Abstract: In recent years, demand has been increasing for target detection and tracking from aerial imagery via drones using onboard powered sensors and devices. We propose a very effective method for this application based on a deep learning framework. A state-of-art embedded hardware system empowers small flying robots to carry out the real-time onboard computation necessary for object tracking. Two types of embedded modules were developed: one is designed using a Jetson TX or AGX Xavier, and the other is based on an Intel Neural Compute Stick. These are suitable for real-time onboard computing power on small flying drones with limited space. A comparative analysis of current state-of-art deep-learning-based multi-object detection algorithms was carried out utilizing the designated GPU-based embedded computing modules to obtain detailed metric data about frame rates as well as the computation power. We also introduce an effective target tracking approach for moving objects. The algorithm for tracking moving objects is based on the extension of simple online and real-time tracking. It was developed by integrating a deep-learning-based association metric approach (Deep SORT), which uses a hypothesis tracking methodology with Kalman filtering and a deep-learning-based association metric. In addition, a guidance system that tracks the target position using a GPU-based algorithm is introduced. Finally, we demonstrate the effectiveness of the proposed algorithms by real-time experiments with a small multi-rotor drone.

Keywords: Multi-Target Detection and Tracking; Multi-copter Drone; Aerial Imagery, Image Sensor, Deep Learning, GPU-based Embedded Module, Neural Computing Stick; Image Processing.

1. Introduction

Target detection has attracted significant attention for autonomous aerial vehicles due to its notable benefits and recent progress. Target tracking with an unmanned aerial vehicle (UAV) can be used for intelligence, surveillance, and reconnaissance missions [1]. Target tracking can be used in autonomous vehicles for the development of guidance systems [2]. Pedestrian detection [3], dynamic vehicle detection and obstacle detection [4] can improve the features of the guiding assistance system. Object recognition technologies for self-driving vehicles have strict requirements in terms of accuracy, unambiguosity, robustness, space demand, and costs [5]. Similarly, object recognition and tracking features in an aerial vehicle can assist in drone navigation and obstacle avoidance. Visual recognition systems in a UAV can be used in many applications, like video surveillance, self-driving systems [6], panoramic aerial view for traffic management, traffic surveillance, road conditions, and emergency response, which has been the interest for transportation department for many years [2] [7].
Previously, target detection in drone systems has mostly used vision-based target finding algorithms. For example, a Raspberry Pi and OpenCV were used to find a target [8]. However, computer vision techniques might provide less accurate results and have issues in predicting unknown future data. On the other hand, machine-learning target-detection algorithms can provide a very accurate result, and the model can make predictions from unknown future data. Visual recognition systems involving image classification, localization, and segmentation have accomplished extraordinary research contributions [6]. Moreover, deep learning has made great progress in solving issues in the fields of computer vision, image and video processing, and multimedia [11]. Because of the critical advancements in neural networks, particularly deep learning [12], these visual recognition systems have shown great potential in target tracking.

On-board and off-board ground-based systems are promising platforms in this context. Most of the time, the aerial vehicle system cannot be equipped with heavy devices due to weight and power consumption. Therefore, off-board ground systems play a vital role. In some cases, communication with ground station could be impossible due to distance or coverage. An on-board system that can support both weight and power consumption would be a perfect framework for such a situation and environment.

An embedded real-object detection system was developed for a warning system using a UAV [9], but they used only one specific algorithm with different resolution as an input and one specific embedded module. In the present study, we used various algorithms and a different embedded system to execute the algorithms. The deep drone project used a Jetson GPU and Faster R-CNN to detect and track objects [10]. In our study, we used Jetson AGX Xavier for better performance.

A GPU enhances the performance in a deep-learning-based visual recognition system. However, such a system also has some disadvantages like more power consumption than CPUs, and they are obviously costlier than an embedded CPU system. These situations can be overcome by implementing a neural computing stick with a CPU device, which is a constraint for executing deep learning models. However, the developed system can be forced to perform efficiently by optimization in the processing unit. In this paper, we discuss an on-board and off-board system that was developed for an aerial vehicle using well-known object detection algorithms.

2. Hardware Development of the Drone Framework

The target detection and tracking system can be easily implemented in an aerial vehicle. The structure of the aerial vehicle is the same for all the algorithms except for some minor changes in the embedded system and the exterior body structure. The below figure represents the 3D cad design of our aerial vehicle. Figure 1 presents the 3D CAD design of our aerial vehicle. Table 1 presents the primary physical specifications of the drone system and the camera mounted on the drone. Figure 2 illustrates the embedded hardware setups used for the target detection and tracking system. Figure 3 shows the detailed hardware setup of the embedded systems used for the detection and target tracking system.

2.1. Technical Specifications of Different Embedded devices used for Target Detection and Tracking

Our main focus is on Jetson modules [13] for target detection. Other than the Jetson modules, we used GPU-constrained devices like Raspberry Pi [14], Latte Panda [15], and Odroid Xu4 [16]. A Movidius NCS [17] is used to thrust the processing power of these limited devices. Moreover, we tried a different approach where we transmitted the aerial image data to the ground station that is equipped with GTX 1080 [18]. The target detection output is directly from the ground station. Below, we give a brief discussion about the embedded devices.

2.1.1. Nvidia Jetson Modules (TX1, TX2 & AGX Xavier)

Nvidia Jetson devices are embedded AI computing platforms that provide high-performance, low-power computing support for deep learning and computer vision. Jetson modules can be flashed with Nvidia JetPack SDK which contains TensorRT, OpenCV, CUDA Toolkit, cuDNN and L4T with LTS Linux Kernel [19].

Jetson TX1 is the world’s first supercomputer on a module and can provide support for visual computing applications. It is built with NVIDIA Maxwell™ architecture and 256 CUDA cores delivering performance of over 1 teraflop [20].

Jetson TX2 is one of the fastest, most power-efficient embedded AI computing device. This 7.5-watt supercomputer on a module brings true AI computing at the edge. An NVIDIA Pascal™-family GPU is used to build it and loaded with 8GB of memory and 59.7GB/s of memory bandwidth. It includes an assortment of standard equipment interfaces that make it simple to incorporate it into a wide scope of hardware [21].

Jetson AGX Xavier has exceeded the limit capabilities of previous Jetson modules to a great extent. In terms of performance and efficiency in deep learning and computer vision, it has surpassed the world’s most autonomous machines and advanced robot [22]. This powerful AI computing GPU workstation works under 30W. It is built around an NVIDIA Volta™ GPU with Tensor Cores, and 2 NVDLA engines, and an 8-core 64-bit ARM CPU. NVIDIA Jetson AGX Xavier is the most recent expansion to the Jetson stage [23]. This AI GPU computer can provide unparalleled 32 TeraOPS (TOPS) of the peak computation in a compact 100-mm x 87-mm module form-factor [24]. The Xavier’s energy efficient module can be deployed in next-level intelligent machines for end-to-end autonomous capabilities. Table 2 shows the basic comparison between all of them.

2.1.2. GPU-constraint Devices (Raspberry Pi 3, Latte Panda & Odroid Xu4)

Raspberry Pi 3 is a tiny, credit card size, cheap, single-board computer that can be used with a display, mouse, keyboard, power supply, micro SD card with installed Linux Distribution. It can be used as a fully-fledged computer with basic computer tasks like games, spreadsheet work, etc. Raspberry Pi is used mainly to construct hardware project, improving programming skill, house automation and industrial appliance [25,26]. Raspbian OS [27] is used to flash the Raspberry Pi 3.

LattePanda is the first development board to operate a full version of Windows 10 OS. It is turbocharged with an Intel Quad Core processor and has excellent connectivity, with three USB ports and integrated WiFi and Bluetooth 4.0 [28]. The Arduino co-processor inside latte panda can be used to control interactive devices using thousands of plug-and-play peripherals. However, we flashed the whole system with Lubuntu [29] Linux OS to suit our purpose.

ODROID-XU4 is a very powerful and energy-efficient computing device in a small form factor that offers open-source support with various types of OS Ubuntu 16.04 and Android 4.4 KitKat, 5.0 Lollipop and 7.1 Nougat. ODROID-XU4 has amazing data transfer speeds because of the support of eMMC 5.0, USB 3.0 and Gigabit Ethernet interfaces which are required to support advanced processing power on ARM devices. Therefore, it provides faster booting, web browsing, networking, and 3D games [30,31]. Table 3 shows the basic comparison between all of them.

Table 3. Basic Comparison between Raspberry Pi 3, Latte Panda and Odroid Xu4
2.1.3. Movidius Neural Computing Sticks

Deep neural networks (DNNs) can be deployed through Intel Movidius Neural Compute Stick (NCS) using the Intel Movidius Neural Compute SDK (NCSDK) into the constrained devices such as raspberry pi, latte panda and Odroid. The Intel Movidius Neural Compute API (NCAPI) is included in the NCSDK to compile, profile and validate DNN using C/C++ or python [17]. The NCSDK has two general usages [32]:

- The tool in NCSDK can be used for profiling, tuning, and compiling a DNN model on the host system.
- NCAPI can be used to access the neural computing device hardware to accelerate DNN inferences by prototyping a user application on the host system.

The NCS is designed for image processing using Deep Learning models. Image processing is very resource-intensive and often runs slowly on devices such as the Raspberry Pi, LattePanda, Odroid. The Movidius NCS speeds up the deep-learning-based model on constrained devices that have less processing power for deep learning models. The constrained devices are Raspberry Pi, latte panda, Odroid, etc. The dimension of the NCS is about 7-cm x 3-cm x 1.5-cm, and it has a USB3 Type A connector. NCS has a low power high-performance Visual Processing Unit (VPU) similar to the “follow me” mode of DJI drones for visual-based functionality [33]. It can save space, money, bandwidth, weight, and power while building drone hardware.

2.2. The Architecture of Developed Embedded System

In this section, we discussed elaborately about the systems that we have used with the main framework of the drone. The purpose of the vehicular system which we developed in this study is to find targets while navigating and following paths, as shown in Figure 4. Moreover, our vision is to compare all the system with respect to a different point of view.
2.2.1. On-Board GPU System

The on-board GPU system takes the aerial footage and feeds the data to the onboard tx1/tx2, as shown in Figure 5(a-b). The system generates a detection result frame with a name and confidence percentage. In this process, TX1/TX2 is responsible for processing the whole algorithm and streaming the data over a network. The ground station that is connected with a similar network receives the streaming data and displays the results. From the monitoring output, it is also possible to obtain the detected target name, confidence, and notification. Later, we implemented similar steps to Jetson AGX Xavier mentioned, as shown in Figure 5(c). It seems that the powerful Xavier GPU system can perform well and efficiently with object detection algorithms like YOLO, SSD, and RCNN.
2.2.2. Off-board GPU-Based Ground Station

An on-board system usually performs all the work by itself, but in this system, the on-board device performs only part of the job. The on-board device is responsible for streaming the captured image data. A real-time imaging processor and transmission system setup were established on the UAV to communicate with the ground station. The GPU-based ground station receives the data, and the algorithm uses the GTX 1080 GPU system [18] to process the raw image data.

Figure 6 shows a diagram of the whole off-board GPU-based ground station. Later, the detected target is displayed with name and confidence in the monitor of the ground workstation. We used python socket [34] to transmit the data over the network to the specific IP address of the drone. The GTX 1080 is a very powerful system for detecting an object or target and is fast and smooth in this system.

![Diagram of the off-board GPU-based ground station](image)

**Figure 6.** Target detection using GPU-based ground station from an Aerial Vehicle

2.2.3. On Board GPU-constraint System

To construct the on-board system, we used cheap devices like the Raspberry Pi, which we combined with a neural stick. We have tried SSD-Mobilenet [35,36] and YOLO object detection algorithm [37] in this framework. Similarly, we tried Latte Panda and Odroid XU4 as the replacement for the Raspberry Pi to check the performance of output results, as shown in Figure 7. We also performed an experiment with SSD-Mobilenet without the use of the neural stick in the system.

![Diagram of the on-board system](image)

(a) (b)
Figure 7. On-board target detection drone system using GPU-constraint devices like (a) Raspberry Pi (b) Latte Panda (c) Odroid Xu4

2.3. Python socket server to send an image to the GPU-based ground station

Socket programming [34] is helpful for communication between a server and a client that are on two different systems. It is a way of connecting two nodes where one node uses a particular IP address to reach to another node. A server that will broadcast the aerial image must specify specific IP and port using a specific network where the client is also connected. The server initiates and always listens to the incoming connection. On the other hand, the client on the same network reaches out to the server and obtains the broadcast message, which is the aerial image in our case.

Using a GPU-based ground station as a client, we use a continuous image stream for our purpose. This socket program shows a small lag in the incoming image stream depending on the type of network to which both the server and the client are connected. However, it does not drastically affect the performance of target detection. This communication tool is used in our off-board GPU-based ground station system.

3. Implemented Object Detection Algorithm in the Drone System

Figure 8 shows a diagram of the deep learning algorithm list used on the embedded systems for target tracking system.

Figure 8. List of deep learning algorithm implemented in the aerial Vehicle (a) On-board embedded GPU system; (b) Off-board GPU-based Ground Station; (c) On-board GPU-constraint system
3.1. You only look once (YOLO) – Real-Time Object Detection

You only look once (YOLO) [37], is a fast object detection algorithms. Although it is no longer the most accurate object detection algorithm, it is a very good choice when real-time detection is needed without loss of too much accuracy. YOLO uses a single CNN network for both classification and localizing an object using bounding boxes [38]. This is the architecture of YOLO is shown in Figure 9.

![Figure 9. Architecture of YOLO](image)

3.1.1. YOLOv2

YOLO provides real-time processing with high accuracy, but it has higher localization errors and lower recall response than other region-based detector algorithms [39]. YOLOv2 [40] is an upgraded version of YOLO that overcomes the lower recall response and increases the accuracy with fast detection. The changes in YOLOv2 are briefly discussed below:

- The fully connected layers that are responsible for predicting the boundary box are removed.
- One pooling layer is removed to make the spatial output of the network to 13×13 instead of 7×7.
- The class prediction is moved from the cell level to the boundary box level. Now, each prediction has four parameters for the boundary box [39].
- The input image size was changed from 448 × 448 to 416 × 416. This creates odd-numbered spatial dimensions (7×7 vs. 8×8 grid cell). The center of a picture is often occupied by a large object. With an odd number of grid cells, it is more certain on where the object belongs [39].
- The last convolution layer is replaced with three 3 × 3 convolutional layers, each outputting 1024 output channels to generate predictions with dimensions of 7 × 7 × 125. Then, a final 1 × 1 convolutional layer is applied to convert the 7 × 7 × 1024 output to 7 × 7 × 125 [39].

3.1.2. YOLOv3

The output object classes are mutually exclusive since classifiers assume that output labels are mutually exclusive. YOLO has a softmax function to convert scores into probabilities that add up to one. YOLOv3 [41] uses a multi-label classification. Non-exclusive the output labels can show score which is more than one. Instead of using the softmax function, YOLOv3 use independent logistic classifiers to calculate the likeliness of the input belonging to a specific label. YOLOv3 uses binary cross-entropy loss for each label instead of mean square error in calculating the classification loss. Avoiding the softmax function reduces the computation complexity [39]. Figure 10 [42] shows the neural architecture of YOLOv3.
3.1.3. YOLOv2 Tiny & YOLOv3 Tiny

Tiny YOLO is based on the Darknet reference network [43] and is much faster but less accurate than the normal YOLO model [40,41]. The full YOLOv2 model uses three times as many layers as tiny and has a slightly more complex shape. The “tiny” version of YOLO has only 9 convolutional layers and 6 pooling layers. Since Tiny YOLO uses fewer layers, it is faster than YOLO but also a little less accurate.

3.1.4. YOLO-9000

YOLO-9000 [40] a better, faster and stronger version of YOLO. In below, brief points are shown regarding the matter of making it better, faster and stronger [44].

The approaches for better:

- **Batch Normalization:** Batch normalization is used in all convolutional layers, which helps to obtain more than 2% improvement in mAP.
- **High-Resolution Classifier:** The classification network is fine-tuned on 448x448 images instead of trained with 224x224 images. This helps the network perform better at higher resolution. This high-resolution classification network gives an increase of almost 4% mAP.
- **Convolutional with Anchor Boxes:** In YOLOv2, anchor boxes are adopted while removing all fully connected layer. One pooling layer is removed to increase the resolution of the image output. This enables more boxes to be generated, which improves the recall from 81% (69.5 mAP) to 88% (69.2 mAP) [40].
- **Direct Location Prediction:** Prediction becomes easier if the location is constrained or limited. YOLO9000 predicts location coordinates relative to the location of the grid cell, which bounds the ground truth to fall between 0 and 1. It does not make predictions by using the offset to the center of the bounding box [44].
- **Fine-Grained Features:** A pass-through layer is included like ResNet to use fine-grained features for localizing smaller object.
- **Multi-Scale Training:** The same network can predict at different resolutions if a dataset with different resolutions is utilized while training the network. That means that the network can make predictions from a variety of input dimensions.
The approaches for faster:
- Instead of using VGG-16, a custom network of 19 convolutional layers and 5 max-pooling layers is used. The custom network that is used by the YOLO framework is called Darnet-19 [45].

The approaches for stronger:
- Hierarchical Classification: To build a hierarchical prediction, several nodes are inserted. A semantic category is defined for each node at a level. Therefore, different objects in one image can be amalgamated into one label since they are from one higher-level semantic label.
- Joint Classification and Detection: For training a large-scale detector, two types of datasets are used. A traditional classification dataset that contains a large number of categories, and a detection dataset [45].

3.2. SSD: Single Shot MultiBox Detector

A typical CNN network gradually reduces the feature map size and expand the depth toward the deeper layers, as shown in Figure 11. Larger receptive fields are covered by the deep layers, which creates more abstract representation. Smaller receptive fields are covered by the shallow layers. Thus, the network can use this information to predict big objects using deeper layers and to predict small objects using shallow layers [36,46]. The main idea is to use a single network for speed and to remove region proposal. It adjusts the bounding box according to the prediction. Last few layers are responsible for smaller bounding box prediction which is also responsible for prediction of different bounding boxes. The final prediction is a combination of all these predictions. To better understand SSD, its structure is explained by its name [47]:
- Single Shot: The tasks of object localization and classification are executed in a single forward pass of the network.
- MultiBox: Multibox is the name of a technique for bounding box regression developed by Christian Szegedy et al. for fast class-agnostic bounding box coordinate proposals [48,49].
- Detector: The classification of a detected object is performed by the network, which is called the object detector.

Figure 11. The architecture of SSD [36]

3.3. Region-based Convolutional Network method (R-CNN) for object detection

The goal of R-CNN [50] is to correctly identify the main objects through the bounding box in the image. R-CNN creates bounding boxes of proposed regions using a technique called selective search [51]. At a high level, Selective Search shown in Figure 12, looks at the image through boxes of different sizes and each size group together to identify objects. Once the process is completed, R-CNN deforms the region to a standard square size and passes it to the modified version of AlexNet to find the valid
region. In the final layer of the CNN, R-CNN adds a Support Vector Machine (SVM, which simply classifies by determining the possibility of finding an object and the object name [52].

![Figure 12](image)

**Figure 12.** After creating a set of region proposals, R-CNN uses a modified version of AlexNet to determine the valid region [50]

3.3.1. Faster R-CNN

R-CNN works really well but is quite slow. One reason is that it requires a forward pass of the CNN (AlexNet) for every single proposed region for every single image. Another reason is that it has to train three different models separately: the CNN to generate image features, the classifier to predict the class, and the regression model to tighten the bounding boxes [52]. Faster R-CNN adds a fully convolutional network on top of the features of the CNN known as the Region Proposal Network to speed up the region proposal [53].

3.3.2. Mask R-CNN

Mask R-CNN is an extended version of Faster R-CNN for Pixel Level Segmentation. Mask R-CNN [54] works by inserting a branch to Faster R-CNN that adds a binary mask to determine whether a given pixel is part of an object. The branch is a fully convolutional network on top of a CNN-based feature map [52]. Once these masks are generated, Mask R-CNN amalgamate them with the classifications and bounding boxes that results from Faster R-CNN. Overall, it generates precise segmentation.

3.4. DeepLab-v3 Semantic Segmentation

We implemented Tensorflow’s Deeblap Model for real-time semantic segmentation in embedded platforms [55,56]. It built on top of a powerful convolutional neural network (CNN) backbone architecture [57,58] to obtain the most accurate results, which are intended for server-side deployment. DeepLab-v3 is extended by including a simple decoder module to refine the segmentation results, especially along object boundaries, which are very effective. Depth-wise separable convolution was later used in both decoder modules and Atrous Spatial Pyramid Pooling [59]. As a result, the output is faster and stronger encoder-decoder network for semantic segmentation.

4. Implemented Target Tracking Algorithm in the Drone System

There are many target tracking algorithm available for both multiple objects and a single object. Most of them use conventional methods and neural networks for tracking. We implemented Deep SORT [60], which seems feasible to track objects in real-time using our own hardware system.

The purpose of this project is to add object tracking to YOLOv3 [41] and achieve real-time object tracking using simple online and real-time tracking (SORT) algorithm with deep association metric (Deep SORT) [60]. The algorithm integrates appearance information to enhance the efficiency of SORT [61]. Thus, it is possible to track objects for a longer time through visual occlusions. It also effectively reduced the number of identity switches by 45%. A large-scale person re-identification dataset was used in pre-training. According to their paper, experimentation also shows overall performance at high frame rates.

SORT has a flaw in tracking through occlusions since an object typically needs to stay in the frontal view of the camera. This issue is successfully overcome by using a more informed metric that combines motion and appearance information instead of the association metric. Specifically, a convolutional neural network (CNN) is implemented after it is trained using a large-scale person re-identification dataset to distinguish pedestrians.

The Hungarian algorithm is used to solve the association between the predicted Kalman states and newly arrived measurements. The mathematical formulation was solved by integrating motion and appearance information through the combination of two appropriate metrics. Both metrics were combined using a weighted sum to build the association problem, and the following equation was presented [60].

\[ c_{ij} = \lambda d^{(1)}(i, j) + (1 - \lambda)d^{(2)}(i, j) \]  \hspace{1cm} (1)

Where an association admissible is called if it is within the gating region of both metrics [60]:

\[ b_{ij} = \prod_{m=1}^{2} b_{ij}^{(m)} \]  \hspace{1cm} (2)

Algorithm 1 is directly taken from deep SORT [60] and displays the matching cascade algorithm that assigns priority to more frequently seen objects. The inputs are the track index \( T \), detection index \( D \), and maximum age \( A_{\text{max}} \). The association cost and gate matrix are computed are line 1 and line 2. The linear assignment problem of increasing age is solved by iterating track age \( n \). The subset of tracks \( T_n \) that have not been associated in the last \( n \) frames of detection is selected in line 6. The linear assignment between tracks in \( T_n \) and unmatched detections \( U \) is solved in line 7. The set of matches and unmatched detections is updated in line 8 and 9. Later, the set value is return in line 11. Like the original SORT algorithm [61] intersection over union association is executed in the last matching stage. The execution of the set of unconfirmed and unmatched tracks of age \( n = 1 \), helps to account for sudden appearance changes.

**Algorithm 1** Matching Cascade

**Input**: Track indices \( T = \{1, \ldots, N\} \), Detection indices \( D = \{1, \ldots, M\} \), Maximum age \( A_{\text{max}} \)

1. Compute cost matrix \( C = [c_{ij}] \) using Eq.1
2. Compute gate matrix \( B = [b_{ij}] \) using Eq.2
3. Initialize the set of matches \( M \leftarrow \emptyset \)
4. Initialize the set of unmatched detections \( U \leftarrow D \)
5. for \( n \in \{1, \ldots, A_{\text{max}}\} \) do
6. \( x_{ij} \leftarrow \text{min cost matching } C, T_n, U \)
7. \( M \leftarrow M \cup \{(i, j) | b_{ij}, x_{ij} > 0\} \)
8. \( U \leftarrow U \setminus \{j | \Sigma_i b_{ij}, x_{ij} > 0\} \)
9. end for
10. return \( M, U \)

A huge amount of data is needed for feasible people tacking based on deep metric learning. A CNN architecture was trained on a large-scale person re-identification dataset [62], which contains over 1,100,000 images of 1,261 pedestrians. **Table 4** presents the CNN architecture of its network [60].
A wide residual network [63] with two convolutional layers followed by six residual blocks is used in their architecture. The final batch and $l_2$ normalization projects feature onto the unit hypersphere.

4.2. Guiding the UAV toward the target using YOLOv2

The purpose of this algorithm is to fly the drone toward the target using only a detection algorithm. In this case, we used a person as a classifier and calculated the area of the bounding box of the person from a certain safe distance, which will be the final goal for the drone. **Algorithm 2** presents the guidance algorithm toward the target. We have used YOLOv2, but it can be applicable to our algorithms as well. Using YOLOv2 algorithm, we easily can obtain coordinates for the bounding box and calculate its center.

Initially, the algorithm either looks for target $N = 1$ in step 1 or it does nothing and waits for the target like in step 11. If there is a target and it is person $L = 1$, the algorithm will loop from step 4 to step 8. In step 4, Area of the bounding box $A$ is calculated as $A = \text{height} \times \text{weight}$. In step 5 and step 6, it calculates $\text{Error}_{\text{center}}$ and $\text{Error}_{\text{area}}$ which value will be used for yaw angle and forward velocity, respectively. The algorithm will perform step 7 until $\text{Error}_{\text{center}} = 0$ and step 8 until $A_{\text{max}} \leq A$.

**Algorithm 2** Following target

**Input:** Class for person $L = 1$, Area of the bounding box $A = \text{height} \times \text{weight}$, Maximum area $A_{\text{max}} = \text{constant}$, Center of the whole image $C_{\text{image}} = \text{const}$

**Output:** $\text{Error}_{\text{center}} = C_{\text{image}} - C_{\text{bounding}}$, $\text{Error}_{\text{area}} = A_{\text{max}} - A$

1: Look for target $N$
2: if $N = 1$ then
3:   if $L = 1$ then
4:     Calculate $A$ & $C_{\text{bounding}}$
5:     $\text{Error}_{\text{center}} = C_{\text{image}} - C_{\text{bounding}}$
6:     $\text{Error}_{\text{area}} = A_{\text{max}} - A$
7:     Repeat step 5 until $\text{Error}_{\text{center}} = 0$ & use $\text{Error}_{\text{center}}$ for yaw angle
8:     Repeat step 6 until $A_{\text{max}} \leq A$ & use $\text{Error}_{\text{area}}$ for forwarding velocity
9:   end if
10: else
11:   Do nothing
12: end if

5. Results
In this section, we present the experimental results from the aerial vehicle and their performance according to the systems we used in the aerial vehicle.

5.1. Detection Results with classification from Drone using on-board GPU system

**Figure 13** below shows the result of target detection with bounding boxes and confidences levels from the on-board GPU system. **Figure 13(a)** shows the segmented result from the UAV using Xavier as on-board GPU system. When the person is small or out of the field of view, this algorithm is unable to detect that person well. On the other hand, using Faster R-CNN for detection shows a very accurate result but reveals a very low-performance rate, as shown in **Figure 13(b)** and **Figure 13(d)**.

The YOLOv2 algorithm reveals a satisfying result in terms of performance rate, but it can only detect the person from less than 20-meter away, as shown in **Figure 13(c)** and **Figure 13(g)**. But it is possible to increase the input image dimension in order to detect a person from a far distance. In that case, the performance rate will be reduced in terms of frames per second (FPS). Our input dimensions were 416 × 416 for all the YOLO detection algorithms. More significantly, YOLOv3 showed more accurate results even from a far distance because of its powerful 75 convolutional layers, as shown in **Figure 13(e)**, (f) and (i).

5.2. Detection Results with classification from Drone using GPU-based ground system

Figure 14 shows the target detection results in the GPU-based ground system. Figure 14(a) shows the segmented result from the off-board GPU system. The aerial image input comes from the Odroid XU4 device which is attached to the drone. Figure 14(b) and Figure 14(h) shows the output of YOLOv3 in this system. Moreover, we implemented Mask R-CNN using this system, as shown in Figure 14(d). This system has a latency gap depending on the communication system, but it does not affect the performance rate of the algorithm. A wide-range of Wi-Fi network module is used to stay connected to the network for both the client and the server.

5.3. Performance Results between On-board and Off-board system

The performance results in form of FPS are shown in Table 5. This table provides a quantitative comparison between on-board embedded GPU system and off-board GPU-Based Ground Station. This quantitative comparison will change with the input dimension of the image. However, using this table, one can choose the best algorithm and system for a specific operation.

5.5. The object Detection result of On-board GPU-constraint System

**Figure 16** shows the output result of object detection from Movidius NSC with Odroid xu4. This system is a suitable package for low-payload UAV and cheaper system. Although the performance rate is not as satisfactory as that of an on-board embedded system, a small task can be done using this system. It is a valid option if either cost, space or thermal limitation is considered. Movidius has its own heatsink that is made of the metal fin to help with cooling.

5.6. Performance Results of On-board GPU-constraint System

The quantitative performance results in form of FPS are shown in **Table 6** for on Board GPU-constraint systems like Movidius NCS with raspberry pi, Latte panda and Odroid xu4. This system has the potential to accelerate the interface where a low-power edge device cannot perform it alone.

Figure 17. Average GPU usage percentage form (a) Xavier (b) TX2

Figure 18 presents the memory usage in MB and the average CPU percentage usage while running different algorithms in the embedded systems like AGX Xavier. It seems CPU percentage is almost similar for all the algorithm(near to 4200). In the case of the TX2 case, the CPU usage is near to 3500 for all the algorithms.

![Memory Usage](image3.png)

![Average CPU Usage](image4.png)

Figure 18. (a) Memory usage (b) Average CPU usage percentage in Xavier

5.8. Guiding the UAV toward the target

Figures 19 represents the error plot between the center of the image and the center of the target using the YOLOv2 algorithm. The algorithm reduces the error between target and image center using the yaw movement of the drone. Meanwhile, it also attempts to reduce the error between the area of the bounding box of the target and the maximum given area using forward movement. The forward movement stops when it reaches the maximum given area specified for it. Similarly, if the error increases in a negative direction, the UAV uses backward movement.
The TX2 embedded module is used to guide the UAV. The error between two centers is used as feedback to the yaw angle of the vehicle. The final error is equivalent to zero, and the UAV is less than 1 meter from the target. We can use this algorithm to follow the target. Accuracy and high frame rate are the major requirements for this algorithm. Because of inconsistent detection, the UAV will cause shaky movement, and a low-performance rate will sabotage the process of the algorithm.

**Figure 19.** Plot diagram of error between image and target center vs. distance

6. Discussion

Since the main focus of this paper is on target detection from a drone, we first need to figure out which algorithm provides faster and more accurate results even from far distances. Even though YOLOv2 is faster and accurate, it cannot detect objects properly from a far distance. If the distance between target and drone is more than 20 meters, YOLOv2 weight becomes unable to detect human. Because of YOLOv3’s architecture, it can detect a target even at 50 meters away from the drone. Therefore, we tried to implement Deep SORT with YOLOv3 in a Jetson Xavier for tracking a target.

YOLO Tiny version is not suitable for target detection since it is inaccurate and it is hard to detect objects from a far distance. The target tracking algorithm works well from 20-30 meters away, because within this range the resolution of the feature from image remains visible to track the features. It becomes harder to track properly if the tracking object loses its feature due to far distances. Deep SORT provides a tracking result by counting the target of similar features. But in some case, it lost track of a counted feature and considered it as a new target.

It is clear that there is an influence of the input resolution on the neural network of the algorithm. The detection frame rate changes with respect to the input dimension that is fed to the neural architecture of the YOLO [9]. In the case of YOLO, we used $416 \times 416$ as our input dimension in the configuration file of the YOLO while executing target detection algorithm.

More significantly, the guiding algorithm to follow the target for person works less than 20-meters away from the target since person detection using YOLOv2 does not work after that limit. The guiding algorithm is purely based on the detection result and the coordinates of the bounding boxes. A poor detection result or poor tracking of the bounding box divert the drone in the wrong direction. This algorithm also has another limitation. When it faces multiple targets of a similar class, it chooses randomly in between them to track. Further research is needed to make the algorithm more robust for such scenarios.
7. Conclusions

From the experiments on different GPU systems, it is evident that Jetson AGX Xavier is powerful enough to work as a replacement of GPU system like Nvidia GTX 1080. All sorts of contemporary target detection algorithm perform very well in Jetson Xavier. Jetson TX1 is feasible if the user uses a small weight or model like YOLOv2 tiny. Because YOLOv2 and v3 tiny shows a reasonable FPS results for object detection, but they are not good enough to detect a target from a far distance. Moreover, the confidence output for using the weight of YOLO tiny is very low.

Jetson Tx2 is a moderate GPU system. Performance is not like that os the Xavier, but it shows outstanding results in the case to YOLOv2 and SSD-Caffe. If there is a limitation in drone weight and power consumption, a neural computing stick attached to the system are quite helpful. Among the three on-Board GPU-constraint Systems, Odroid XU4 with NCS shows better performances. We also presented the algorithm procedure for tracking with the respective embedded system. We also presented the runtime, GPU consumption and size of the platform used for the experiment.

Author Contributions: For this research article, methodology, software, validation, formal analysis, investigation, resources, data curation, writing, visualization and supervision section is contributed by 1st Author Sabir Hossain. Professor Dr. Deok-jin Lee contributed to conceptualization, project administration, funding acquisition, initial draft, review, resources and supervision.

Funding: This [paper/research/work/...] was supported by Korea Institute for Advancement of Technology(KIAT) grant funded by the Korea Government(MOTIE) (N0002428, The Competency Development Program for Industry specialist). This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (NO.2019R1F1A1049711).

Acknowledgments: I would like to express my special thanks of gratitude to my supervisor Professor Deok-jin lee for his guidance and support through this paper. I would also like to pay my deep sense of gratitude to all CAIAS (Center for Artificial Intelligence and Autonomous System) lab members for their support and CAIAS lab for providing me all the facilities that were required from the lab.

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the results.
