Abstract: The kinetics of the hydrolysis of hyaluronic acid (HA) of cosmetic fillers using the homogenate of the red king crab hepatopancreas was studied for the first time. Turbidimetric analysis of the reaction mixture revealed a bell-shaped time dependence of aggregation formation. The HA fillers were examined by atomic force microscopy (AFM) and it was found that they were represented by spherical-like structures. These structures were disrupted under the action of the homogenate of the red king crab hepatopancreas. It was shown that the prepared homogenate has the activity which is similar to that observed in the commercially available hyaluronidase products. The preparation with hyaluronidase activity obtained from the red king crab hepatopancreas could be used as potentially safe product for treating filler complications.

Keywords: treating filler complications, hyaluronidase, red king crab, hepatopancreas, hyaluronic acid (HA), hyaluronidase activity, turbidimetric method, atomic force microscopy (AFM), Revofil Ultra filler, Hyaluform deep filler, Lydase, Liporase.

1. Introduction

The increasing popularity and relatively affordable prices of contour plastic using HA-based fillers are followed by an increasing rate of cases of unwelcome effects and hypercorrection. The main complaints of patients after contour plastic are dissatisfaction with the aesthetic appearance, swelling, and hypercorrection. Sometimes, the HA injection triggers the process of acute inflammation, which requires quick intervention and removal of HA. Development of safe and effective way to rule out the negative effects of HA injections is therefore an urgent issue for cosmetology and medicine. Moreover, it is known that a high content of HA around cancer cells increases their resistance to the immune system, positively influences the ability of cancer cells to migrate, and therefore raises probability of metastatic spreading. As a consequence, the use of hyaluronidases in the treatment of cancer is crucial issue.

HA is a high molecular weight negatively charged polymer, glycosaminoglycan, consisting of repeating disaccharide units (D-glucuronic acid and N-acetyl-D-glucosamine) linked by β -1,4 and β -1,3 glycosidic bonds. Depending on the source of HA, disaccharide units can be repeated 2000–25000 times (10^6 – 10^7 Da). In an aqueous environment, HA has a complex secondary and tertiary structure. In an electron microscope, HA is observed as a cluster of interwoven filaments or star-shaped leaves formations, the filaments can intertwine [1,2]. It forms loops and loose glomus. Quite the same result was obtained by AFM method [3]. HA is involved in the proliferation, differentiation and migration of cells, also it is the main component of the synovial fluid and extracellular matrix, and it regulates water balance.

Due to the chemical properties of HA, numerous approaches were developed for its chemical modification, on an industrial scale as well, which contributed to the emergence of a number of HA

forms of medication successfully used in medicine and cosmetology. Most commercially available fillers contain high molecular weight (about 1 MDa or even higher) and low molecular weight (several hundred kDa) HA molecules. Furthermore, high-molecular weight HA molecules often contain transverse covalent cross-links between themselves, and are therefore less susceptible to degradation by endogenous hyaluronidases [4]. Low molecular weight forms of HA do not contain cross-linking and provide lubrication during injection. The ratio of the two forms varies from product to product (Table A1).

Up to the present the hyaluronidase injection directly into the HA area is the most reliable and painless way to manage the adverse events. A positive effect is achieved because the enzyme degrades the polymeric form of HA to its monomers. HA-based fillers produced by different manufacturers are degraded in different efficiency by hyaluronidase. In vitro studies have shown differences in degradation of cosmetic preparations of HA with hyaluronidase (bovine or ovine testis), as a result, determination of the correct dosage of hyaluronidase is quite a challenge [4,5].

Previously, hyaluronidase activity was detected in the enzyme complex of the hepatopancreas homogenate of the red king crab *Paralithodes camtschaticus* [6]. In this study, the molecular weight of HA after incubation with the collagenolytic protease complex from the hepatopancreas was estimated with the help of capillary viscometer method. The authors seem to think that this hyaluronidase activity belongs to some (or several) of the nine proteases of the complex. Indeed, the several cases describe of broad specificity of enzymes. For example, some lipase and papain enzymes hydrolyze chitosan [7,8]. It is also likely that hepatopancreas of the red king crab in addition to the proteases, contains hyaluronidase. Representatives of malacostraca class (lobster *Nephrops norvegicus*, krill *Euphausia superba*), which includes the red king crab, contain hyaluronidases; their biochemical properties are characterized [9,10]. The hyaluronidase activity of hepatopancreas homogenates of some shrimps is shown [11]. At the moment, the structure of hyaluronidases of this class of animals has not been studied at all. In the GenBank database there is only one predicted gene of a representative of this order—shrimp *Penaeus vannamei*, NCBI Reference Sequence: XM_027376109.1.

Summing up, the commercial species of crustaceans are a promising source of hyaluronidase production for the needs of cosmetology and medicine. Considering that hepatopancreas of the red king crab is a commercial waste, this raw material is available for large-scale processing in order to obtain a cosmetic hyaluronidase product.

In this study, using the turbidimetric method and AFM, we investigated the degradation of HA of fillers with the help of commercially available hyaluronidases and the hyaluronidase of the red king crab hepatopancreas that we are investigating. The results of this work show the comparable effectiveness of all the studied hyaluronidases and consequently demonstrate the opportunities to create a new hyaluronidase product based on the red king crab hepatopancreas. In addition, the results of AFM provide insights into the structural transformations of filler HA following exposure of hyaluronidases.

2. Results

2.1. Turbidimetric analysis of HA-based fillers

We used a turbidimetric method for determination of hyaluronidase activity. The turbidimetric method, in contrast to the method for measuring the viscosity of HA solution, is less laborious and requires a small amount of substrate. This method is based on the property of high molecular weight HA to bind to albumin in acidic conditions and form aggregates, which scattered light is registered by the light-scattering method or the optical density measurement of the sample. As high molecular weight forms of HA transit to low molecular weight (due to hydrolysis), the ability to form aggregates disappears. This phenomenon underlies the determination of hyaluronidase activity by this method and allows kinetic studies. Previously, it was implicitly shown that the average molecular weight of HA, at which it stops to form aggregates with acidic albumin, is 6–8 kDa [12].

The curves of concentration dependence of optical density on amount of HA registered by turbidimetric analysis vary for different HA-based filler manufacturers, which is probably connected to the difference in the ratio of cross-linked to free form of HA and in molecular masses of HA in the fillers, which are likely to bind to acidic albumin with different efficiencies (Figure 1(a)). In further studies, the optical density values were considered as correct if the values were on a linear part of these curves.

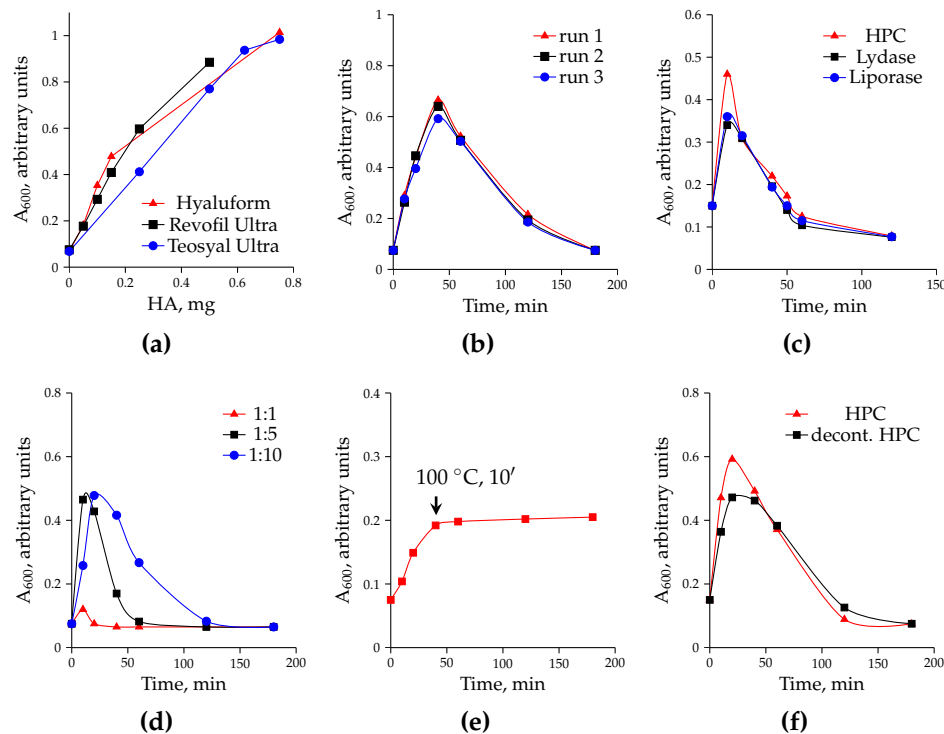

Figure 1. The study of Revofil Ultra, Hyaluform and Teosyal Ultra fillers HA in turbidimetric analysis: (a)—concentration dependence of the amount of HA of Revofil Ultra, Hyaluform and Teosyal Ultra and optical density in turbidimetric analysis, (b)—kinetics of hydrolysis of Revofil Ultra filler HA using HPC homogenate in triplicate, (c)—kinetics of the hydrolysis of the Hyaluform filler HA using commercially available hyaluronidases and HPC homogenate, (d)—kinetics of hydrolysis of Revofil Ultra filler HA using three different concentrations of HPC homogenate protein, (e)—kinetics of hydrolysis of Revofil Ultra filler HA using HPC homogenate before and after increasing the temperature of the reaction mixture to 100 °C for 10 minutes, (f)—kinetics of hydrolysis of the Hyaluform filler HA using the HPC homogenate and its decontaminated sample («decont. HPC»).

Turbidimetric analysis of HA hydrolysates induced by the homogenate of hepatopancreas of the red king crab (HPC) showed an unexpected result (Figure 1(b)). Instead of the anticipated reduced capacity of HA to bind to acidic albumin, the opposite effect was observed in the first 40 minutes—the reaction products of hydrolysis of the HA bound the protein and formed aggregates with it more effectively (optical density increases). After 40 minutes of the reaction time, the optical density in the turbidimetric samples decreased. The same result of hydrolysis of HA of the Hyaluform (Figure 1(c)) and Revofil Ultra (Figure A1) was obtained for commercially available hyaluronidases Lydase and Liporase.

We investigated the dependence of the hydrolysis efficiency on the amount of total HPC homogenate protein in the reaction mixture (Figure 1(d)). The increase of concentration resulted in hydrolysis of HA into fragments that are incapable to bind to acidic albumin at a quick rate. So, when ratio of the total HPC homogenate protein to HA was 1 to 1 (by weight), on the 10th minute

of hydrolysis an insignificant level of aggregation was detected, that is, within 10 minutes almost all HA turned into short forms. When concentration of the enzyme in the reaction mixture decreased, HA transitioned to such short forms more slowly. The hydrolysis time, at which the forms of HA more effective for binding to albumin formed, shifted to later time points: in the ratio 1:5 (protein to HA) peak on the 10th minute, in 1:10 peak on the 20th minute. The ratio of 1:10 or 1:15 was taken as optimal for the experiments.

Raising the temperature of the reaction mixture to 100 °C for 10 minutes allowed to stop the hydrolysis reaction: after 40 minutes of incubation at 37 °C the reaction mixture was placed for 10 minutes in a boiling water bath, after which the incubation continued at room temperature (Figure 1(e)). Such a simple approach will make it easy to obtain partial hydrolysates of cross-linked HA and to study them in future researches (see Discussion).

2.2. Atomic force microscopy of HA-based fillers

To study HA hydrolysates using AFM, the sample of the HPC homogenate had to be decontaminated of pigments and other non-protein contaminants (see Materials and Methods). Decontaminated homogenate showed the same level of hyaluronidase activity as the initial one (Figure 1(f)). Protein electrophoresis in denaturing SDS-polyacrylamide gel did not reveal significant differences in the set of proteins between these two samples of the preparation (Figure A2).

The AFM images of the HPC homogenate 21 times diluted by phosphate buffer showed the presence of amorphous structures, but the decontaminated homogenate resembled «pea»-like structures with 4 to 30 nm in height (Figure A3). Probably, these are complexes of proteolytic and other enzymes.

As filler HA solutions were stored at 4 °C, the samples were preliminary warmed up at 37 °C for 40 min to be studied using AFM. The heat treatment did not significantly affect the results of turbidimetric analysis (Figure A4). The AFM images of Hyaluform filler showed spherical-like structures from several nm to 300 nm in height (Figure 2).

Figure 2. The AFM images of Hyaluform HA-based filler, obtained in the tapping mode: (a)—field 50x50 μm, (b)—field 1.4x1.4 μm.

Population of these spherical-like structures can be divided into 3 groups by size and quantity. The first group includes small-numbered population structures 150–300 nm in height (Figure 2(a)). The similar structures were observed in Revofil Ultra filler preparation but the structures were up to 150 nm in height (Figure A5). The second group is represented by large population structures 10–20 nm in height. The much numerous structures several nm in height were attributed to the third group. These group forms a dense layer surrounding structures mentioned above (Figure 2(b)).

AFM was used to study the hydrolysates of Hyaluform filler HA; hydrolysates were obtained with the decontaminated HPC homogenate. The aliquots were picked out from the reaction mixture at the 5, 40 and 120 min of incubation of the reaction mixture and were transferred to mica to be studied using AFM (Figure 3, Figure A6).

Figure 3. AFM-images in the tapping mode of the hydrolyzates of Hyaluform HA-based filler: **a**—5 min, **b**—40 min, **c**—120 min of the hydrolysis of HA with the HPC homogenate.

We found that at time point of 5 min of hydrolysis the empty spaces without presence of HA are formed in the layer of spherical-like structures (Figure 3(a)). After 40 min of the hydrolysis these empty spaces expanded (Figure 3(b)). After 120 min of the hydrolysis the spherical-like structures almost disappeared and a filamentous mesh structures formed (Figure 3(c)). The filamentous mesh structures are similar to those resulted from AFM imaging of noncross-linked HA presented in the paper of Jacoboni et al [13].

Besides, the AFM image of the reaction mixture after 5 min of incubation showed also the spherical-like structures about 600 nm in height and greater (Figure A7). After 40 min of the hydrolysis the number of these big structures decreased and there were many spherical-like structures up to 150 nm in height. After 120 min of incubation the structures up to 80 nm were seen rarely, sometimes the amorphous structures were visible.

3. Discussion

In this research we investigated for the first time the kinetics of the hydrolysis of HA of the fillers with the help of the red king crab hepatopancreas homogenate. The turbidimetric analysis showed the bell-shaped dependence between the efficiency to form aggregates with albumin and reaction time. The ascending part of the turbidimetric curve could be explained by accumulation in reaction mixture of some HA molecule species which are more effective to form aggregates with albumin than initial one. The descending part of the curve is degradation of the HA molecules to short species which are unable to form the aggregates with albumin.

Using AFM it was shown that the HA of the fillers has a spherical-like structure in the size range from several nm to several hundred nm. Obviously, such a structural organization should be more stable than non-modified HA to the action of hyaluronidase, since only the surface molecules of HA of the structures can undergo hydrolysis, while the molecules inside are protected from the action of enzymes. Under the action of the hyaluronidase of the HPC homogenate, these structures decompose into a filamentous mesh structure.

The observed big spherical structures with a height of approximately 600 nm (Figure A7) can be explained by the attaching of proteins of the enzyme preparation into HA in the reaction mixture. Earlier, Flynn et al. investigated the kinetics of changes in the molecular weight of HA of the Belotero Balance, Restylane, and Juvéderm Ultra fillers during a hydrolysis reaction using ovine testicular hyaluronidase [5]. The results of liquid chromatography showed an increase in the molecular weight of

HA in the first 30 minutes of the reaction. The authors explained this phenomenon as the result of the formation of enzyme–substrate complexes during the reaction. Most likely, the enlarged spherical-like structures observed by us in the first 5 minutes of the reaction and the detected increase in the molecular weight of HA in the work of Flynn et al. are reflection of each other.

To the first approximation the binding of HA to acidic albumin may be the model of normal to the organism HA aggregates formation with proteins. It follows that the partially hydrolyzed cross-linked HA is potentially new form of HA which combines two properties necessary for its administration into the joint cavity and periarticular space in case of locomotor apparatus injuries and treatment of arthritis and osteoarthritis. It is essential to provide prolonged effect of HA in therapy for such diseases and at the same time the administered HA has to bind to protein molecules efficiently. The partially hydrolyzed cross-linked HA meets these requirements—it is more stable to action of endogen hyaluronidases than noncross-linked HA and at the same time it forms aggregates with protein efficiently. To check this hypothesis additional research is needed, however just a thermal processing of reaction mixture makes it easier to get the samples of HA of different degree of hydrolysis.

The HPC homogenate has hyaluronidase activity comparable to commercially available products, if the total protein concentration of the compared hyaluronidase preparations is equalized in the reaction mixtures. Thus, for the first time in this work, we have demonstrated the prospects of using hepatopancreas of the red king crab as resource to create a new hyaluronidase product for treating filler complications.

Products obtained from mammalian tissues contain a potential danger to the consumer if the animal has spongiform encephalopathy. Prion proteins of such an animal can cause development of Creutzfeldt–Jakob disease in humans. Despite the fact that at the moment not a case of this route of infection through the hyaluronidase preparations has been described, state regulators of many countries prohibit the import and sale of these products on their territory. An exception is hyaluronidase preparations obtained from tissues of the testes of bulls grown in Australia. A quarantine regime of animal importation has been introduced in this territory, and it is believed that the local cattle population has never been exposed to spongiform encephalopathy. In this regard, the preparation of the red king crab hepatopancreas hyaluronidase has a significant advantage, since it cannot carry such a potential danger.

The main problem in the commercial scale production of hyaluronidases from hepatopancreas is the difficulty to remove from the organism, store and transport hepatopancreas in complicated marine fishing conditions. The solution of this problem and preclinical studies on the model animals demonstrating the safety and therapeutic efficiency of the red king crab hepatopancreas hyaluronidase can replenish arsenal of preparations in treating filler complications in the near future.

4. Materials and Methods

HA products: Revofil Ultra (Lot RTU–13–08), Teosyal Ultra Deep (Lot TSU 110503B), Hyaluform filler deep (Lot E0102 04/19). All tested fillers consist of cross-linked and free HA at different ratios, contain different amounts of HA in 1 ml (Figure A1, Teosyal Ultra Deep filler stock preparation is 25 mg HA per mL). The HA fillers were stored in a place protected from light exposure at temperature not exceeding 25 °C, prepared solutions of the HA fillers were stored at 4 °C. Hyaluronidase products: Lidase (Lot 110319) and Liporase (Lot 080521). The preparations are of animal origin; they contain different amounts of the units of activity per 1 g of dry substance (Figure A2). The hyaluronidase products were stored at 4 °C, prepared solutions of the hyaluronidases were stored at –20 °C.

The tested products of HA and hyaluronidase were purchased at a pharmacy.

4.1. A turbidimetric method for determination of hyaluronidase activity

The analysis was conducted according to previously developed protocols with minor changes [12]. The content of the fillers was diluted by phosphate buffer (160 mM sodium hydroorthophosphate*12H₂O, 39 mM sodium chloride, pH 5.55 was adjusted with hydrochloric acid)

up to the concentration of 2.5 mg of HA in 1 mL. An aliquot of the hyaluronidase solution was added to 0.2 mL of the HA solution, the reaction mixture was thoroughly mixed and incubated at 37 °C. At time points during incubation, 10–35 μ L aliquots were taken, then immediately mixed up with the phosphate buffer (up to 0.5 mL) and 2.5 mL of acid albumin (24 mM sodium acetate, 79 mM acetic acid, 50 mM sodium chloride, 1% albumin, pH 3.5). The mixture was thoroughly mixed and incubated at room temperature for 50 min. Optical density was then measured at 600 nm on a Hitachi U–2000 spectrophotometer.

4.2. Preparation of a homogenate of hepatopancreas of the red king crab (HPC)

The HPC homogenate was prepared as follows. The red king crab *Paralithodes camtschaticus* was caught by the crab catching vessel from the company CJSC «ArcticService» in the Barents Sea during crab fishing season. The hepatopancreas of several crabs was separated and immediately frozen, stored and transported at –25 °C. To the hepatopancreas thawed at room temperature in laboratory conditions, distilled water and ice were added in the ratio of 1:8:2, and stirred at low speeds for 60 min. All final mixture was placed in a separating column and left for 2 h at –14 °C. An aqueous phase of the homogenate was filtrated on a hollow fiber ultrafiltration module «AP–3–300» (Scientific–Production Complex (SPC) «Biotest», Russia). The sterile solution had a dark amber color. This solution was concentrated on a hollow fiber ultrafiltration module «AP–3–1» (SPC «Biotest», Russia). An aliquot of the final product (a concentrated product) was stored at –20 °C. Protein concentration was determined with a colorimetric method using the biuret reagent [14]. Albumin («Amresco», USA, Lot 0205C125) served as calibration protein.

4.3. Decontamination of the homogenate of HPC

Ammonium sulfate up to 50% saturation was added to 1 mL of the homogenate to purify the obtained preparation from impurities. Decontamination procedure was carried out at 4 °C, ammonium sulfate was slowly added while stirring. After centrifugal precipitation for 10 min at 10,000 g and 4 °C, the precipitate was solved by 0.5 mL of phosphate buffer, and dialysis was performed in the same buffer for 24 hours. The preparation obtained was centrifuged for 10 min at 10,000 g and 4 °C and passed through a 0.22 μ m filter («Millipore», USA). The solution was colorless. The sample was analyzed by gel electrophoresis according to Laemmli [15].

4.4. Atomic force microscopy (AFM)

Sample preparation procedure for AFM was as follows. Buffer solution was used to bring the fillers up to 2.5 mg/mL. To prepare samples for AFM, the filler samples after incubation for 40 min at 37 °C were used. For hydrolysates, an equal volume of the sample was taken from the reaction mixture after 5, 40 and 120 min of incubation at 37 °C. Also, we analyzed the decontaminated preparation of the HPC homogenate 21 times diluted by phosphate buffer after its incubation for 40 min at 37 °C. For preparing samples for AFM, 2 μ L of the sample were taken and transferred to freshly cleaved mica and incubated for 5 min. The sample was then washed twice in a drop of distilled water deionized by a type I Milli–Q system for 30 sec and dried in the air. AFM imaging was performed with AFM Integra–Vita microscope («NT-MDT», Russia) in noncontact (tapping) mode in air. The typical scan rate was 0.5–1 Hz. Measurements were carried out using cantilevers NSG03 with a resonance frequency of 47–150 kHz and ensured 10 nm tip curvature radius. The processing and presentations of AFM images were performed using Nova software («NT-MDT», Russia) and Gwyddion 2.44 software (<http://gwyddion.net/>, Czech Republic).
