbed surface polypeptide and polysaccharide chains, as well as microvilli (Fig. 12) [15, 17]. The epitaxial effect and the presence of chiral sugars affect the kinetics of reversible adsorption of ions and neurotransmitters on the surfaces of neuronal membranes, both in Ranvier intercepts and in synapses [14].

*Figure 12. Diagram of the membrane and the polysaccharide and polypeptide chains emerging from it.*

Metabolites having a charge, dipole, mechanical or magnetic moments, and also chirality, affecting the electrodynamic constant ( $\epsilon\mu$ ) of the medium, the metric and the dynamics of

supramolecular structures, can vary widely the cooperative properties of solutions, the generation efficiency, and the mechanism of motion of QPH. This applies primarily to ions ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ ,  $\text{P}^{3+}$ ) (Table 1) and to molecules that play the role of carriers, acceptors and converters of QPH (oxygen, carbon dioxide, water, sugars, ATP, neurotransmitters, hormones, enzymes).

Figure 13. Diagram of the fusion of two mirror-symmetric mobile EFs ( $\mathbf{v/g}$  pairs) into a quasiphoton at rest with a tetrahedral metric (a) and a scheme of electron orbitals of a water molecule (b)

The main mechanism of motion of QPH will be their resonance absorption and reradiation by medium molecules, metabolites and supramolecular structures. The main element of the three-dimensional metric of the liquid medium and most of the organic metabolites is a tetrahedron whose electron-nuclear matrix is the  $\text{sp}^3$ -hybridized system of electron orbitals of carbon, nitrogen and oxygen atoms. Consequently, a quasi-photon localized on a particular metabolite is most likely to have a metric in the isomorphic geometry of  $\text{sp}^3$ -hybridization.

Using the concept of  $\mathbf{v/g}$ -pairs, a resting EF or a localized QPH with a tetrahedral metric can be obtained by the scheme shown in Fig. 13. The rules for combining and condensing EF ( $\mathbf{v/g}$ -pairs) [6] allow one to model and calculate the metric of QPH of various types, including isomorphic metrics of  $\text{sp}$ - and  $\text{sp}^2$ -hybridized atomic orbitals. The energy of QPH associated with  $\pi$ -electrons will be less than the energy of QPH corresponding to vibrational-rotational excitations of atoms or deformations of the  $\sigma$ -skeleton. The lower vibrational levels of the carbon dioxide molecule ( $\text{O}=\text{C}=\text{O}$ ), having an energy of  $10^{-21}$  to  $10^{-20}$  J, can be populated by absorption of thermal quanta ( $kT$ ). The specificity of the location of the levels allows their inverted population, which allows the use of carbon dioxide as the active medium of the laser ( $\lambda \sim 10 \mu\text{m}$ ). In liquid media predisposed to self-organization, the  $\text{CO}_2$  molecule can be a donor of vibrational QPHs for molecules with a carboxyl group ( $-\text{HCO}$ ). Similarly, molecules with aromatic rings will accept

QPHs corresponding to conformational vibrations of saturated carbon cycles isomorphic to them and heterocycles. High activity, for example, of steroid hormones of cholesterol derivatives, having condensed hexane cycles, can be caused by the saturation of their molecules with QPHs with  $sp^3$ -metric (Fig. 13). At the same time, aromatic molecules (benzene, anthracene, pyrene) isomorphic to fragments of hormones, effectively deactivating hormones and distorting their metabolic functions, can initiate carcinogenesis [39].

**Table 1.****Nuclear-electronic characteristics of elements**

Element	Characteristics of nucleus				Main electronic state of atom	Ionic radius (nm)
	Spin (I)	Magnetic moment ( $\times \mu_H$ )	Magnetic susceptibility ( $C^{13} = 1,00$ )	Quadruple moment ( $Q \times 10^{28}, m^2$ )

**3.3. Metabolic quasiphotons**

For the unification of the language of bioenergetics, the energy of the QPH of the corresponding metric is correlated with the values of the energies of chemical bonds, vibrational-rotational and thermal motions of atoms and molecules. The ability of the brain to provide energy enzymatic reactions of oxidation of glucose in the mitochondria and anaerobic glycolysis in the eyeball. In these reactions, the energy of the chemical bonds of glucose and oxygen is transformed into energy of the macroergic bonds of ATP, which in the subsequent ATP hydrolysis reactions are converted into the kinetic and vibrational-rotational energy of metabolites and molecules of the medium. The chemical activity of these molecules is then realized through the action of their excitation energy, which is simulated by QPHs of the corresponding energy and metrics.

The total energy effect of all stages of the enzymatic reaction of glucose oxidation in mitochondria has as its limit the thermal effect of the burning reaction of glucose in an oxygen atmosphere:

The reaction of glucose oxidation in mitochondria is associated with the ATP synthesis reaction, with one molecule of glucose accounting for 38 ATP molecules [40]. In the anaerobic glycolysis of glucose, only two molecules of ATP and two molecules of chiral lactic acid are formed, which obviously contribute to the chirality of the energy of the eyes and brain. The maximum yield of metabolic energy will give hydrolysis of 38 ATP molecules according to the following schemes:

The total energy of the macroergic bonds of 38 ATP molecules is 2640 kJ/mol, which is ~ 95% of the limiting value of the combustion energy of one glucose molecule. This indicates the high efficiency of enzymatic reactions of transformation of QPH corresponding to  $\sigma$ -bonds of C-C, C-O-C, C-H glucose into QPH localized on two macroergic bonds P ~ O- in ATP.

Suppose quasi-photons are equally distributed over the bonds of the products of the reactions of glucose oxidation and ATP hydrolysis, then the limiting values of the energies of the QPH corresponding to these reactions will be 1/12 and 1/152 of the thermal effect of reaction (12) equal to  $4.5 \cdot 10^{-18}$  J, that is,  $\sim 3 \cdot 10^{-19}$  and  $\sim 3 \cdot 10^{-20}$  J, respectively. If we apply to these QPH the universal relation between energy and the characteristic size ( $r$ ) of the discrete element of matter ( $v$  / g-pair, elementary particle) [6]:

$$E \sim \hbar c/r, \quad (13)$$

then for a QPH acting as a quantum of metabolic energy, we obtain a radius of  $\sim 1 \mu\text{m}$  comparable to the axon radius.

Metabolic QPH can take an active part in the enzymatic synthesis of proteins and nucleic acids, as well as in the replication and transcription of DNA. One can imagine the participation of QPHs in the interlacing of the double helix of DNA in the following way. In the region of the replicative fork, the sugar-phosphate backbone of the DNA chain resonantly absorbs metabolic quasi-photons of vibrational type. The elasticity of chains increases, which leads to the rupture of hydrogen bonds between them. Taking into account that one hydrogen bond is necessary for two

sugar-phosphate links of the DNA helix and its energy is  $\sim 19$  kJ/mol ( $3 \cdot 10^{-20}$  J), it turns out that for its rupture it is sufficient to take a single metabolic QPH by the DNA chain.

The presence of isomorphic amino acid fragments in peptide chains of the protein and in the structure of neurotransmitters (glycine, acetylcholine, glutamic acid, dopamine, serotonin, etc.) makes it possible to propose a resonant mechanism for the transfer of a quasi-photon of vibrational type upon contact of the neurotransmitter with the receptor. Because of the presence in the structures of the mediators of the electron and proton-donor and acceptor groups, their main electronic state is characterized by intramolecular charge transfer  $D^{+\delta}-C-A^{-\delta}$ . Here D - amino groups, methoxy group, benzene ring and A - carbonyl and hydroxyl groups, and C - a chain of  $\sigma$ -bonds. This factor and predisposition of mediators to the formation of hydrogen bonds are the basis of their physical and chemical sorption at receptors of postsynaptic membranes. The receptor, when taking or giving off a QPH upon contact with a neurotransmitter, changes its conformation by locking or opening the membrane of the membrane.

#### 4. Thermodynamics of the brain

The brain as a whole can be considered a reaction thermodynamic system, which is in a stationary state. The influx of energy and the discharge of excess heat by the brain are balanced in a narrow temperature range from  $\sim 37^{\circ}\text{C}$  (the center of the brain) to  $\sim 36^{\circ}\text{C}$  (brain cortex) [15]. This temperature gradient, due to the lower temperature of the external environment, can play a significant role in the orientation of heat flows within the brain. A similar temperature gradient is observed for the body, it has a maximum in the rectum, and a minimum in the surface layer of cellulose and male testicles [15]. The range of the optimal temperature of metabolism is within the limits of temperatures for which the isobaric heat capacity of pure water has a minimum [41]. The peculiarities of the thermodynamics of phase transitions of aqueous solutions in the process of phylogenesis formed the basis for the adaptation of living systems, which, in essence, are isoenergetic transitions or transitions with an activation energy of the order of  $k\Delta T$  (at  $\Delta T \sim 0.1-1$  K) between states of different order of the protein molecules or homogeneous, molecular-cellular ensembles. The decrease in the entropy component of the internal energy of a living system is associated with the resonant absorption of a quantum of external EM or neutrino energy, which it converts into an active metabolic QPH [3]. The liquid medium provides for the removal of the quantum of thermal energy (entropy) beyond the boundaries of the system, and the function of a

QPH realizes the function of one or another brain structure that includes an ordered subsystem. The energy released or absorbed during such transitions may be much smaller than  $kT$ . In nonequilibrium conditions, the vibrations of individual macromolecules can be synchronized, in particular, by means of an electromagnetic field [36].

Thus, the thermodynamics of the brain combines the equilibrium-stationary thermodynamics of metabolism and the nonequilibrium thermodynamics of a neural network, the "working body" of which is the Bose gas of QPHs. Accordingly, the internal energy  $U$  of the brain as a function of its state will depend, in general, on the temperature (or entropy  $S$ ), on the strain tensor  $G$ , on the magnetic moment  $M$  of individual metabolites and macrostructures, on the total angular momentum of nuclei and atoms  $L$ , and on the polarization of the medium  $P$ . Therefore, the total differential of the internal energy  $U = U(S, G, M, L, P)$  will have the form:

$$dU \equiv TdS - PdG + BdM + DdP + FdJ, \quad (14)$$

where  $T$  is the absolute temperature of the system;  $\Pi$  is the pressure tensor;  $F$  is the vector of the orientational polarization of the system of spins or momenta [42]. In expression (14), the term  $FdL$  characterizes the work associated with the orientational polarization of the system of nuclear spins or momenta of atoms and molecules (just as the terms  $DdP$  and  $BdM$  determine the work associated with the polarization and magnetization of the system).

Orientational and polarization effects play an important role in initiating phase transitions in homogeneous gas and liquid systems of the brain and organism. The high sensitivity of these systems to the parameters included in (14) ensures the chirality of metabolites (mainly sugars [3, 29]) and the physicochemical features of molecular and liquid water. Such systems are formed in the following structures and environments of the body and brain:

- stomach, uterus, trachea, craniofacial sinuses, cavity of the epiphysis;
- membranes and ventricles of the brain, venous sinuses, eyeball;
- blood and lymphatic systems;
- parenchyma of organs (lungs, liver, spleen, testicles, female breast);
- Subcutaneous tissue, connective and bone tissue.

All these systems function normally in two modes - stationary (quasi-equilibrium) and nonequilibrium. The first is characteristic for the waking state of the body and brain not engaged in mental work, and the second regime corresponds to the state of sleep or creative work. In the first mode, energy exchange with the medium occurs continuously, and in the second, it is

quantized. The mechanism of accepting the quantum of external energy in the phase transition of the cooperative system illustrates the processes of condensation of water vapor at the dew point and quantum Bose condensation.

Acceptance of quanta of the energy of the MW-band or neutrino energy in these media is facilitated by a decrease in body temperature in sleep by  $\sim 1\text{K}$ , as well as lower temperatures of the vitreous of the eyes, peripheral (deposited) blood and testes. In the acceptance of chiral quanta of neutrino energy, a large role is played by sugars, whose content in the blood increases in the morning hours before sunrise. At this time, the neutrino component of solar radiation is filtered from the EM radiation by the surface segment of the crust of the globe. An important role in the acceptance of energy by the vitreous eye is played by the polysaccharide-hyaluronic acid [3, 29]. Almost half of all human hyaluronic acid is concentrated in its skin, where it is located in the connective tissue of the dermis between collagen and elastin fibers, as well as in corneocyte corneal cells. The dermis contains 70% water, which is  $\sim 20\%$  of the body's water [15]. The energy absorbed by the body, condensing on metabolites in the composition of liquid media (blood, cerebrospinal fluid), is transmitted to the brain via neurohumoral and air channels (from the lungs).

The absorption of the external EM-quantum and the formation of a QPH from the energy forms in the general case obeys the fractal-resonance mechanism and the principle of isoenergetic. With allowance for (13), the principle of isoenergetic for resonant interactions and phase transitions in cooperative systems can be expressed by the relation [6]:

$$\hbar C/r = N (\hbar C/R), \quad (15)$$

here  $r$  characterizes the metric of the QPH, and  $R$  is the energy form and  $r = R/N$ ; the number  $N$  takes any values smaller than the Avogadro number when the EF is condensed into QPH and reaches the Avogadro number with the participation of the EF in weak interactions [39].

## **5. Physics of the brain organization**

### **5.1. Functional hierarchy of the brain**

Functional hierarchy of the human brain is built on the physical properties of its following structures: the neocortex, basal nuclei, limbic brain, thalamus, hypothalamus, pituitary gland, epiphysis, reticular formation and cerebellum. The fluid system of the brain (blood and liquor), as well as the whole complex of intracranial nervous communications, should be referred to separate

elements of the hierarchy, highlighting the corpus callosum, optic nerve and radiance of the thalamus.

### 5.1.1. Bark of the cerebral hemispheres

In the structure of the cortex, surface special zones (up to 100 pieces) and six layers are distinguished [15]. The topmost layer is formed by horizontally oriented apical dendrites of pyramidal cells and axons of stellate cells, which provide intracortical connections between neighboring neurons

The horizontal orientation of the neuron dipoles of this layer corresponds to a dynamic electric field, which can play the role of a protective EM screen. The remaining five horizons of the cortex are first structured into neural-glia modules (diameter  $\sim 100\text{-}150\ \mu\text{m}$ ), and then, in columns up to 1 mm in diameter and with an average number of neurons of  $\sim 100$  pc [15]. Synchronization of the electrical activity of neurons in modules and columns leads to the formation in the beams of volleys pulsing out from them axons. The process of summing the PD into volleys can be preceded by the condensation by (15) of external EM-quanta or QPH of PD stimuli on individual neurons in modules, and then in columns. For example, with the condensation of  $\sim 100$  QPH with a characteristic radius of  $100\ \mu\text{m}$ , a QPH with a radius of  $1\ \mu\text{m}$  (energy  $\sim 10^{-19}$  J) can be formed in the salvo pulse, which will send the column to the conjugate structure of the subcortex or inject it into the liquor.

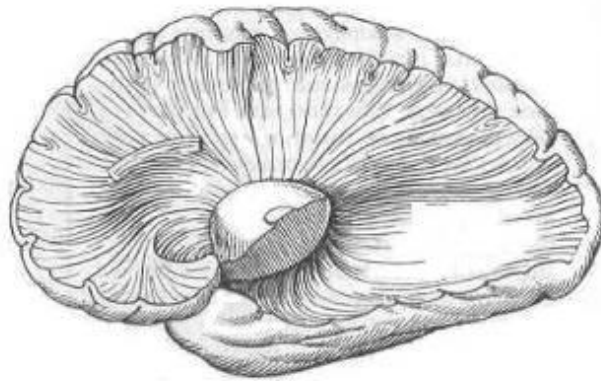

The outer layer of the cortex, together with the layer of cerebrospinal fluid in the subarachnoid space of the brain, obviously play the role of a spherical EM filter or an MWR resonator ( $R \sim 7 \cdot 10^0$  cm), the absorption of which has several maxima, including those for the wavelengths of external EM quanta ( $\lambda$ ) of the order of the radius of the sphere [37]. In the brain tissues, the wavelength of the MKW quantum decreases by a factor of  $\sim 7$ , and the depth of its penetration proves to be comparable to  $\lambda$  [37]. It can be assumed that the horizontal stratification of the cortex (Fig. 14) is associated with the dispersion of the absorption by the brain material of biogenic MKV quanta. And at a bark thickness of  $\sim 2 - 5$  mm, its stratification into three myelin layers (Fig. 14) can be phylogenetically caused by the action of three types of EM quanta with a wavelength of 1 cm to 10 cm. Assuming that from EM quanta with  $\lambda \sim 1$  cm, QPH-PD stimuli are formed, according to Eq. (15), their number (N) can be estimated from the radius of a QPH of  $100\ \mu\text{m}$ . The estimate of N gives a value of  $\sim 1\ \text{cm}/100\ \mu\text{m} = 100$ , equal to the number of pyramidal neurons in the column.

### 5.1.2. Thalamus, the ventricles of the brain

The geometric and energy information center of the brain is a dicotyledonous thalamus having an axis orthogonal to the plane of the third ventricle (intertalamic fusion). Its fan nerve connections with the bark (radiance, Fig. 15) can synchronize their electrical activity to generate a macroscopic EM vortex with a magnetic vector directed along the axis of the medulla oblongata.

*Figure 14. A micrograph of a section of a cortex dyed with a dye, an absorbed myelin*

*Figure 15. Radiation of the thalamus*

Similarly, volley pulses in the nerve fibers of the hippocampus will generate an EM vortex with a magnetic vector parallel to the axis of intertalamic fusion. A thin layer of cerebrospinal fluid in the brain's ventricles is saturated with metabolites under the influence of epitaxial effects and under the conditions of sleep it evidently passes into the liquid crystal state acquiring the property of a condenser-synthesizer of macroscopic QPH of the brain or external energy forms (including neutrinos). Physicochemical connection of cerebrospinal fluid of the third ventricle with glandular epiphysis and pituitary gland ensures their participation in mechanisms of adaptation, homeostasis and reproduction. The bodies of both glands are immersed in the cerebrospinal fluid of the brain, and their funnel necks are in contact with the cerebrospinal fluid of the third ventricle (Fig. 16).

Moreover, if the epiphysis participates in the formation of energy-information codes of the cerebrospinal fluid and venous blood, the pituitary gland only translates some of them into the information level of the circulatory system.

*Figure 16. Tanks of the brain. Black arrows of venous blood*

### 5.1.3. Epiphysis

In [6], a hypothesis was advanced that the phylogeny of the visual system and the epiphysis as the third eye is caused by the exposure to the biosphere of solar radiation not only of electromagnetic but also neutrino nature. According to the standard model of the Sun, the fraction of neutrino energy is about 3% of the EM energy and therefore the error of the experiment or statistics should not exceed  $\sim 1\%$  in order to reveal its effect in the daytime. Since the neutrino is practically not absorbed by the inert matter, it easily passes through the Earth, the magnetic field of which can only lead to the dispersion or focusing of the neutrino flux incident on it. Thus, one can expect a significant contribution of neutrino energy to the physics of the brain at night and when the brain is in a state of sleep. It is obvious that the need for sleep itself is phylogenetically conditioned by the neutrino factor, under the influence of which the mechanisms of condensation of quanta of biogenic energy of various nature developed in the liquid media of the organism. This energy is especially important for the development of the embryo in the womb of the mother, and then the infant of the infant. In addition to the specific functional characteristics of the woman's brain [32], her body during lactation intensifies the process of accepting neutrino energy with the participation of metabolites that make up breast milk. It is possible that this physical feature of

mother's milk is due to the rapid rate of development and structuring of the neocortex in mammals, both in phylogeny and in ontogeny.

It is also impossible to exclude the effect on solar systems of live EM systems at night of solar EM-quanta reflected by the Moon and planets (Mercury, Venus, Mars) (Fig. 17). The intensity of these emissions is obviously comparable to the intensity of the neutrino energy flux, and their total effect will have the maximum effect when Mars and Venus are in opposition to the Earth. Since the atmosphere of Venus consists mainly of CO<sub>2</sub>, the spectrum of reflected (re-emitted) light will be modulated by the vibrational frequencies of CO<sub>2</sub>, which will ensure resonance excitation of CO<sub>2</sub> molecules in the earth's atmosphere and in saturated CO<sub>2</sub> (marine waters, lithosphere, venous blood). In certain cosmic situations, the galactic radiation of electromagnetic and neutrino nature can influence the biosphere at night. All this gamma of physical factors of phylogenesis was reflected in the peculiarities of the physics and chemistry of the sleeping brain, as evidenced, in particular, by the chronobiology of the brain (Fig. 18).

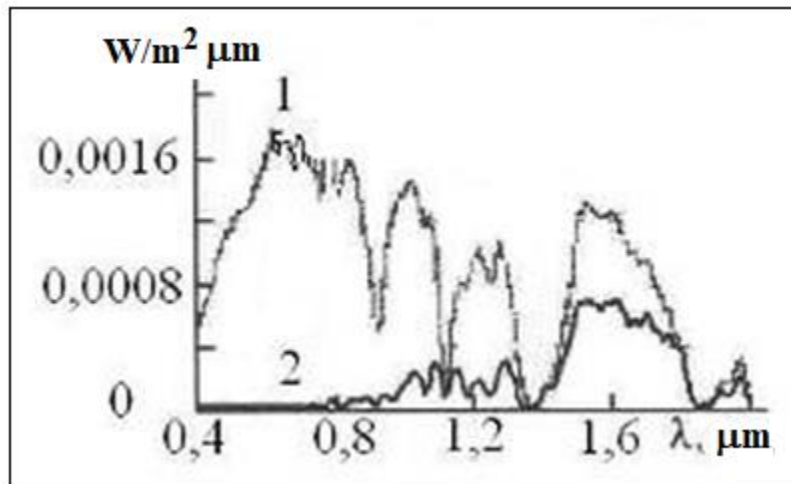

Figure 17. The spectra of irradiation of the earth from the Moon (1) and the starry sky (2)

Figure 18. Concentration of melatonin in the blood plasma of a healthy person (1) and variations in the intensity of the solar neutrino flux (2). The arrow shows the sunrise.

One of the ways of metabolizing neutrino energy can be the synthesis reaction in the epiphysis of neurohormone melatonin, which plays a key role in the process of puberty and in the formation of the spectral and energy characteristics of the surface layer of the skin. The process of melatonin synthesis is modulated by circadian rhythms and suppressed by bright light. Melatonin is discharged into the cerebrospinal fluid of the third ventricle and into the venous blood, and its maximum concentration in the cerebrospinal fluid is observed about three o'clock in the morning, reaching an order of magnitude greater than its content in the blood [43]. It should be noted that at three o'clock in the morning the blood pressure and body temperature are of minimal importance, which contributes to the process of self-organization of liquid media and thereby increases the efficiency of accepting quanta of biogenic energy [3, 29]. In the processes of acceptance and utilization of energy in addition to melatonin involved chiral sugars and phosphorus. Their concentrations reach a maximum also in the early morning hours before sunrise [15] (Fig. 18). In the summer dew drops out at the same time. Saturation with neutrino energy of liquid media intensifies the enzymatic oxidation of sugars, which together with an increase in the concentration of phosphorus gives an increase in the rate of ATP synthesis. Thus, neutrino energy at night can play the role of chiral kinetic factor of bioenergetics.

Figure 19. Schemes of structures of serotonin and melatonin

The phylogenetic and chemical precursor of melatonin is the neurohormone serotonin (Fig. 19). Substitution of substituents in the ring and under nitrogen during the transition from serotonin to melatonin significantly changes its physicochemical properties. Due to  $-C=O$  group, melatonin will accept quasi-photons from  $CO_2$  of venous blood. In addition, melatonin can serve as an acceptor of energy quanta, which condense in the vitreous body of the eye and in the cerebrospinal fluid in a state of sleep. In the metabolism of nutrient energy, other neurohormones can also participate with melatonin. First of all, this refers to dopamine, as evidenced, for example, by such experience. The intake of motilium (an antagonist of peripheral dopamine receptors) and

omeprazole (a hydrogen pump inhibitor) for two weeks along with a positive effect led to a decrease in libido, sleep disturbances (regular awakenings at three o'clock in the morning) and an increase in the allergic reaction of the skin (hives). Synchronization of these disorders with the melatonin synthesis kinetics (Fig. 18) allows them to be associated with hypertrophy of the hormonal function of melatonin, the cause of which may be a concentration imbalance between melatonin and dopamine.

Since the epiphysis is completely immersed in incompressible cerebrospinal fluid and close to it there is a large venous junction that includes a large cerebral vein of Galen (Fig. 16), the volume of the epiphysis, and hence the volume and pressure in its internal cavity [44] will pulsate. At the expansion stage, on the gas molecules in the volume and on the structures of the inner surface of the cavity, quanta of biogenic energy will condense, which at the compression stage can be translated together with metabolites into the parenchyma of the epiphysis, activating its metabolism, and also into the cerebrospinal fluid of the third ventricle.

## **5.2. Kinetic parameters of the physics of the brain**

The rhythm of some physical processes in the brain can be caused by periodic metabolic reactions. Such processes obviously include the pulsation of the neuroglia - 12 seconds the phase of tension and 240 with the relaxation phase, while their volume changes, their outgrowths swell and swell [45]. The vibrations of the chemical activity of the synapses have a time constant of the order of 100 ms, which corresponds to the total duration of the exciting and inhibitory postsynaptic potentials ~30 and ~70 ms, respectively. Given the predominance of circadian rhythms in chronobiology, it can be assumed that the basis of the mechanism of the pacemaker of the brain or heart is the connection of the electrical activity of special nerve cells with this or that periodic phenomenon of electromagnetic nature of geophysical or cosmic scale [46]. Spontaneous relic radiation, pulsations of the geomagnetic field and its periodic disturbances by the Sun, the Moon and other planets can serve as examples of such phenomena [47]. High sensitivity of pacemakers to weak external signals is achieved due to cooperative effects in the ordered beams of neurons of suprachiasmatic nuclei, the bundle of His and the nuclei of the reticular formation.

Figure 20. Amplitude-frequency ratios of bioelectric signals [46]

The brain rhythm frequency spectrum corresponds to the electrical activity of various structures in the brain hierarchy (Fig. 20). The stable rhythms of the EEG spectrum include: delta rhythm (0.5-4 Hz); theta rhythm (5-7 Hz); alpha-rhythm (8-13 Hz); mu-rhythm - similar in frequency-amplitude characteristics to alpha-rhythm but predominates in the anterior cortices of the cerebral hemispheres; beta-rhythm (15-35 Hz) and gamma-rhythm (above 35 Hz). Mu-rhythm, possibly associated with the electromagnetic activity of the eyes and the rhythm of scanning the EM-vortex of the frontal lobes of the brain. The cause of other rhythms can be electromagnetic oscillations that capture the cortex and various structures of the subcortex. In principle, for each type of oscillations in the EEG spectrum, capacitive-induction LC structures can be isolated in the brain and model their interconnection by an equivalent circuit of the oscillatory circuit, which has its own frequency according to (6).

For example, the alpha rhythm, responding to the background electrical activity of the cortex, maintains at the proper level the stability of the neocortical and thalamus connections. When removing the thalamus or cutting off its bonds with the bark, the alpha rhythm disappears. Right-left parts of the thalamus and the cortex of the hemispheres can be represented by dissimilar plates of two spherical capacitors, and the nerve connections between them (the radiance of the thalamus) will simulate ohmic connections and inductive coils in equivalent circuits of circuits operating at the alpha-rhythm frequency (alpha-circuit) (Fig. 21). The asymmetry of the inductive elements of the alpha contours of the right and left hemispheres can be the basis of their functional specification. The frequency of oscillations in the alpha contour is presumably given by the

pacemaker nuclei of the reticular formation, which is closely related to the thalamus. The characteristic time for tuning synchronized with the alpha rhythm is  $\sim 100$  ms.

Figure 21. Equivalent oscillatory circuits modeling the alpha rhythms of the brain.  $L$ ,  $L^*$ ,  $R$  - inductive and ohmic models of the radiance of the thalamus (sign  $*$ ) means a mirror inversion of the chiral structures of the right hemisphere);  $r$  - interthalamic fusion;  $C$  and  $U$  are the capacitance and potential difference between the thalamus and the cortex.

Currents in the nervous structures of the reticular formation and the medulla oblongata can generate vortex magnetic fields in the structures of the variolium bridge and the cerebellum (Fig. 22). The appearance of this formation, in principle, is isomorphic to c) the model of the transformed vibrational contour (Fig. 1). Consequently, pacemakers of the reticular formation can resonantly tune to oscillations of a standing EM wave of the geomagnetic field (see Section 2.4.2) and to regular perturbations of the geomagnetic field by solar activity or planets.

The time to assimilate one bit of visual information is 15 - 50 ms [28]. The time of the elementary mental act lies in the range of 150-300 msec [48]. From the evaluation of the speed of mastering the meaning of a readable text consisting of known words, it follows that on average, about 200 ms are required to understand the meaning of a single word. This time constant can be associated with the theta rhythm, which manifests cortico-limbic interactions, regulating emotions and mental activity [15].

Figure 22. Cerebellum and medulla oblongosa

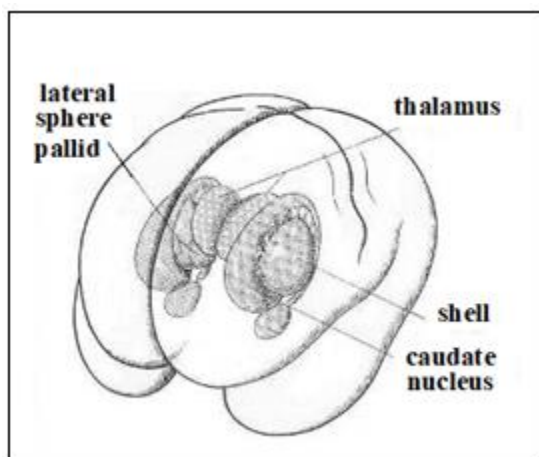

Fig. 23. Basal ganglion structures

A pair of equivalent vibrational circuits having a theta-rhythm frequency (theta-circuit) will be similar to the alpha-circuits (Fig. 21), but instead of the thalamus and its radiance, the corresponding structures of the hippocampus and basal ganglia (the shell, caudate nucleus). Since the characteristic times of transfer of PD within the brain structures are of the order of magnitude less than  $\sim 10$  ms, it can be assumed that the speed of the cogitative act is limited by the chemical mechanism of information coding, which requires the activation of synaptic connections.

The characteristic time of the kinetics of the energy consumption of the brain in the process of thinking and its subsequent recovery can be related to the kinetics of eye metabolism, the energy of which determines the intensity of the stimulating effect on the frontotemporal lobes of the EM vortex (Fig. 11). Metabolism of the vitreous eye is limited by the rate of its hydrodynamics, the characteristic time of which is  $\sim 900$  s. And for the restoration of this eye resource, a daytime sleep of  $\sim 15$  minutes is enough. Phylogenetically, this time constant of brain energy can be due to the biogenic effect of the decay products of the thermolysed neutron [6], whose lifetime is  $\sim 900$  s.

### **5.3. Nonlocal quantum correlations**

#### **5.3.1. Consciousness and memory.**

The physics of consciousness or self-consciousness, being identical with the physics of thinking and speech, is based on the ability of the brain to respond to external signals, transform them into electromagnetic codes of the neural network, remember and recognize these codes, transform and synthesize the template of them. All these operations are possible with the presence in the brain of physicochemical mechanisms of reading-activation and memorization-conservation codes. The process of reading and recognizing the thought-form itself implies the existence of a stable dynamic reference system of reference codes, which constitutes the physical basis of the subject's self-consciousness. This system is formed in the process of phylogenesis and ontogeny according to the genetic program with continuous influence on the brain through the sense organs (sight, hearing, touch, smell, taste) of the whole range of physical and social organizing factors. In the absence of the latter, the ontogeny of the brain normal from the child's birth does not reach the mental level at all. On the other hand, deaf-blind children from birth, having only tactile contact with the teacher, are able to form a sufficiently adequate reference frame reference system that allows them to learn the world and communicate with people.

The genetic program of the reference codes that determine the individuality of a person is laid already when the metric of the genetic material is formed in the process of fertilization of the female cell. The unfolding of this program at the stage of embryogenesis is subject to the law of fractal-resonant action [6], which is realized through the physical mechanisms of energy-information exchange and memory underlying the psycho- or spiritually-physical isomorphism.

Genetic codes, making up the basic level of memory, operate throughout the life of a person, determining the racial, sexual and mental characteristics of his brain physics. The next level of memory is made up of unconditioned reflexes, the principles of its organization are laid at the stage of morphogenesis. At the same stage, the chemical basis of the memory resource of the initial sensory impressions and sensations is created. Within the resource of unconscious memory, under the influence of social factors, an array of a reference system of reference codes of consciousness is formed. The mechanisms for memorizing and retrieving the necessary reference code combine the electrophysics and biochemistry of the brain with the physics of dynamical systems of QPH localized on the structural and functional elements of the brain.

The first, gene level of memory is realized spontaneously at the molecular-cellular level in the synthesis of nuclear DNA, which, in turn, programs the growth and functions of the nerve cell. In general, the thermodynamic features of the tertiary structure of protein molecules (DNA, hemoglobin, enzymes, etc.) allow them to condense thermal or metabolic QPH, transforming them into vibrational-rotational energy of atoms of characteristic amino acid groups. When the excitation energy of the threshold level is reached, it is transmitted along the fractal-resonance mechanism to the metabolite, thereby initiating its participation in the chemical synthesis of a completely defined structure. In this way, gene information can be transmitted from the molecular to the macroscopic level of the organization of living systems.

The following memory levels are formed by the development of stable neural connections between the zones of the neocortex and the basal ganglia, limbic brain, thalamus and cerebellum. The specialization of such memory blocks is determined by the functional dominance of its second element. Given the synchronism of the morphogenesis of the fronto-parietal lobes of the brain and the cerebellum, we assume that this block is the main repository of the base codes of consciousness frames. The background activity of this memory unit ensures continuity of orientation of the somatic and mental components of consciousness in space and time. The rhythm of this mode of consciousness can be set by an alpha contour, providing a link between the visual cortex, the cerebellum and the frontal lobes (Fig. 24).

Figure 24. Scheme of the structure (a) and connections with the cortex of the cerebral hemispheres; (b) cerebellum – layered "crystal" of the basic block of brain memory. Dotted lines layers and levels of the cerebellum organization are shown.

The switching of consciousness to the mode of thinking is associated with the replacement of the alpha rhythm with the theta rhythm and, accordingly, with the activation of the memory block of the mental reference codes, the key structures of which are obviously the basal ganglia. It can be assumed that the functional asymmetry of the brain and the very logic of thinking are the result of the synergy of the physics of chiral inductive-magnetic elements of the theta-contour (caudate nucleus), olfactory organ (hippocampus) and hearing (Ammon horn) in each hemisphere. Participation in the physics of thinking of the capacitive-electrical element of the organ of vision (retina) is evidently the activation of the basic memory block by the action on the frontotemporal lobes of the brain of the EM vortex of the eyes. A similar function of the activation of the parietal and occipital (preklinya, Fig. 11e) regions of the cerebral cortex, apparently, is performed by the second capacitively-electric element of the visual system - the external geniculate body. It may well be the generation of quasiphotons-phosphenes in the fusion-recombination of mirror-symmetric EFs from the right and left eyes.

The physics of thinking integrates in itself to some extent the functions of all brain structures. The morphological basis for such an association is the fluid system of the brain. At the initial stage of embryogenesis, the entire nervous system is localized in the neural tube [49], the inner layer of which subsequently becomes a single-connected inner surface of the ventricles of the brain and the central channel of the spinal cord. Subsequently, the cerebrospinal fluid, filling these volumes and communicating with the cisterns and outer shells of the brain (Fig. 16), assumes the role of an integrating "bus", on which, in one way or another, all the functional elements of the nervous system are closed.

### **5.3.2. The mechanism of quantum correlations**

Following the logic of [50], we model a hierarchy of physical states of structural and functional brain blocks by a multilevel fractal from local dynamical systems of QPH. The basic unit of this fractal, starting from the level of the neural network, to the hemispheres of the brain, is the LC-structure, isomorphic to the vibrational contour (Fig. 9, 21). The geometric and electrophysical parameters of LC structures will determine the type and energy of dynamic QPH, and their action should formally satisfy the fractal-resonance principle [6]. From chains of LC-circuits there are self-excited (reverberating by the principle of feedback) closed circuits in neural networks, which can correspond to images of perception or images of operative memory. The excitation data can be modeled by damped oscillations, linking their cyclicity and frequency with

Q-factor and resonance frequencies of LC-circuits, as well as with the length and degree of branching of the loop of the neural network. In addition to electrodynamics, in principle, quantum mechanics (Bose condensation, confusion of states), physics of wave and nonlinear processes (interference, holography, coherence) can be used to model the cooperative properties of systems of similar QPH.

The limiting time of a psychic reaction or mental act is of the order of  $\sim 100$  ms. During this time tens of thousands of synaptic connections are involved in the brain and tens of zones of the cortex and structures of the subcortex are activated. Even if the operations in the neural network are parallel and the associative and reflexive connections between the cortical zones and the memory blocks are high in order to ensure the purposefulness of the functional activity of the brain, a quantum mechanism of searching and selecting information must operate in it, the kinetics of which should not be limited by the rates of transport of matter and energy. The morphological basis of this mechanism is the single-connectedness of the aquatic environment of the brain and the fractality of its EM structure. For example, each layer of the basic memory block (Figure 24), consisting of a pair - a Purkinje tree cell and a lianon neuron [49], can be considered isomorphic to the entire fractal of the neural cortical and spinal neural connections, together with the vagus nerve (vagus). Isomorphism of the nerve cell - macrostructure provides high efficiency of the basic memory block of the reference codes with the maximum value of its specific capacity.

The interconnection of quantum systems can be of two types. The first one presupposes the overlapping of the wave functions of the electrons of two spatially separated structures of the nervous system of the brain. In the energy-information exchange, QPH of various types (solitons, phonons, EM quanta), and electron or proton (tunnel junctions) are involved. Such a relationship, in fact, is analogous to the mechanism of saltatory conductivity and is effective for chemically bound systems. The second type of connection - nonlocal quantum correlations [7] assumes an information exchange between isomorphous structures of the brain by the mechanism of fractal-resonant coupling [6]. This mechanism can be extended to the exchange of information between the brain and the environment. It operates at the molecular level with DNA replication, and at the socio-biological level, especially between mother and daughter.

In general, for the implementation of the mechanism of nonlocal correlations, systems must satisfy two requirements. The first is that in the embryonic state they must form a simply-connected system in a quantum state determined by one or another type of interaction (nuclear,

electromagnetic, weak, gravitational, biological, social). Examples: positronium, radioactive nucleus, protostar, DNA molecule, neural tube, embryo and the mother's body. The second requirement is called the inseparability or entanglement of states of chemically unrelated systems and consists in the presence of a mechanism of quantum correlation of the physical characteristics of states. For the above systems, their daughter correlating subsystems will be, respectively: two photons, products of radioactive decay, binary stars or star-planetary systems, split DNA, cerebellum and neocortex, mother and daughter.

The mechanism of quantum entanglement implies the preservation of the information connection between the daughter subsystems at the level of interactions that determine the intrinsic integrity of the subsystems. The universalism of quantum entanglement is genetically conditioned by the subordination of the process of formation of discrete forms of matter, and then of elementary particles to the bootstrap mechanism [6]. At the level of elementary particles and nuclei, on which nonlocal correlations are experimentally observed [7], the nature of information interactions has not yet been established, one can only assume that their kinetics is limited by the momentum transfer rate in the physical vacuum (ether)  $\sim 10^{22}$  cm/s [6]. At the same speed, obviously, information is exchanged at the level of social and space subsystems.

As a basis for the mechanism of entanglement of the structural and functional subsystems of the brain, it is possible to take the single-connected nature of its aqueous basis, thanks to which information exchange with a velocity  $V = C/n$  (5) is possible between systems of QPH. Submission of this exchange to the fractal-resonance principle of the action reduces its probabilistic nature to a purposeful selection between isomorphic structures of the pair, for which the level of entanglement of the states of QPH is maximal.

## 6. Conclusion

A century and a half ago Maxwell Maxwell linked the development of fundamental physics with the knowledge of the brain [5]. More than 30 years ago, F. Creek suggested that molecular biology can very well establish the biochemical basis of the most complex mental and mental functions of the brain, reaching a level of "biochemical theology" or "theochemistry" [51]. However, in 2000, F. Krik had already refrained from predicting the development of brain biochemistry, emphasizing only the *great importance of nonlinear dynamic systems in biology at all levels*. This clarification can easily be taken as an adaptation of the idea of Maxwell to

biological objects and conclude that the transition of brain biochemistry to "theology" can be realized only simultaneously with the replacement of the materialistic paradigm of physics by the spiritual. In other words, the physics of thinking can take place only as a natural theology or theophysics. The evolution of natural science already has one dialectical leap in the form of a transition from classical physics to quantum physics. Obviously, the next jump in the depths of natural science has ripened - from quantum physics to physics of spirit or theophysics [52]. For all its dramatic nature for the materialist physicists and idealist psychologists, this leap is inevitable, and taking into account this, an analysis of the probable path of its realization is carried out in this paper.
