16 Abstract: It is unclear which noise exposure time window and noise characteristics during 17 nighttime are most detrimental for sleep quality in real life settings. We have conducted a field 18 study with 105 volunteers wearing a wrist actimeter to record their sleep during seven days, 19 together with concurrent outdoor noise measurements at their bedroom window. Actimetry 20 recorded sleep latency increased by 5.6 minutes (95% confidence interval: 1.6 to 9.6 minutes) per 21 10 dB(A) increase in noise exposure during the first hour after bedtime. Actimetry assessed sleep 22 efficiency was significantly reduced by 2-3 percent per 10 dB(A) increase in measured outdoor 23 noise (Leq. 1h) for the last three hours of sleep. For subjectively reported sleepiness, noise exposure 24 during the last hour prior to wake up was most crucial with an increase in the sleepiness score of 25 0.31 units (95% CI: 0.08 to 0.54) per 10 dB(A) Leg.1h. Associations for estimated indoor noise were 26 not more pronounced than for outdoor noise. Considering noise events in addition to equivalent 27 sound pressure levels (Leq) only marginally improved the statistical models. Our study provides 28 evidence that matching the nighttime noise exposure time window to the individual's diurnal 29 sleep-wake pattern results in a better estimate of detrimental nighttime noise effects on sleep. We 30 found that noise exposure at the beginning and the end of the sleep is most crucial for sleep 31 quality.

34

35 1. Introduction

36 There is increasing epidemiological research demonstrating negative effects of transportation 37

noise exposure on various chronic diseases such as cardiovascular disease [1-4], metabolic 38 syndrome [5-9], depression [10-12], and cognitive functions [13-16]. Several mechanism are

39

implicated in these negative noise effects like the activation of the hypothalamic-pituitary-adrenal 40 axis (HPA), which leads to increased cortisol and glucose levels as well as increased blood pressure,

41 with consequences for blood viscosity and blood coagulation [17]. Also, chronic sleep deprivation is

- 42 a stressor which contributes to allostatic load and has been found to be connected to all these
- 43 outcomes above. High allostatic load, characterized by repeated stress responses, affects the brain
- 44 regions involved in memory consolidation and affective processing with potential long term effects
- 45 on cognitive and mental health [18]. In large population studies, impaired sleep quantity and

2 of 13

quality has been associated with increased risk of developing coronary heart diseases [19]. There is
also solid evidence that short sleep duration, lack of slow wave sleep, and circadian

48 desynchronisation of sleep increases the sensitivity to food stimuli contributing to adverse

49 metabolic traits, in particular obesity and type 2 diabetes [20]. Further, sleep deprivation reduces

50 the motivation for physical activity and thus reduces the energy expenditure [21], which further

51 contributes to the risk for cardiometabolic syndromes.

Noise induced sleep disturbance as demonstrated in experimental human laboratory studies [22-24], field trials [25] and observational epidemiological studies [26,27] are thus likely to be on the pathway for detrimental effects on the cardiometabolic system and mental health. Strikingly, evidence for noise effects on various sleep outcomes is only considered "very low" to "moderate" in the recent systematic review of the World Health Organization Environmental Noise Guidelines for the European Region [28]. Thus, many questions remain open.

58 Sound pressure level at the ear of the sleeper is the relevant entity for quantifying noise effects 59 on sleep. It is possible to quantify reactions of sleepers to noise in field experiments using contrived 60 exposure settings (i.e. reproducing noise in a controlled fashion with loudspeakers). This approach, 61 however, does not adequately consider long-term habituation to a noise source, which may be 62 relevant in a real life situation at home. Observational studies would be appropriate to account for 63 potential habituation effects, but are usually based on noise exposure modeling for the outdoor 64 facade thus rather imprecise regarding noise exposure at the ear.

façade thus rather imprecise regarding noise exposure at the ear.
 Further, the average sound pressure level (Leg and similar indic

Further, the average sound pressure level (Leq and similar indicators) may not be the only
relevant factor; other noise exposure characteristics not captured in energy-based exposure
indicators may also be important. For instance, in experimental sleep studies on noise effects on
sleep, different effects have been observed for road, rail, and aircraft noise [22,23]. Thus, the effect

sleep, different effects have been observed for road, rail, and aircraft noise [22,23]. Thus, the effects
of noise on sleep might either be better predicted by the number of noise events [29], the maximum

70 sound pressure level [30], the sound pressure level slope [24,31] or by the order of events [31].

70 Sound pressure level [50], the sound pressure level slope [24,51] of by the order of events [51]. 71 Confronted with the challenge of how to sum up and weight noise events we have developed an

acoustical metric, the intermittency ratio (IR), to characterize short-term temporal variations of
 transportation noise exposure [32]. In a large cohort study, we found some evidence that IR may

have a modifying effect on the cardiovascular mortality risk [33].

Timing of noise exposure is also considered to be relevant for sleep effects. For instance, an experimental sleep study observed that noise curfews at the end of the night are most beneficial for sleep, because noise induced sleep disturbances at the beginning of the night were at least partly compensated during the rest of the night [34].

In order to quantify relevant factors that affect sleep quality through noise exposure in a real life situation, we conducted an observational field study with volunteers wearing wrist actimeters to record their sleep-wake behavior during seven days with concurrent in- and outdoor noise exposure measurements. The study explored i) the relevance of indoor noise compared to outdoor noise, ii) the predictive contribution of IR to sleep effects in addition to equivalent continuous sound pressure levels (L_{eq.night}), and iii) the effect of noise exposure at different times during the

sound pressure levels (Leq,night), and iii) the effect of noise exposure at different times during the
 night. We also tested potential effect modification by noise annoyance, noise sensitivity, and sex.

86 2. Materials and Methods

87 2.1. Study population and procedures

88 Study participants were recruited from a previous nationwide survey on transportation noise

89 annoyance and sleep disturbances among participants who expressed their willingness to be

90 contacted for further research [35]. Only adults with German language skills were included. People

91 with severe chronic disease or shift work were excluded. Calculated Lden for road traffic at the most

92 exposed façade had to be at least 50 dB to ensure sufficient outdoor noise to be detected inside. In

93 order to explore effects of road traffic noise exposure minimally contaminated by other noise

94 sources, modeled aircraft and railway noise had to be at least 10 dB lower than road traffic noise.

3 of 13

95 During recruitment we ensured no other relevant noise sources such as construction work or 96 tramways could disturb the sound level measurements.

97 After recruitment, study participants were visited at home between May and November 2016

98 and instructed about the procedures. All participants filled in a baseline questionnaire about

99 sociodemographic and other relevant characteristics such as noise annoyance (using the 11-point

100 ICBEN scale for road traffic noise in general [36]), noise sensitivity (using a 6-point Likert scale to

101 rate the statement "I am noise sensitive" from NoiSeQ) [37], and window opening habits during

102 night.

103 2.2. Sleep outcomes

104 Objective sleep behavior was evaluated using movement data collected by an actimeter device 105 (Daqtometer v2.4 by Daqtix GbR, Oetzen, Germany) continuously worn on the non-dominant wrist 106 during the seven day study period. Data were collected in 10-s to 60-s bins. Participants were 107 provided with diaries in which they logged sleep-relevant information two times during the day. 108 Prior to sleep, they gave information on consumption of coffee and alcohol, daytime naps, screen 109 time use, and medication intake during the preceding day. In the mornings, participants evaluated 110 the preceding sleep episode and noted bed and rise times, and whether or not they used an alarm 111 clock. Additionally, subjective sleep quality was rated on a verbally anchored visual analogue scale 112 from 0 (the worst sleep) to 100 (the best sleep). Subjective sleepiness was rated on a verbally 113 anchored Likert-type scale that ranged from 1 (extremely alert) to 9 (very sleepy-fighting sleep) 114 [38].

115 Actimetry data were analysed using the "Actiwatch Activity and Sleep Analysis" software 116 (Actiwatch software version 7, Cambridge Neurotechnology Ltd., Cambridge, United Kingdom). 117 Bed and rise times were entered manually based on actimetry records and sleep diary entries, while

118 sleep on- and offset were determined automatically by the algorithm to derive sleep efficiency

119 (proportion of actual sleep time per time in bed), sleep duration, sleep latency (time between

120 bedtime and sleep onset), and moving time (minutes moving per assumed sleep period as time

121 between sleep on- and offset).

122 2.3. Noise measurements and modelling

123 Noise exposure assessment included a seven-day outdoor measurement, a controlled short-124 term measurement to derive the sound insulation of each bedroom for different window positions 125 and noise exposure modeling to identify eligible households. We modelled road traffic noise 126 exposure calculation at the most exposed façade of each study participant using the sonROAD 127 emission model [39] and the sound propagation model StL-86 as described in detail in Karipidis et 128 al, 2011 [40].

129 Outdoor noise at the study participant's bedroom window was measured with sound level 130 meters type Noise-Sentry RT, a class II measurement device with a measurement uncertainty of 131 about 1 dB(A) [41]. The sound level meters were flush mounted to the outer face of the closed 132 window and logged A-weighted 1-second- L_{eq} 's. To obtain free field estimates, a correction of -6 dB 133 was applied to the raw data. After a measurement period of seven days, the participants removed 134 the sound level meters and sent them back. From the measurement files Leq,night and IRnight (23:00-135 7:00) were computed for each night and participant. Further, Leq and IR for a priori specified time

136 windows during the night were derived: 19:00-23:00, 23:00-1:00, 1:00-5:00, 5:00-6:00, and 6:00-7:00.

137 We also calculated, for each individual, Leq.1h exposure for the first four hours of sleep as well as the

138 last four hours prior to wake up taking into account their individual sleep pattern on the 139 corresponding night.

140 Sound transmission of outdoor noise into the bedroom was measured during the home visit. 141 Outdoor and indoor (at the position of the pillow) levels were measured in parallel for three

142

window positions (open, tilted, closed) during three minutes in one-third octave bands from 50 Hz 143 to 10 kHz with a class I sound level meter (type NTI XL2, NTi Audio AG, Schaan, Liechtenstein)

144 and a free field microphone. Temporal resolution was set to one second. The indoor measurements

4 of 13

- 145 were compared with the concurrently conducted outdoor measurements and an algorithm was
- 146 developed to derive the A-weighted attenuation factor in dB based on the correlation and the offset
- 147 of these parallel measurements [42]. Finally, estimated indoor levels for analysis were obtained for
- 148 each study participant by subtracting the individual attenuation factor from the outdoor
- 149 measurements taking into account the preferred window position for the season when the data
- 150 were collected, as indicated in the baseline questionnaire.

151 2.4. Data analysis

152 Primary endpoints were actimeter-derived sleep efficiency, sleep latency, sleep duration, and 153 moving time. Secondary endpoints were subjective sleep quality and sleepiness as rated each 154 morning in the sleep diary.

155 Association between sleep outcomes and noise exposure was analyzed using mixed regression

156 models with auto-correlated residuals lag=1 and robust standard errors. To account for repeated

- 157 nights from the same individual and multiple study participation per household a three level
- 158 random intercept model was applied. Models were adjusted for confounding factors as indicated in
- 159 the footnote of corresponding result tables (Table 3 and 4). Effect modification by noise annoyance
- 160 and noise sensitivity was investigated by interaction analysis on dichotomized variables.

161 3. Results

162 For the study, we included 107 individuals from 96 households resulting in 720 nights with 163 complete noise exposure data and recorded data on at least one sleep outcome (actimeter-derived 164 or self-reported). Data from two individuals (14 nights) were excluded because their sleep was 165 affected by their children. An additional 10 nights were excluded from the dataset because of 166 sleeping out of home, two nights due to acute respiratory infection, and nine nights due to a 167 recorded sleep duration of less than four hours. This left 694 nights from 105 individuals from 94

168 households for further analyses, although number of observations were somewhat smaller for 169 specific outcomes because for two individuals only actimetry data was available, and for two 170

individuals only the subjective sleep quality data.

171 Mean age of the study participants was 52.1 years (SD=14.4 years, age range: 23 to 78 years). 172 Fifty-tree participants (51%) were female and 52 male. Twenty-nine individuals (28%) had a 173 University degree, 34 (32%) a higher education, 39 (37%) an apprenticeship, and 3 (3%) compulsory

174 education. Median noise annoyance was 6 with 23% being classified as highly annoyed (score \geq 8).

- 175 Forty-one subjects (39%) tended to agree (score 4-6) to the statement "I am noise sensitive".
- 176 Average sleep efficiency as recorded by actimetry was 88% and average sleep duration 7.0 h 177 (Table 1). Subjective sleep quality scores ranged from 4 to 100 with a mean of 65. Average subjective
- 178 sleepiness score was 4.1. Sleep efficiency was strongly negatively correlated with sleep latency (-
- 179 0.79) and subjective sleep quality was negatively correlated with subjective sleepiness (-0.49).
- 180 Correlations of all other outcomes were low (see Supplementary Table 1).

183Table 2 shows the summary estimates for the various noise exposure metrics. Mean measured184nighttime noise level (Leq.night) outside the window of the study participants' bedroom was 47.0

185 dB(A) with a maximum of 62.7 dB(A). Estimated mean indoor nighttime noise level at the pillow of

186 the study participants was 30.2 dB(A) (maximum: 55.3 dB(A)). Measured exposure was about 10

187 dB(A) lower during 01:00 to 05:00 compared to the beginning and end of the night. Correlation

188 between estimated indoor and measured outdoor nighttime exposure was 0.46 reflecting variation

189 in noise attenuation between study participants. Correlations were ≥ 0.63 for measured L_{eq} between

190 different time periods of the night (see Supplementary Table S3).

¹⁹² 193

¹ all estimated indoor values <20 dB(A) have been replaced by 20 dB(A)

Measured nighttime noise (L_{eq,night}) tended to be negatively associated with sleep efficiency and positively associated with sleep latency, although not statistically significant (Table 3). For instance sleep efficiency decreased by 1.11% (95%-CI: -2.44% to 0.21%) and sleep latency increased by 5.67 min (95% -CI: -1.00 to 12.34) per 10 dB(A) increase in L_{eq,night}. No indications of an association

198 (p \ge 0.27) were seen for the other sleep outcomes including subjective sleep quality and sleepiness.

199 200 **Table 3.** Adjusted association between sleep outcomes and measured *outdoor* nighttime noise (Leq.night) per 10 dB(A) increase; ACT=Actimetry; SR=Self reported,

Outcome	Ν	Coefficient	Confidence interval	р-
				value
ACT Sleep efficiency [%]	634	-1.11	-2.44 to 0.21	0.10
ACT Sleep latency [min]	634	5.67	-1.00 to 12.34	0.10
ACT Sleep duration [h]	634	0.01	-0.17 to 0.19	0.94

SR Sleep quality [0-100]	639	-1.09	-4.96 to 2.78	0.58
SR Sleepiness [1-9]	633	0.02	-0.29 to 0.32	0.91

¹ adjusted for age, sex, education, evening caffeine intake, evening alcohol consumption, evening screen time,
 day of the week, season and whether woken up by an alarm clock

203 Using estimated indoor noise instead of measured outdoor noise yielded similar results in

terms of regression coefficients, but none of the associations was even close to significance (Table 4).

205 Similarly, we did not obtain any indications that IR was associated with any of the objectively

206 recorded or subjectively reported sleep outcomes when also considering Lequight in the same model

207 (see Supplementary Table S4). A model with quartiles of IR_{night} instead of a continuous variable

208 suggests a non-linear association for sleep efficiency and latency. For the second quartile of IR_{night}

209 (50-63%), sleep efficiency was reduced by 1.24% (95% confidence interval: -2.73 to 0.25) and sleep

210 latency was increased by 3.48 minutes (95% CI: -2.54 to 9.50) compared to the first quartile (4-50%).

213 ¹ adjusted for age, sex, education, evening caffeine intake, evening alcohol consumption, evening screen time,

214 day of the week, season and whether woken up by an alarm clock

215 Since most indications for noise effects were found for sleep efficiency and sleep latency in

216 relation to outdoor noise, we investigated the effect of noise exposure in potential critical time

217 windows for these two outcomes in more detail (Figure 1). Noise exposure in the evening (19:00-

218 23:00) and in the early morning hours (05:00-06:00) was significantly associated with sleep

219 efficiency, whereas the other time windows reached only borderline significance. For sleep latency,

220 noise exposure until 01:00 was most relevant.

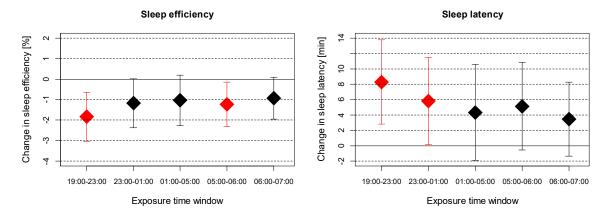

Figure 1. Association between measured outdoor noise exposure (L_{eq}) at different time windows during night and changes in all-night sleep efficiency and sleep latency per 10 dB(A) increase in noise exposure. Significant associations are highlighted in red. Analyses adjusted for age, sex, education, evening caffeine intake, evening alcohol consumption, evening screen time, day of the week, season, and whether woken up by an alarm clock.

227 Exposure within fixed time periods (as shown above) may not match the individual time 228 period a person is asleep or in bed. For instance, for somebody rising before 06:00, noise exposure 229 between 06:00 and 07:00 is not relevant regarding sleep disturbance. We have thus calculated 230 hourly noise exposure levels that matched the individual sleeping pattern of each night for the first 231 four and the last four hours of sleep. The corresponding analyses with all actimetry-derived sleep 232 outcomes are shown in Figure 2. This individualized noise exposure provides stronger associations 233 between measured noise exposure and sleep efficiency. Sleep latency increased by five to seven 234 minutes per 10 dB(A) increase in outdoor noise exposure during the first four hours after bedtime. 235 For sleep efficiency, noise exposure during the last three hours prior to wake up was most critical 236 with reductions of 2-3% per 10 dB(A) increase in measured outdoor noise exposure (Leq.1h). For sleep 237 duration and moving time, no significant associations were found; although for the latter, noise 238 exposure two to four hours after bedtime tended to increase moving time during sleep and noise

239 exposure two hours before wake-up tended to be negatively associated with moving time.

- 240 Subjective sleepiness in the morning was significantly associated with noise exposure in the 241 last hour of sleep, whereas no associations were observed for noise exposure at the beginning of 242 sleep (Figure 3). For subjective sleep quality, none of the noise exposure time windows were 243 significantly associated, but noise exposure in the middle of the sleeping period (±4 hours from 244 bedtime and wake up) and at the end of the sleeping period showed the strongest trends for a 245 relation. For IR matched to individualized sleep patterns, no significant effects on actimetry-derived 246 and subjective sleep outcomes were observed. 247
- Noise annoyance, noise sensitivity and sex were not significant effect modifiers for any of the 248 outcomes and noise exposure time windows. A slight non-significant trend was seen for a stronger 249
- association of nighttime noise (Leq.night) with sleep efficiency for males (p=0.11), people with a high 250
- (\geq median) annoyance score (p=0.23), and people not reporting to be noise sensitive (p=0.25).

260 4. Discussion

261 Our study suggests that the timing of noise exposure within the night is a relevant factor for 262 the deterioration of objective and subjective sleep quality. Using individual noise exposure time 263 windows, matched to the individual bed- and rise times of each night, provided stronger 264 associations compared to fixed time intervals (such as e.g Leq between 19:00 and 23:00). Sleep 265 latency, as expected, was most consistently associated with noise exposure at the beginning of the 266 night, while for sleep efficiency and self-rated sleepiness noise exposure prior to wake up was most 267 relevant. This suggests that noise exposure in the middle of the night may be less relevant for sleep 268 quantity and quality, whereas noise exposure towards the end of the night, when sleep pressure is 269 reduced and noise levels tend to be higher, is most disturbing for sleep.

270 This is in line with a field study using contrived aircraft noise exposure observing that aircraft 271 noise events in the early morning elicited stronger reactions, as measured with high-resolution 272 actigraphy, than events at the beginning of the sleep period [31]. Our findings are also in line with a 273 large population based survey conducted 2009-2010 in Oslo with 13,019 participants. Road traffic 274 nighttime noise was mostly associated with waking up too early and with difficulties falling asleep, 275 but barely with awakenings during night [27]. In a Finnish study of 7,019 public sector employees, 276 people exposed to >55 dB road traffic nighttime noise were more likely to report non-restorative 277 sleep (OR=1.29, 95% CI: 1.01-1.65) and waking up too early (OR=1.24, 95% CI: 0.96-1.61) compared 278 to people exposed to 45 dB or less. No associations were observed for frequently waking up during 279 the night, short sleep duration, and difficulties falling asleep, the latter not in line with our results 280 [43]. In a smaller Swiss survey of 1,375 adults, various self-reported sleep quality indices were not 281 significantly related to road traffic nighttime noise [26]. However, most indications for an exposure-282 response trend were found for "waking up too early in the morning", and least indications for 283 "agitated sleep" and "waking phases during the night" in that same study [26].

284 Whether, or how, the observed pattern with stronger effects for evening and early morning 285 noise translates into chronic health effects is unclear. Separating long-term noise effects regressed 286 on average night noise exposure from time-specific effects in specific time periods is challenging for 287 epidemiological studies, primarily because transportation noise in different time periods within the 288 night is highly correlated, at least if no night curfews are in force. This is especially the case for 289 modeled road traffic noise when traffic input data are based on traffic count samples, which are 290 then extrapolated [2,3]. In reality, as demonstrated in our study, diurnal and day-to-day variation in 291 traffic flows leads to a lower correlation between environmental noise exposures at different time 292 intervals than one would observe between such computed standard metrics [44]. For large-scale

9 of 13

293 epidemiological studies on long-term risks, individual noise measurements as done here are not 294 feasible. A Swiss cohort study on cardiovascular mortality has evaluated the effects of diurnal noise 295 variation in their analysis by combining road, rail and aircraft noise. Although such a combination 296 introduces additional diurnal variability due to different pattern and night curfews for aircraft 297 noise, the correlation between different exposure time windows remained high (≥0.94), precluding 298 any firm conclusion. There was a trend that, for all cardiovascular causes combined, exposure 299 during 01:00 to 05:00 was most relevant. For hypertensive related causes of death early morning 300 noise (05:00-06:00) was most relevant; and for ischemic stroke and heart failure early evening and

arly morning noise were more detrimental than the rest of the night, although strongestassociation were seen with daytime noise [45].

We hypothesized that we would find stronger associations for estimated indoor noise than measured outdoor noise but could not confirm this with our data. This is in line with results from a survey on self-reported sleep disturbance in the same special issue of this journal [46]. However, our findings do not match the results of an epidemiological study done on indoor noise, which found stronger associations for hypertension with indoor noise compared to modeled noise at the most exposed façade [47].

309 We did not measure indoor noise, but rather applied an indirect procedure to estimate indoor 310 noise levels from measured outdoor noise because our main interest was outdoor noise penetrating 311 into the building. Direct indoor noise measurements would be heavily affected by the behavior of 312 the participants. For instance, a sleepless person may produce some sound, which would yield a 313 biased correlation between sleeplessness and noise exposure. There is no obvious explanation why 314 indoor noise was less good a predictor than outdoor noise in our study. One may speculate that 315 people who feel disturbed by outdoor noise close their bedroom window and thus have a lower 316 indoor noise estimates, as this is the strongest predictor of indoor noise. This would mean that we 317 deal with reverse causation in the sense that the sleep quality affects the noise exposure and not the 318 other way round. Alternatively, estimated indoor noise levels may be subject to higher exposure 319 misclassification as some levels were low. Estimated indoor noise levels below 20 dB(A) were 320 censored and replaced with 20 dB(A) for the analysis; this was the case for 79 nights in 21 321 individuals. Finally, we obtained window opening habits for each season from the baseline 322 questionnaire but did not specifically ask about the window position for each night, which may also 323 add to exposure misclassification. Exposure misclassification may have resulted in reduced 324 statistical power, which would explain the observed similar regression coefficients for indoor and 325 outdoor noise but higher p-values for indoor noise.

326 We also hypothesized that sleep effects depend on the exposure characteristics. In particular, 327 exposure situations with individual noise events clearly standing out from average (background) 328 noise, as quantified with the Intermittency Ratio (IR) [32], were considered to be more detrimental 329 for sleep than exposure to a steady sound level. However, we could not confirm that sleep 330 disturbances are increasing with increasing IR. There was a non-significant non-linear pattern with 331 lowest sleep efficiency for moderate (50-63%) levels of IR, which is in line with findings of the effect 332 of IR in a cohort study on cardiovascular mortality [33]. However, in a cross-sectional survey on 333 arterial stiffness, rather number of events during night was relevant [48]; and in a cohort study on 334 diabetes IR was not associated with the diabetes risk [7]. Thus, it remains open whether IR is 335 contributing to Leq-based metrics for predicting long term health effects of noise.

336 The strengths of this study include the prospective and detailed data collection with 337 acquisition of objective sleep data (actimetry) and measurement of noise exposure. By measuring 338 instead of calculating outdoor noise exposure, we could adequately record the diurnal variability of 339 noise acting upon study participants. Our measurements allowed us to estimate outdoor noise 340 passing into the sleeping rooms for individual bedroom characteristics. We could also match 341 exposure time windows to the individual bed and rise times. The relatively small sample is a 342 limitation and thus the power of the study rather limited. P-values of the analyses are not adjusted 343 for multiple comparisons because we were interested in the pattern of the effect estimates rather 344 than hypothesis testing. Thus some significant coefficients may in fact be chance findings. Note also

10 of 13

- 345 that some of the exposure and outcome measures are correlated and thus analysis should not be
- 346 considered as mutually independent. This explains, for instance, the paradox result that noise
- 347 exposure two hours prior to wake up is significant associated with sleep latency.

348 5. Conclusions

- 349 Our study provides evidence that matching the nighttime noise exposure time window to the
- 350 individual's diurnal sleep-wake pattern results in a better estimate of detrimental nighttime noise
- 351 effects on sleep. The study suggests that noise exposure in the early morning hours is probably
- 352 most crucial for a negative impact on objective sleep efficiency and subjective sleep quality.
- 353 However, evening noise exposure was also associated with longer sleep latency. We could not
- 354 confirm that noise induced sleep effects are better explained by indoor noise compared to outdoor
- 355 noise, which might be due to reverse causality. This needs to be confirmed in larger studies.
