1 **Abstract:** Eight samples of limestones and marbles were studied by neutron diffraction to collect
2 Quantitative Texture (i.e., Crystallographic Preferred Orientations or CPO) of calcite deforming at
3 different depths in the crust. We studied the different Texture patterns developed in shear zones at
4 different depth and their influence on seismic anisotropies. Samples were collected in the French and
5 Italian Alps, Apennines, and Paleozoic Sardinian basement. They are characterized by isotropic to
6 highly anisotropic (e.g., mylonite shear zone) fabrics. Mylonite limestones occur as shear zone horizons
7 within the Cenozoic Southern Domain in Alpine thrust-and-fold belts (Italy), the Briançonnais domain
8 of the Western Alps (Italy-France border), the Sardinian Paleozoic back-thrusts or in the Austroalpine
9 intermediate units. The analyzed marbles were collected in the Carrara Marble, in the Austroalpine Units
10 in the Central (Mortirolo) and Western Alps (Valpelline). The temperature and depth of development of
11 fabrics vary from < 100°C, to 800°C and depth from <10 km to about 30 km, corresponding from upper
12 to lower crust conditions. Quantitative Texture Analysis shows different types of patterns for calcite:
13 random to strongly textured. Textured types may be further separated in orthorhombic and monoclinic
14 (Types A and B), based on the angle defined with the mesoscopic fabrics. Seismic anisotropies were
15 calculated by homogenizing the single crystal elastic tensor, using the Orientation Distribution Function
16 calculated by the Quantitative Texture Analysis. The resulting P- and S-waves anisotropies show a wide
17 variability due to the textural types, temperature and pressure conditions, and dip of the shear planes.

18 **Keywords:** calcite; seismic anisotropy; texture; CPO; thrust; shear zone; neutron diffraction; crust

19 1. Introduction

20 The quantification of the seismic response of rocks is a fundamental task in understanding Earth's
21 structure, from the core to the surface [1]. The large-scale seismic experiments, now with high-resolution
22 arrays, is the most used approach to image the Earth and to resolve the distribution of natural resources
23 in-depth, e.g. water, ore minerals, and oil & gas [2,3]. However, the interpretation of seismic images
24 strongly relies on the knowledge of seismic response of the anisotropic aggregates of minerals composing
25 the rocks, which in turn is intimately related to the textures of rocks [4], as well as on their extrinsic shape
26 preferred features [5]. In the last two decades, a great effort has been made to quantify the seismic response

of natural aggregates, chiefly by using the 2-Dimensional approach of the EBSD (Electron Back Scattered Diffraction) to reconstruct the Orientation Distribution Function (e.g. [6–8]). Carbonate rocks occur at the Earth's surface and upper crust levels, as sedimentary cover, but can be found within the intermediate and lower crust, as marbles. Within the upper crust, the tectonic deformation often localizes within carbonate rocks, producing thrust-folds systems [9,10]. Though less diffuse within the metamorphic basements, carbonate rocks are known to be equally crucial at depth because they likely represent weak horizons, often separating tectonometamorphic units [11,12]. For these reasons, the knowledge of the texture and seismic response of carbonate rocks is essential to interpret seismic anisotropy at various depth within the crust [13]. Several works have been dedicated to study the behavior of calcite single crystal, limestones, and marbles at different temperature and pressure [14–19]. A general scheme of the expected textures has been developed, combining natural and numerical data (see [20] and references therein), but data are still needed. Moreover, virtually no work has been dedicated to combining the neutron diffraction textural data with the prediction of seismic velocities through the homogenization of the elastic tensor [21,22].

With this contribution, we aim at producing new data related to the textures of carbonate rocks. In particular, we aim at relating different pressure, temperature, and shear geometry conditions of deformation with the type of texture developed. We also aim at investigating the control of texture types on the seismic anisotropies. The presented study will hence provide a reference to interpret measured seismic anisotropy in the continental crust [23], where carbonate rocks might be also involved in accommodating shearing along mylonitic horizons.

For this aim, we selected carbonate rocks characterized by fabrics developed at different temperature and pressure conditions and different strain geometries, from pure to simple shear, representing some of the large number of possible combinations in naturally deformed rocks. The samples have been collected mainly in the Alpine system and display a various degree of planar fabrics, developed at different depths within the crust. In this contribution, we will produce new texture data to be included in the general scheme of texture development. Moreover, we will calculate the component of the seismic anisotropies due to the texture by homogenizing the stiffness tensor using the Orientation Distribution Function obtained with the Quantitative Texture Analysis. Finally, we will investigate the influence of the orientation of the foliation plane on the seismic anisotropy [24] at different depth in the crust and with different textures.

2. Samples description and geological setting

Samples were collected in the French and Italian Alps, Apennines, and Paleozoic basement (Figure 1). Different locations (Figure 1) were chosen to sample carbonate rocks from different crustal levels, from upper/intermediate crust limestones to lower crust high-temperature marbles (Table 1).

According to Figure 1, upper crust samples were collected in the Southalpine domain, Sardinia and Helvetic-Dauphinoise (e.g., Triassic and Jurassic limestones). All samples preserve at macroscopic scale their primary features; intermediate crust samples were collected in the Briançonnais domain and in the Central Austroalpine domain, where Mesozoic sediments were involved in the Alpine tectonics at relatively upper levels. However, they still preserve their stratigraphic relations with the surrounding rocks, as sedimentary strata or laminations. The last group of samples, collected in the Carrara metamorphic complex, and in the Western-Central Austroalpine domain, are metamorphic marbles. In this last group, no sedimentary features are preserved.

- The BAS sample is a light gray crystalline limestone, fine-grained, homogeneous, and free of any planar fabrics at the macroscopic scale, both primary or secondary, as fractures or joints. It is Jurassic in age and it belongs to the External thrust-belt French Subalpine system [25,26]; it is part of the so-called Calcaires "tithoniques" [27]. It was sampled close to Grenoble (France), La Bastille, the southernmost part of the Chartreuse massive. According to the tectonic reconstruction and the local

72 geologic map [27,28], the thrust system developed a km-scale anticline, associated with brittle faults
73 and fracture systems. The BAS sample has been collected within this anticline but far from the brittle
74 system. The fold and thrust system occurred at < 3km depth, at temperature <100°C.

75 • The SOD sample was collected in the Southalpine domain. The sample is part of the Triassic cover,
76 which crops along the entire Southalpine domain. The general interpretation infers the thrust and
77 fold system to convergent tectonics active during the formation of the Alpine system (Figures 1 and
78 2). It was collected within the meter-scale mylonitic horizons associated with a meter to tens of
79 meters asymmetric folds [29]. According to these authors, the thrust horizons occurred at relatively
80 upper depth, not exceeding 5-7 km, corresponding to a maximum of 200°C. The studied sample
81 shows an abrupt change in fabric from undeformed to highly strained domains (Figure 2), often
82 associated with grain-size reduction, pressure-solution, and plastic deformation in carbonate grains,
83 testified by mechanical twinning. These meso- and microstructures support temperatures as high as
84 200°C [30,31]. The kinematics of these thrust horizons have been reconstructed based on stratigraphic
85 and structural constraints, being characterized by strong simple shear components also testified by
86 classical shear indicators, as cm- to mm-scale drag folds and porphyroclasts geometries [32].

87 • SA1 sample was collected in the Sardinia basement. It is part of the Ceroidi Limestone (Gonnesa
88 Fm.), pre-Ordovician protholith of the External Zone. This metasedimentary cover has been deeply
89 involved in the Paleozoic-Variscan tectonics [33]. During the Variscan tectonic activity green-schists
90 metamorphic conditions were attained [34], locally associated with high strain shear horizons, from
91 meters to tens of meters thick [35,36]. The SA1 sample was collected in one of these high strain
92 horizons, made by meta-carbonate limestone. The Variscan deformation developed as pervasive
93 folding systems. However, the SA1 sample was collected far from folds and within the domain where
94 the mylonitic foliation is well visible at macroscopic scale (Figure 2). As qualitative estimates for
95 pressure and temperature, the intermediate limit can be put following the metamorphic evolution of
96 the inner part of the belt, as described by Elter et al [37]. Consequently, a limit of 350°C and 4-5 kbar,
97 corresponding to roughly 12-15 km depth can be used to constrain the development of the fabric in
98 this horizon. Moreover, mesoscopically no asymmetric shear sense indicators have been recognized,
99 supporting the microstructural and textural observations [35], which suggested a pure shear strain.

100 • STE sample was collected in the Central Alps, within the intermediate Austroalpine domain [38].
101 Here the Mesozoic sedimentary cover was involved in the Alpine tectonics, occurring as thick-skinned
102 thrusting of cover and its pre-alpine basement [39]. Thrusting localized along high strain horizons
103 within cover and basement [40]. The temperature conditions of this event were estimated at
104 T=300-350°C at depth=15-20km [41,42]. We collected a sample within the mylonite horizons in
105 the Mesozoic cover, namely the Fraele Fm. It is characterized by a strongly developed mylonite
106 fabric, associated with a meter- to tens of meter folds. A strong transposition of the lithostratigraphic
107 features has been recorded along this horizon [43]. A simple shear component has been described
108 for this deformation based on meso- and microstructural analysis [41]. Sample scale features, as
109 mm-sized drag faults (Figure 2), support the simple shear component.

110 • CC sample was collected in the Western Alps, in the sub-Briançonnais domain. It consists of Jurassic
111 limestone strongly deformed during Alpine thrusting of the external part of the chain [44]. According
112 to [45,46] the External Briançonnais units equilibrated at pressure not exceeding 5 kbar, corresponding
113 to depth <15 km, and T=300-350 °C. Moreover, an overall simple shear kinematics is constrained
114 by map- to micro-scale indicators, extensively described in the area [47-49]; however, the studied
115 sample does not show clear microstructures that could be uniquely related to a simple shear geometry
116 (Figure 2).

117 • P1 was collected in the well-known Carrara marbles quarries. They consist of Mesozoic cover of
118 the Autochthon of the Tuscan Units metamorphosed during the Alpine evolution [50,51]. Km- to

119 meter-scale folding systems have been mapped, and several kinematics reconstructions have been
120 proposed [52] suggesting large scale shear, related to the thrusting of the deep units, resulted in
121 meso- and micro-scale simple shear fabrics (e.g. [20,53]). However, large scale strain partitioning also
122 occurred, allowing large volume of marbles to escape the development of planar or linear fabrics [54].
123 In fact, the studied sample is characterized by isotropic equigranular texture of recrystallized calcite
124 (Figure 2), suggesting a static recrystallization process associated with grain-boundary migration
125 both leading to grainsize increase [32]. Within the Alpi Apuane Metamorphic Complex the estimated
126 conditions of metamorphism point to $T=400-500^{\circ}\text{C}$ at 8-10kbar [50,55,56], corresponding to 25-30 km
127 depth.

128 • VP3 and MA1 were both collected in the Austroalpine domain of the Alps [44]. The Austroalpine
129 domain is interpreted as fragments of the pre-alpine continental crust involved in the Alpine
130 subduction-collision system. The collected samples are marbles whose metamorphism has produced
131 during high-temperature Permian-Triassic extension [57]. VP3 was collected in the Valpelline
132 Series, Austroalpine of the Western Alps [58,59], while MA1 was collected in the Languard-Campo,
133 Austroalpine domain of the Central Alps [60]. They are characterized by 0.5-1.5 mm (VP3) to <0.5
134 mm (MA1) grain-size and a strong planar fabric, marked by the shape preferred orientation of
135 calcite and local diopside and quartz (Figure 2). They display diffuse mechanical twinning and
136 undulose extinction, both suggesting grain-scale plastic deformation [32]. Shear indicators are not
137 univocal, MA1 often shows asymmetrical bending of calcite tails around porphyroblast suggesting a
138 component of simple shear, but pure shear cannot be ruled out. Similarly, VP3 displays a less tendency
139 to develop asymmetric microstructures, point to a greater contribution of pure shear. Metamorphic
140 conditions have been quantitatively determined for both samples, VP3 developed at $T=700-800^{\circ}\text{C}$ and
141 $P>6\text{kbar}$, corresponding to >18km depth, while MA1 fabric was estimated to form at $T=600-750^{\circ}\text{C}$
142 and $P=6.5-7.5\text{kbar}$, corresponding to 20-24km depth [58,60].

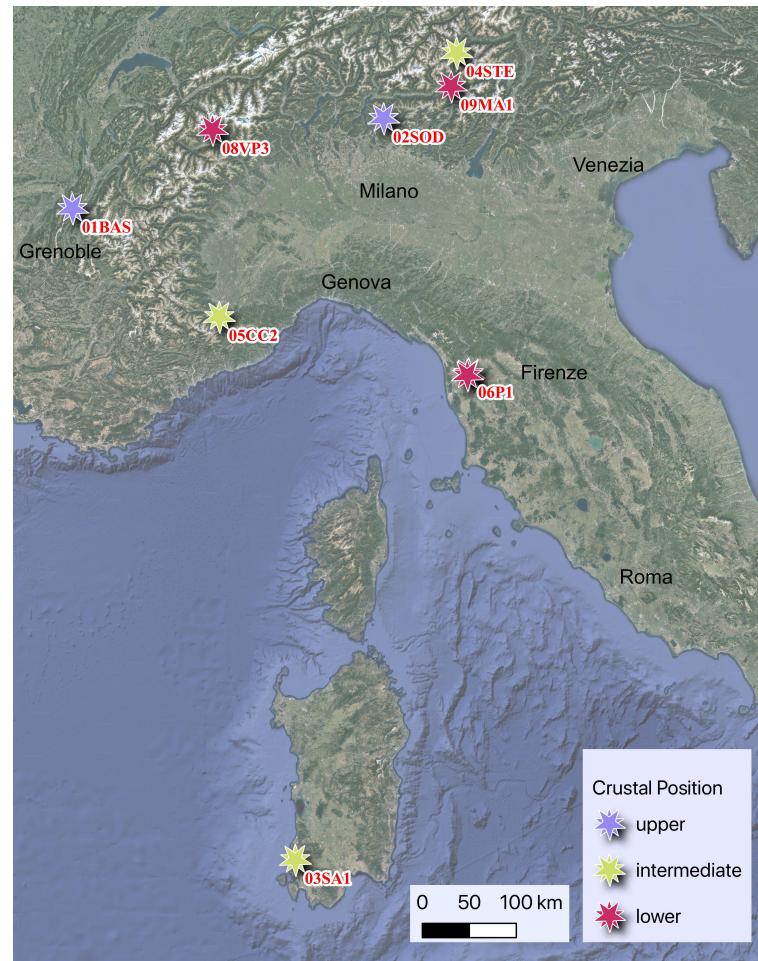

Figure 1. Location and crustal position of the studied samples, see text for explanation

Table 1. List of samples labels with Alpine geological domain, crustal position with depth in km, temperature in °C and shear geometry. Labels are the same as used in figures and text. See text for references on P, T and shear geometry. **Upper crust** for depth <10km at T < 300°C, **intermediate crust** for depth between 10 and 20km and T between 300 and 400 °C, and **lower crust** for depth >20km and T> 400°C

Label	Domain	Crustal Position	Temperature	shear geometry
01BAS	Helvetic-Dauphinoise	upper (<3km)	<100°C	no shear
02SOD	Southalpine	upper (<5-7km)	≈200°C	simple shear
03SA1	Sardinia Basement	intermediate (12-15km)	≈350°C	pure shear
04STE	Austroalpine	intermediate (15-20km)	300-350°C	simple shear
05CC2	Briançonnaise	intermediate (<15km)	300-350°C	pure/simple shear
06P1	Apuane Metamorphic Complex	lower (25-30km)	400-500°C	no shear
08VP3	Austroalpine	lower (>18/20km)	700-800°C	pure/simple shear
09MA1	Austroalpine	lower (20-24km)	600-750°C	simple/pure shear

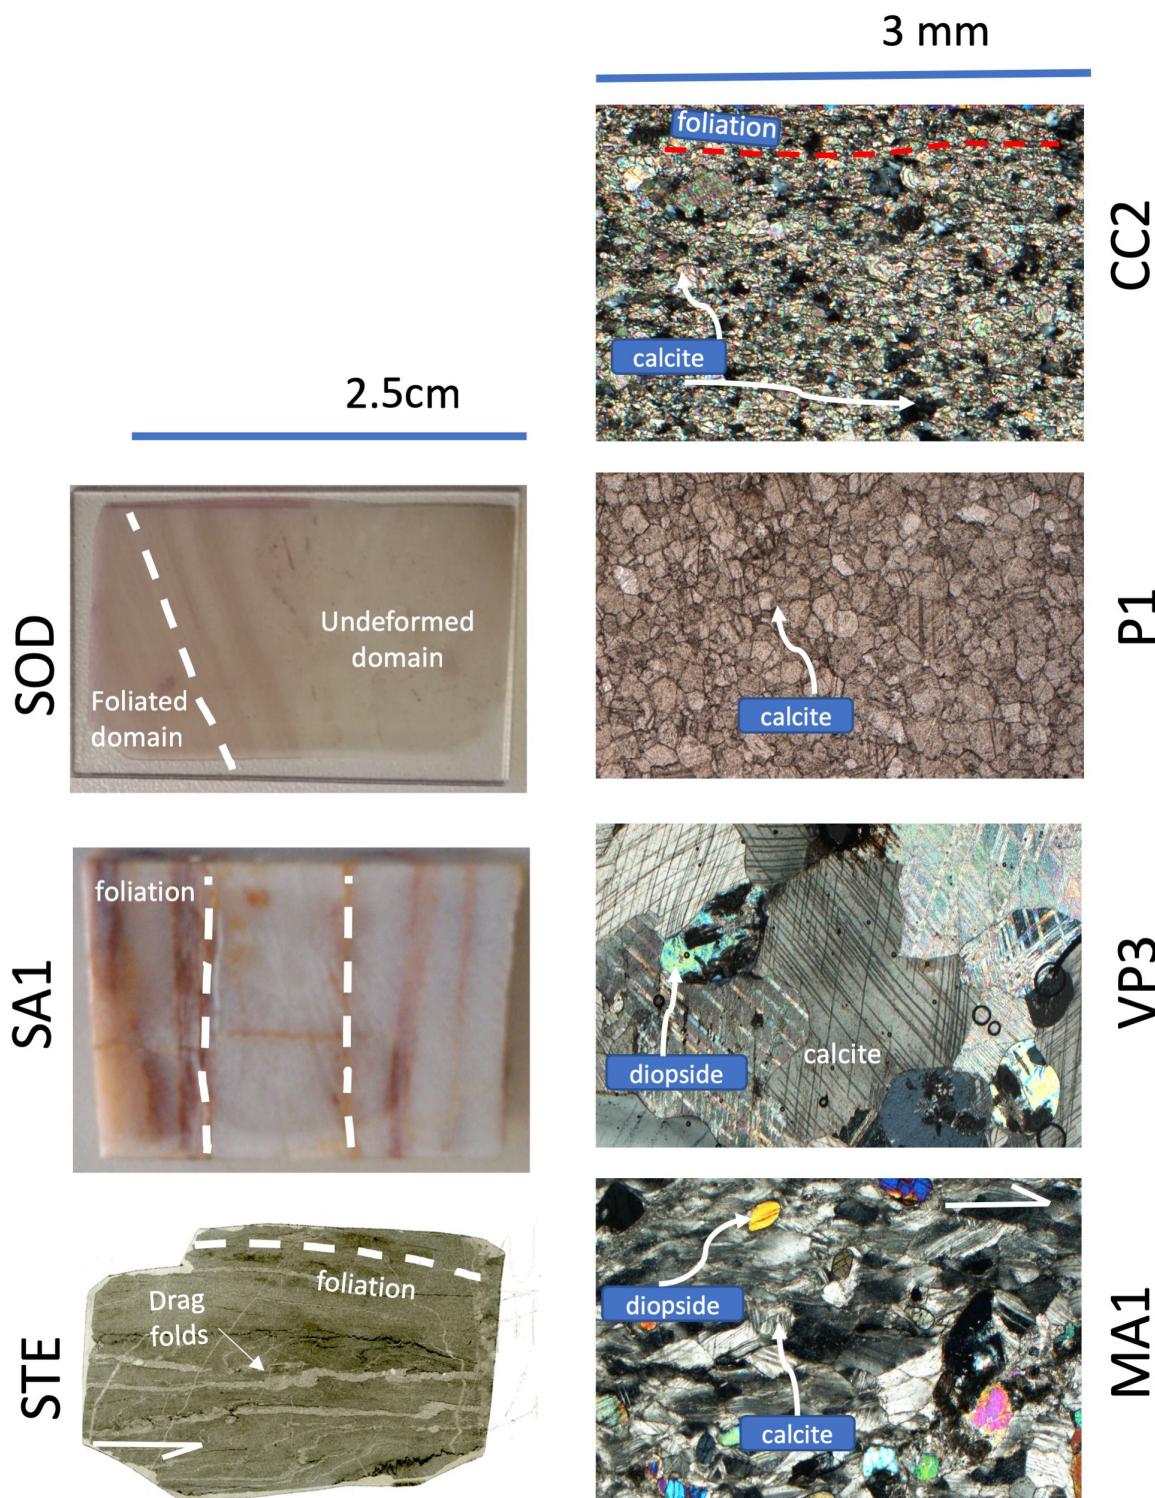

Figure 2. Images of selected samples showing main fabric features as layering or foliation. Scale is indicated. Long side of the image 2.5 cm for STE, SA1 and SOD; long side of the image is 3.0 mm for MA1, VP3, P1 and CC2. MA1, VP3 and CC2 images with crossed polarizers. P1 image with plane polarizers.

143 3. Sample Reference System and Methods

144 The samples were cut in cubes of $\approx 1\text{cm}$ edge (Figure 3); the three axes of the cube correspond to
 145 the orthonormal reference of the sample. In this orthogonal Sample Reference System, the plane XY
 146 corresponds to the stratification or shear plane, while X direction is taken parallel to the flow direction or
 147 lineation, if it exists (Figure 3). The references in figure 3b are used in all the Pole Figures (Figures 4, 5, 6).
 148 Pole figures display pole densities in multiples of a uniform distribution (mud).

Sample Reference System

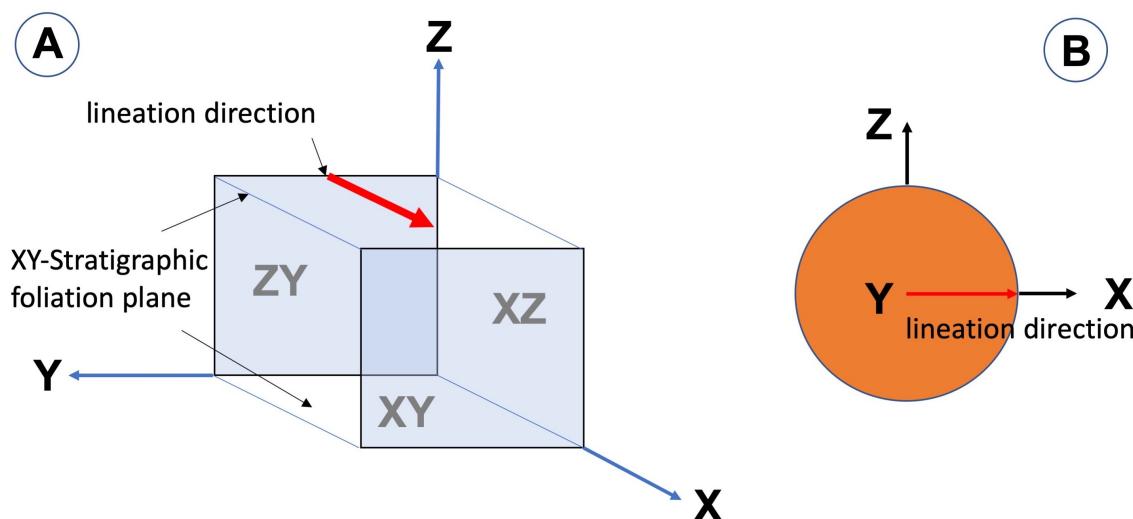

Figure 3. Sample Reference System and Pole figure representation. (a) Sample Reference System showing a simplified cubic sample with respect to the orthogonal reference. X, Y and Z axes are shown (b) Pole figure reference representation with X, Y and Z axes.

149 We used the non-disruptive method of the Quantitative Texture Analysis (QTA) by neutron diffraction.
 150 This method allows the evaluation of the Texture (also called Crystallographic Preferred Orientation,
 151 CPO) of the samples. It has been successfully applied to various types of rocks and synthetic materials:
 152 monomineralic quartzites [61], marbles [20], limestones [62], dunite [63] or glaucophanite [64], in
 153 poly-phasic rocks, as amphibolite [65,66], quartz-feldspatic mylonitic orthogneisses and gabbros [67,68],
 154 subaqueous lavas [69] or sandstones [70]. This procedure uses the high penetration and high flux of
 155 neutrons available at the nuclear reactor at the Institute Laue-Langevin (Grenoble, France) allowing
 156 the measurement of samples with volumes of approximately 1 cm^3 in one to eight hours [71]. Here,
 157 we present the results from the D1B, D19 and D20 diffractometers (<http://www.ill.eu>). The raw data
 158 have been analyzed using the software package MAUD (Materials Analysis Using Diffraction [72]):
 159 diffracted intensities are used to calculate the Orientation Distribution Function (ODF [73]), from which
 160 the representative lattice planes are extracted and represented as Pole Figures (PF). PFs were represented
 161 showing the reference axes from the Sample Reference System (X, Y, Z in Figure 3). The coverage of
 162 the three-dimensional sample space has been acquired differently at the three beam lines (D1B, D19 and
 163 D19), due to their technical specifications. Briefly, D1B works at $\lambda=2.52\text{\AA}$, equipped with a position
 164 sensitive detector, covering a 2θ range of 128° ; D19 is equipped with a very large ($120^\circ \times 30^\circ$) 2-dimensional
 165 position-sensitive detector, and works best in the wavelength range 0.8 to 2.4\AA ; D20 offers wavelength
 166 range 1.4 to 2.1\AA and the position sensitive detector covers 153.6° . The respective angular settings are

167 reported in Table 2. The ODF was calculated using the E-WIMV approach [73]. The reliability of the
 168 refinement is shown by the refinement parameters reported in Table 3. Calcite lattice parameters used for
 169 the refinements are $a=4.9849\text{ \AA}$ $c=17.0479\text{ \AA}$. 2Theta offset, sample position, and background parameters
 170 were also refined.

171 The Seismic Properties were obtained using petrofabric data, as extensively explained by [7]. Here we
 172 calculated the sample seismic properties by averaging the single crystal elastic tensor [77] weighted by the
 173 ODF, as obtained by Quantitative Texture Analysis by neutron diffraction. In practice, the ODF calculated
 174 using the Maud procedure was used to homogenize the single crystal tensor in Maud. Results for ODF
 175 refinements are reported in Table 3. Although various averaging procedures can be adopted [78], we used
 176 the arithmetic mean of Hill [79]. The resulting homogenized tensors were used in MTEX Matlab Toolbox
 177 [80] to compute and plot seismic properties [81] shown in Figure 6. The same averaged tensors have been
 178 then used to calculate the seismic anisotropies at different dip angles of the foliation plane, simply rotating
 179 the tensors and changing the plane of projection for the pole figure in Figure 8. Pole figures in Figure 8 are
 180 plotted in a way that only the Y axis remains constant and the observer is looking down from the Earth's
 181 surface having the macroscopic foliation plane rotating with respect to the Y axis.

182 As a general consideration, this approach to computing seismic velocities generally produces higher
 183 values when compared to natural samples. The most likely reason for this is that other important factors,
 184 intrinsic and extrinsic, controlling seismic velocities and anisotropies are not included in the calculation.
 185 These factors are fluid pressure, cracks density and their orientation, porosity, grain boundaries geometry
 186 and their shape preferred orientation [5,53,82,83].

187 A thermodynamic approach [66,84] was also used to calculate the seismic properties of a modeled
 188 carbonate rock at different pressure and temperature conditions, roughly corresponding to the estimate
 189 conditions of texture development of the studied samples. We used the PerpleX software package (version

6.8.6 [85]) to compute the seismic parameters as dependent on the thermodynamic function G (molar Gibbs free energy), which is minimized to establish phases, amounts and compositions stable as a function of pressure and temperature. The software requires a chemical composition of the system as input. Software and data used for the calculation of phase relations and seismic velocities are freely available at <http://www.perplex.ethz.ch>. The graphical outputs were obtained using pyWerami source [86]. The calculated seismic properties correspond to those of a polycrystal rock with no preferred orientations. An averaged composition of carbonate rocks has been used as the model chemical system [87]. The model system composition (in wt %) is: $\text{SiO}_2=3.02$, $\text{Al}_2\text{O}_3=0.56$, $\text{FeO}=0.39$, $\text{MgO}=0.75$, $\text{CaO}=52.40$. In the computation CO_2 is considered saturated and, as solid solutions were chosen $\text{Do}(\text{HP})$ dolomite-ankerite solution, $\text{M}(\text{HP})$ for the magnesite-siderite solution, and $\text{Cpx}(\text{HP})$ clinopyroxene [88] and [Perplex datafile repository](http://www.perplex.ethz.ch/datafiles/). Holland and Powell (1998) [88] and successive update [89] (datafile hp62ver.dat at <http://www.perplex.ethz.ch/datafiles/>) was used as thermodynamic database. A typical output (Figure 7A) consists of pressure and temperature grid (in this calculation, $P=1-15$ kbar and $T=100-1000^\circ\text{C}$) where the stable phases and assemblages are shown (i.e., pseudosection). Using the application Werami, which is part of the PerpleX package [85], specific properties were investigated in the P-T space and plotted in Figure 7B and 7C. Namely, we investigated the variations of modes, density, V_p and V_s of all phases within the investigated P-T ranges. Input data for PerpleX calculation may be found as supplementary materials.

4. Results

4.1. Textures

Figure 4 reports the calculated PFs for a single crystal-like of calcite, an aggregate of equigranular randomly-disposed crystals, and an aggregate of equigranular grains, by a statistical Fibre-Bingham distribution.

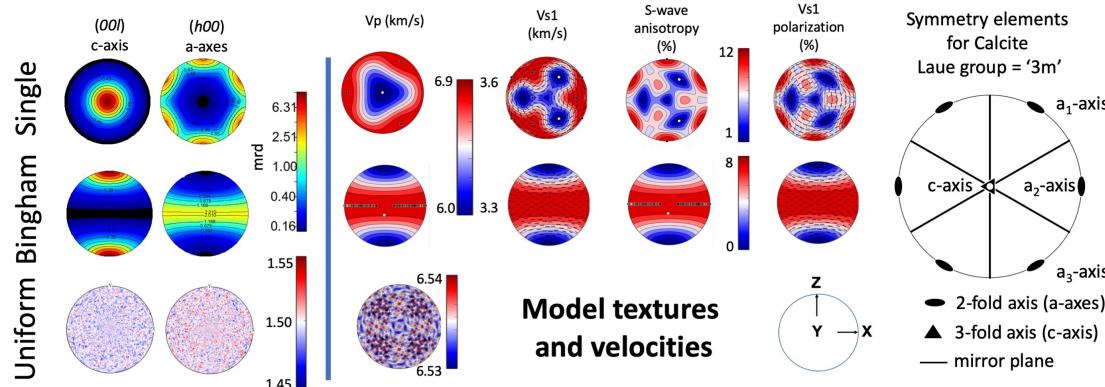

Figure 4. Pole Figures for model Textures and Seismic Velocities for Single Crystal-like, Uniform and Bingham Textured samples. Symmetry elements are shown for calcite crystal

They show the contributions to Texture expected by the crystallographic symmetry only or by textures: i) single crystal distribution is characterized by a strong c -axis maximum and a three-fold axes distribution in the plane normal to the c -axis; ii) oppositely, a random or uniform distribution of equigranular aggregate will reduce or obliterate the crystal symmetry anisotropy, producing a random statistical distribution, in any directions of the 3d space; iii) lastly, an imposed (e.g., tectonic stress) distribution, here represented as

217 the Fibre Bingham distribution [90], will produce strong maxima that follow neither the crystal symmetry
218 and nor a random distribution.

219 Figure 5 reports the pole figures representing the lattice planes (001), (110), (100) texture measured for
220 the studied samples. Calcite texture are commonly expressed showing c- and a-axes distributions (e.g. (001)
221 and (100)) and m-planes (110) since these orientations better describe the deformation mechanisms active
222 during plastic deformation at lattice scale and are commonly reported in the literature. Table 3 reports
223 the R factors and F^2 factor, commonly used in texture analysis to assess the quality of ODF refinement.
224 In general, the samples show different texture distributions and densities but they can be divided into 2
225 principal types: a random distribution (01BAS, 06P1); c-axis textured distribution (02SOD, 03SA1, 04STE,
226 05CC2, 08VP, 09MA). The c-axis textured distribution may be further divided into orthorhombic (02SOD,
227 05CC2, 09MA) and monoclinic symmetry (03SA1, 04STE, 05VP) types. The orthorhombic type (A) is
228 characterized by parallelism between the (001) poles and the Z direction. On the other hand, monoclinic
229 type (B) shows an angle between the (001) poles cluster and the Z direction. Symmetrically, the (100) poles,
230 which generally display a girdle distribution, may lay orthogonal to the Z direction or with an angle,
231 generally 30 to 45 degrees. F^2 values (Table 3) may be used as overall index to assess the randomness of
232 the texture [91,92]. As expected for poorly textured samples, 01BAS, 06P1 have F^2 close to 1 mrd², even
233 though 01BAS displays a minimum amount of preferred orientation. 02SOD, 04STE, 05CC2 and 09MA are
234 characterized by well developed textures, though the F^2 index is relatively low, being between 1.10 and
235 1.26 mrd². Higher F^2 values are shown by 03SA1 and 09MA.

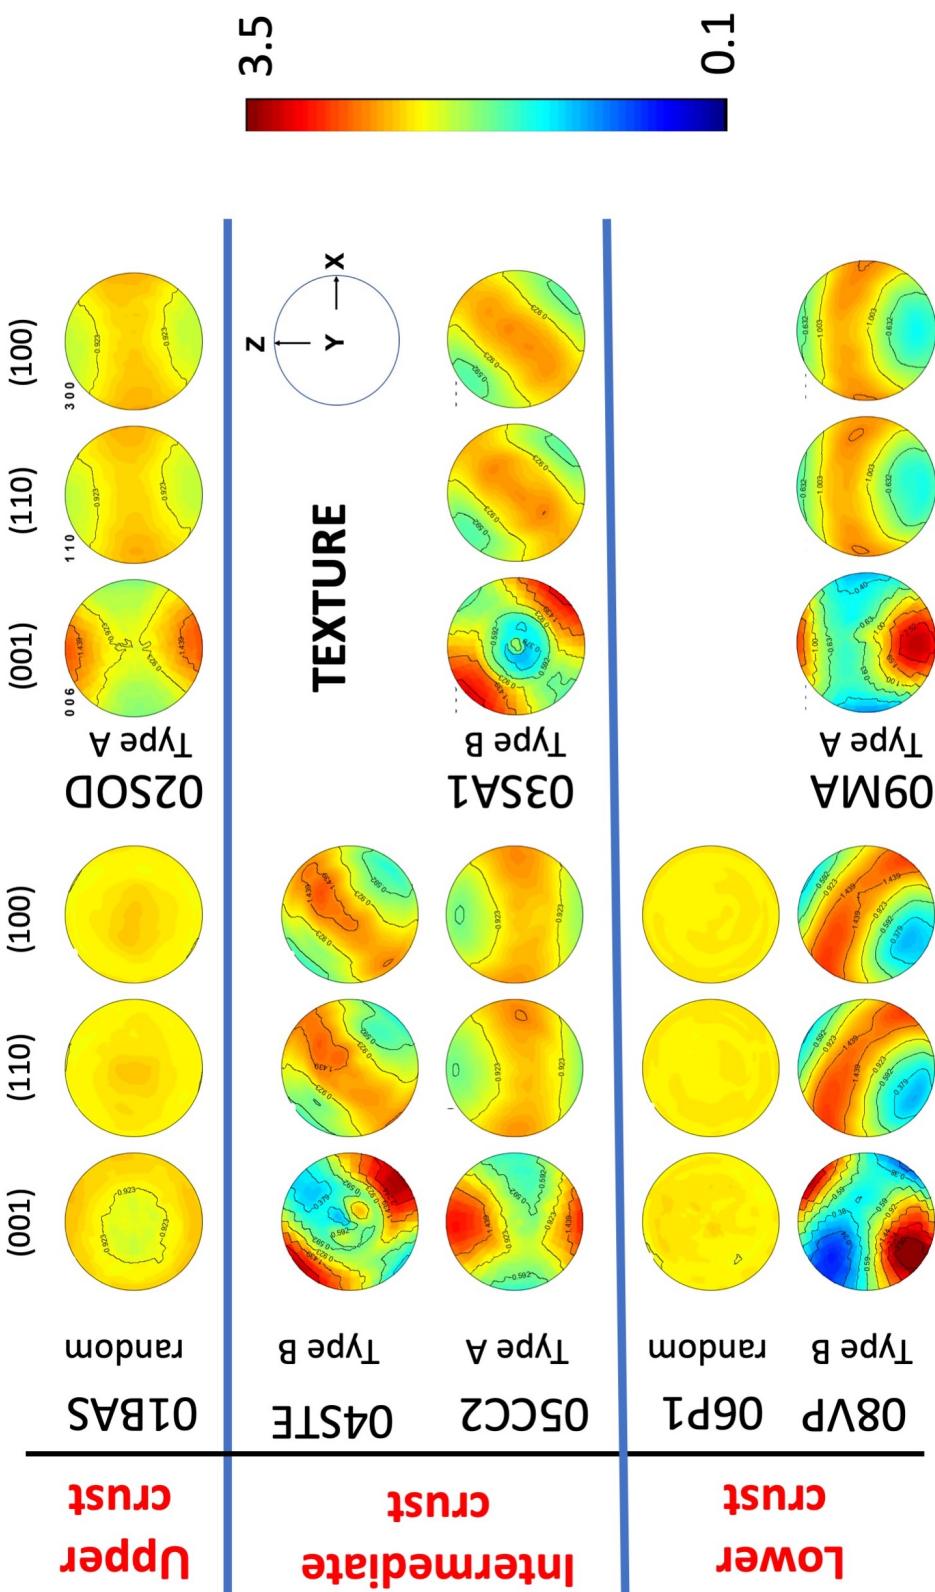

Figure 5. Texture for the studied sample. Pole Figures represents density contours of poles to plane (001), (110), (100), in multiple of uniform distribution (mud). Axes reference as in Figure 3b

236 4.2. *Seismic Velocities*

237 Figure 6 reports the calculated seismic velocities. Namely, P-wave V_p (km/s), S-wave anisotropy and
238 V_{s1} and V_{s2} polarization. Their distributions closely resemble the main texture feature (Figure 5). In fact,
239 since the c-axis direction is the slowest V_p in the single crystal setting, and the a-axes directions are close
240 to fastest (Figure 3), the general feature that shows up is that the pole to (001) distribution correspond
241 to the slowest directions in the V_p plots. So, the prediction of the slowest direction in carbonate rocks is
242 relatively straightforward since it is influenced by the c-axis distribution. In contrast, S-wave anisotropies
243 are more complex to predict since they result from a combination of textures (Figure 5). Specifically, 02SOD,
244 06P1, 08VP and 09MA display a girdle distribution of the poles to (100) and (110), which correspond to a
245 pronounced direction of fastest propagation. Conversely, 01BAS, 03SA1 and 05CC2 are characterized by
246 single or multiple clusters for S-wave anisotropies, giving a more complex pattern of polarization. 04STE
247 displays a mixed distribution, where a weak fastest S-wave girdle links the two clusters.

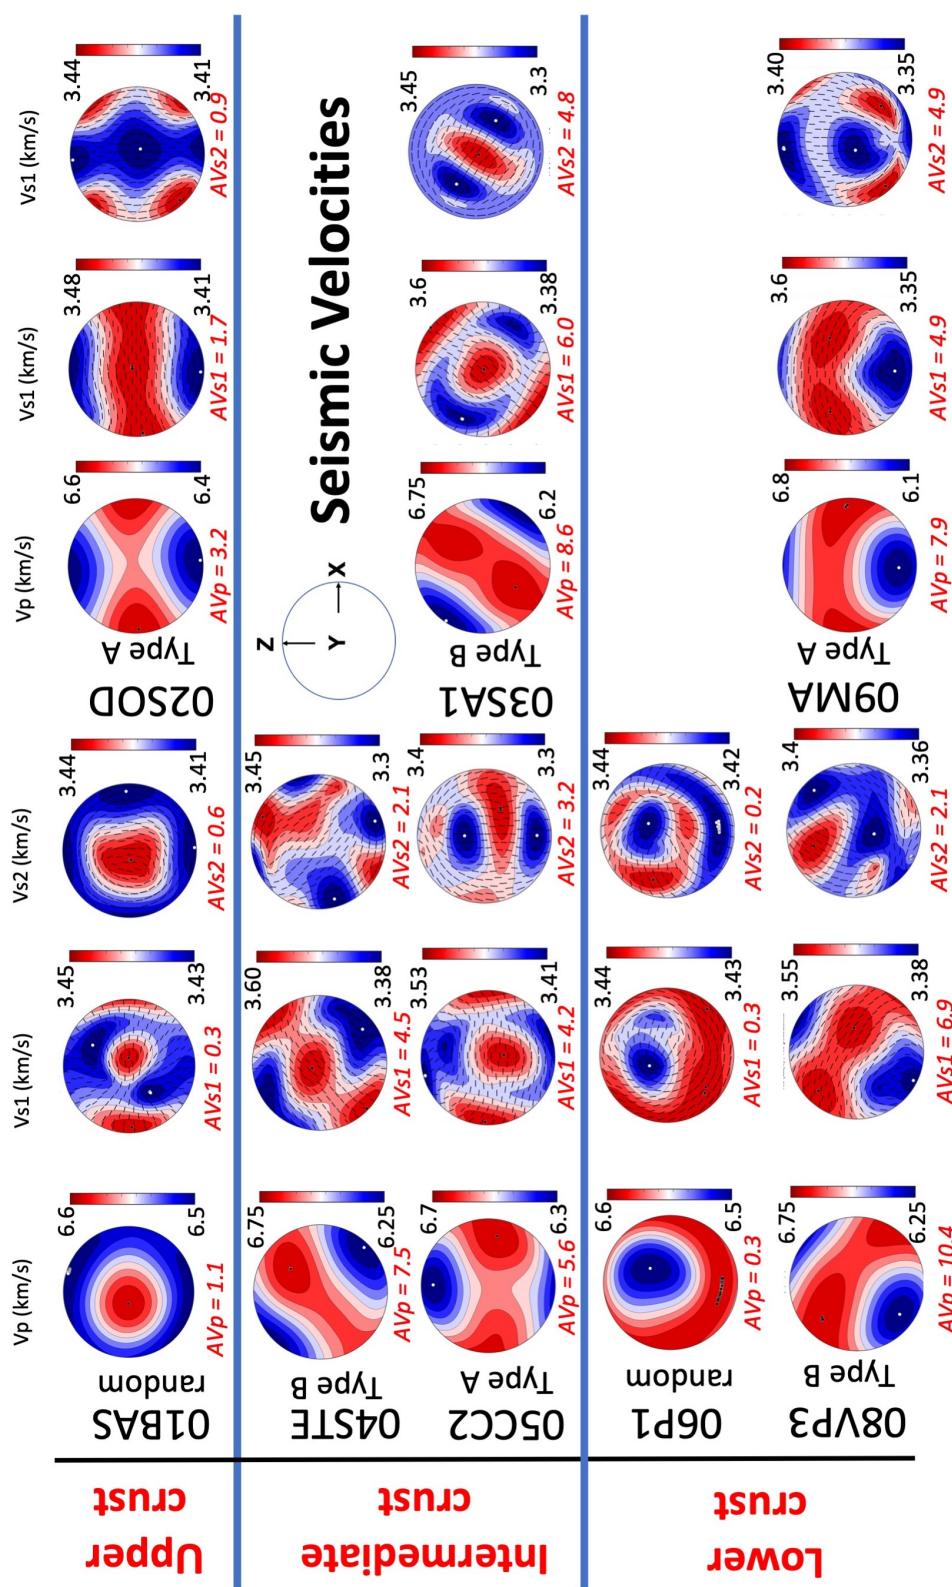

Figure 6. V_p (km/s), V_{s1} (km/s) and V_{s2} (km/s) seismic waves velocities for the studied samples. Anisotropy for V_p (AV_p), V_{s1} (AV_{s1}), V_{s2} (AV_{s2}) are calculated as $A = 200 * (\max V - \min V) / (\max V + \min V)$. For AV_p $V = V_p$, for AV_{s1} $V = V_{s1}$, for AV_{s2} $V = V_{s2}$.

248 5. Discussion**249 5.1. Texture types evolution with temperature, pressure, shear geometry and strain**

250 Texture data reported in Figure 5 fall into the types of calcite texture most commonly described for
 251 natural rocks [93] and reported in experimental results [16,17,94,95]. In particular, we separated two types:
 252 random, where no or a little preferred orientation is found, and textured, characterized by a strong c-axis
 253 maximum and a-axes girdle distribution. Textured types have been further separated in Type A and Type B,
 254 to emphasize the relations between Texture and shear plane, as described for pure shear (i.e., orthorhombic
 255 geometry, Type A) and simple shear (i.e. monoclinic geometry, Type B) [20,93,96]. Type A and B have been
 256 used to infer the deformation regime and the sense of shear (e.g. [97–100]). However, Pieri et al. (2001)

[101] demonstrated the risk of simplifying those textural relations with deformational regimes. In fact, the most common calcite deformation mechanisms may allow, even at low temperature, a quick transition from monoclinic to orthorhombic symmetries, even under a simple shear regime and at low strain (>2). Similar observations have been made on naturally deformed marbles [102]. Accordingly, the studied samples also show that discriminating between high temperature (HT) and low temperature (LT) textures is not an easy task. For example, 02SOD, 05CC2 and 09MA1 samples, though their textures developed respectively at $\approx 200^{\circ}\text{C}$, $300\text{--}350^{\circ}\text{C}$, and $600\text{--}750^{\circ}\text{C}$ (Table 1), they all display a similar orthorhombic symmetry; specularly, 04STE, 03SA1, 08VP share the same texture but developed at different temperatures, $300\text{--}350^{\circ}\text{C}$, $\approx 350^{\circ}\text{C}$, and $700\text{--}800^{\circ}\text{C}$ (Table 1). Literature data, between **100 and 400°C** at increasing shear strain, suggest a general evolution from Type A texture, generally far from the shear zone core, to Type B textures and, more often, the coexistence of Type A and B [82]. Type A seems to become dominant at very high shear strain values and very high pressures [16,103]. At low temperature ($<300^{\circ}\text{C}$) and low pressure ($<3\text{kbar}$), as in carbonate fault gouges or thrust systems, Type B is generally favorite [104–106] while A and B types start to compete where temperature, pressure and shear strain all overcome certain thresholds. These threshold values are hard to quantify; most likely pressure should exceed 3–4 kbar and shear strain 1–2 [13,16,82,96,103,106]. Similar competing textures were also described for dolomite deforming between $240\text{--}300^{\circ}\text{C}$ under simple shear geometry [107]. Besides, the recent experimental work of Schuster et al. (2019) [16] shows that very high shear strains (>80) tent to stabilize Type A texture that replaces early A or B types. This experimental work also strongly supports the findings by Ebert et al (2007) [103] that constrained similar evolution from field observations. In particular, Ebert et al (2007) [103] showed evolving random to Type A and B textures as temperature and shear strain increase. Ebert et al (2007) [103] also showed textures similar to those of 04STE and 03SA1 samples where the angle between the c-axis maximum and the Z axis is much higher than typically described.

Similar considerations may be done on metamorphic marbles produced at intermediate temperature ($\approx 400\text{--}600^{\circ}\text{C}$) and pressures related to subduction-collisional tectonics ($\approx 10\text{--}20\text{ kbar}$). In particular, the large literature available on the Carrara Marble allow us to constrain textural types with shear strain geometry and grainsize. Large (1–2 mm) to intermediate (0.1–0.5 mm) grainsize marbles, characterized by granoblastic textures may show random texture [53,108] as well as Type A [52]. The first most likely due to static annealing or larger scale strain-partitioning and the second associated with grain boundaries migration and subgrain rotation dynamic recrystallization processes [32]. In marbles showing shape preferred orientations and microscopic foliation, the Type A is better developed [20] suggesting a high shear strain condition. Experimental work on Carrara marbles under torsion [109], ranging between 500 and 700°C and shear strain from 0 up to 50, support the observations [110] that Type A easily stabilizes at high strain conditions replacing Type B, no matter if coaxial and non-coaxial. Again, this process seems to be more likely occurring at high temperatures ($>500^{\circ}\text{C}$) [110]. Barnhoorn et al. (2004) [109] also showed that at low temperature ($\approx 500^{\circ}\text{C}$) random texture may replace Type B textures increasing shear strain. Other intermediate temperature marbles ($400\text{--}500^{\circ}\text{C}$), from elsewhere (e.g. [11,102,111,112]) support this shift from B to A types texture. However, no shear strain constraints are available to include these observations in the above scheme. Higher temperature ($>600^{\circ}\text{C}$) marbles, similar to samples 08VP3 and 09MA1, naturally [22] or experimentally [14,109] deformed do not show a strong shift from B to A type texture. These observations may be taken to support the idea that shear strain most likely controls the textural type, more than temperature. However, more observations are needed to build a valid general scheme. More observations are also needed to produce a solid scheme to relate deformation mechanisms with the observed textures. The texture observed in these samples do not uniquely relate to specific deformation mechanisms. Type A and B textures are present in samples where intra-crystalline slip mechanisms are relevant, as 08VP3 and 09MA1. On the other hand, where twinning is present, together with grainsize reduction deformation mechanism (02SOD, 04STE, 05CC2), both Type A and Type B may

304 develop [100]. Moreover, the combination of sub-grain rotation mechanisms, known to be important at
305 similar conditions [16], and grain-boundary migration may have contributed to the observed random
306 texture in P1.

307 *5.2. Seismic anisotropy*

308 Seismic velocities and anisotropy of carbonate rocks in the studied samples change with texture types
309 (Figure 6). Vp velocities vary from a minimum of 6.1 km/s to a maximum of 6.8 km/s; AVp anisotropy
310 varies between 0.3 and 10.4 (Figure 6). Vs varies from 3.3 and 3.6 km/s, while Vs1 anisotropy varies
311 between 0.3 and 6.8. The direction of maximum Vp varies from parallel to X direction of the fabrics
312 (05CC2, 02SOD, 09MA), corresponding to Type A texture, to more than 45 degrees in the XZ plane (04STE,
313 03SA1, 06P1, 08VP3), for Type B texture. Vp displays a general girdle distribution that roughly describes a
314 plane of max Vp. Max Vp plane changes its orientation even within the same group of Vp max direction.
315 Vp max in Type B samples has an angle with X direction that varies between 20 to 50 degrees. More
316 interestingly, the Vp maximum frequently dips about 20-30 degrees away from the circumference (XZ
317 plane). Similarly, the Vp max girdle plane dips between 20 to 50 degrees from the plane of shear. Besides,
318 Vs velocities frequently show a double to triple maxima distributions. A large literature is available
319 for sedimentary rocks, though the large majority is dedicated to shales and sandstones (see complete
320 review [7]). Similar Vp and Vs values have been measured and calculated for calcite [13,22,82,113,114]
321 at different temperature and depth conditions. Vp velocities most frequently show a girdle distribution
322 of maxima variably dipping to the plane of shear, recalling Type A and Type B distributions. In general,
323 the Vp and Vs velocities overlap with those calculated for our samples, a part for those samples from
324 very shallow depth (<1000m) [113,114] where only after reducing porosity and increasing cementation the
325 Vp values go from low (<5km/s) to higher values, more similar to those here measured and calculated
326 (>6 km/s). These observations support the general idea that carbonate rocks anisotropy also contributes
327 to the overall anisotropy of the crust [7,22,82], at any depths. To further investigate the nature of this
328 anisotropies we calculate the seismic isotropic component by the thermodynamic modeling described in
329 chapter 3. The thermodynamic modeled seismic velocities, Vp and Vs (Figure 7), describe a range of Vp
330 wave velocities from \approx 6.0 km/s to 6.5 km/s. Vs velocities vary from 2.6 to 3.0 km/s. The P-T plots in
331 Figures 7B and 7C are characterized by three main parts where Vp and Vs vary progressively as a function
332 of the changing mineral assemblages and mode proportion, as described in the pseudosection of Figure
333 7A. The three sectors are characterized by: i) the presence of aragonite instead of calcite at high pressure
334 and low temperature; ii) the association of calcite and dolomite at intermediate temperature and pressure
335 from low to high; ii) the stabilization of clinopyroxene at high temperature, for low to high pressures. In
336 general, Vp and Vs wave velocities decrease moving toward higher temperatures and increase moving
337 toward higher pressures. According to the pressure and temperature constraints for the studied samples
338 (Table 1) we are below the aragonite phase transition and the Vp should vary from 6.0 to 6.5 km/s, and Vs
339 from 2.8 to 3.0 km/s. The calculated values from texture analysis [68,84] as well as those reported in the
340 literature, differ by about 10% from these calculated values. These values are generally closer to measured
341 seismic velocities taken orthogonal to the maximum shear direction (i.e., lineation) [53] or in the more
342 isotropic samples or very shallow sample, dominated by low porosity (<10%) [114]. Consequently, these
343 Vp and Vs can be used as a reference for the isotropic component of carbonate rocks, to investigate the
344 amount of anisotropy to be expected when observing real seismic data for similar rock composition. In
345 general, the analyzed samples show an increase of seismic velocities due only to textural anisotropies
346 that can be about 0.2 to 0.8 km/s for Vp and 0.3 to 0.6 Vs. These results show that seismic properties
347 (e.g., velocities and anisotropies) even for a single rock type (e.g., carbonate rocks) may strongly change in
348 the crust, as function of temperature, pressure, and shear strain, as a result of texture types that strongly

control seismic propagation. Similar considerations have been proposed for other rock compositions. In these rock types specific mineral phases showed preferred orientations that produced relevant deviations from the isotropic component of the seismic properties (e.g. [7,13,23,84]). This evidence suggests that at depth there is important overlapping between different rock types in term of their seismic properties, such that unambiguous determination of geological information from natural seismic data imply a combined use of many parameters [115]. In addition, it is clear that also the orientation of the macroscopic fabric, shear foliation, lineation, or any fabric associated with texture in rock-forming minerals play an important role in defining seismic anisotropies [24,84].

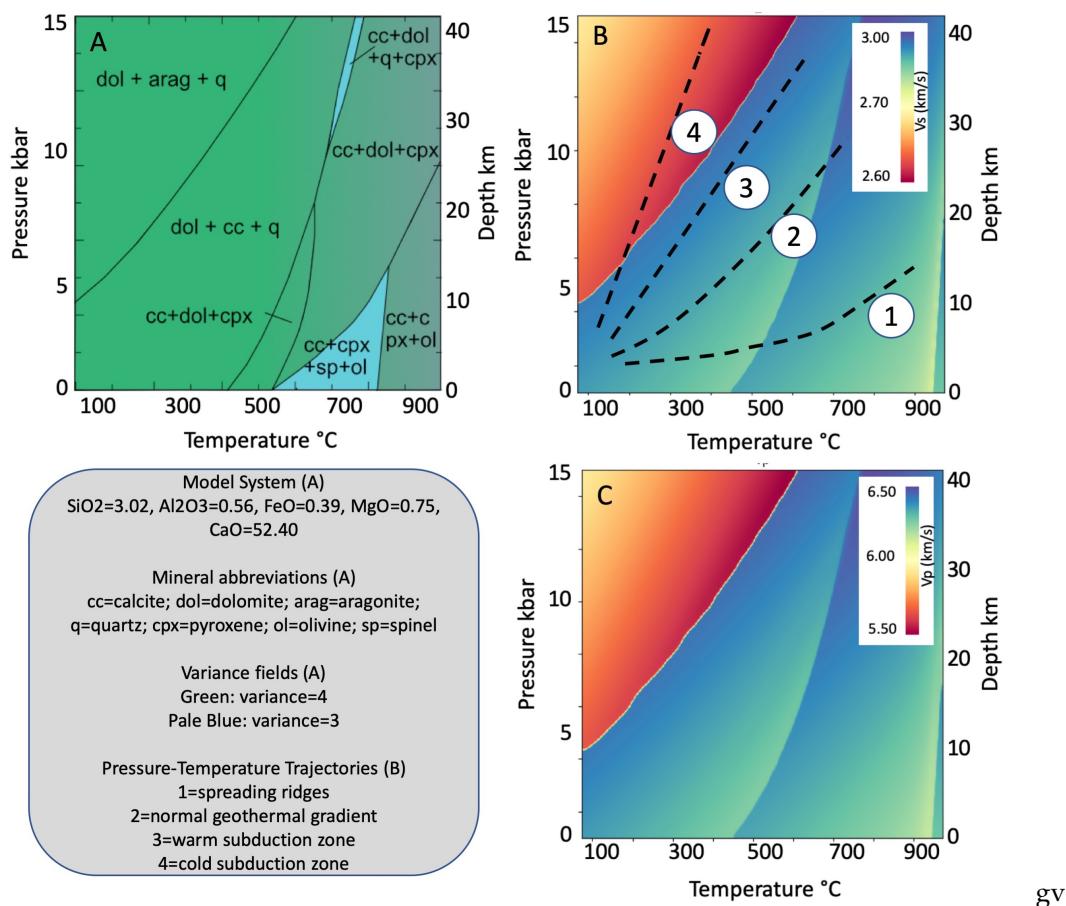

Figure 7. A) Pseudosection calculated using Perple_X thermodynamic packages [85]. B) Vs (km/s) seismic waves contour diagram. C) Vp (km/s) seismic waves contour diagram. Geothermal gradients in B after Cloos (1993) [116].

To further investigate the relevance of the orientation of the shear plane at different depth in the crust, we used the approach of Ko and Jung (2015) [24] by rotating the shear flow plane around the Y axis. In Figure 8 the results are shown by changing the plane of view, from XZ, used in Figures 3, 4, 5, 6, to XY. Figure 8 shows the progressive variations of the seismic properties by changing the dip angle from 0 to 90 degrees (0, 30, 45, 70, and 90). From the resulting rotated tensors, the components of Vp, Vs1 and Vs2 were read parallel to the horizontal component of the X direction (X' in Figure 8), as well as parallel to the normal to the Earth's surface (T in Figure 8). Random textures are characterized by a constant Vp and Vs2 maxima parallel to the Y direction and the lowest direction being within the X'T plane. The lowest velocity is always recorded parallel to the vertical T direction, at any dip. A relevant deviation is found

366 for the Vs1 where the highest velocities parallel to T are recorded at dip >45 degrees, while parallel X'
367 at dip <45. Type A shows relatively similar features for samples at different depth, with a general trend
368 with the X' component of Vp which decreases for steep dipping shear zones, while the T component
369 increases, becoming the fastest at depth >30-45 degrees. The Vs1 component generally decreases for the
370 three samples at different depth, but it is steeper for the lower crust sample (e.g., 08MA1). On the other
371 hand, Vs2 components show that the intermediate crust sample 05CC2 has a different trend compared to
372 the other samples. Type B has more diversification than Type A, Vp parallel to T may vary from slowest to
373 fastest, independently by the dip. 08VP3 and 06P1 show the fastest values parallel to T at dip>30. Vs1 and
374 Vs2 fastest are more commonly found at Y for 03SA1 and 04STE intermediate crust samples, while in 06P1
375 Vs1 fastest velocities describe a girdle close to the X'T plane at any dip and in 08VP3 sample become closer
376 to T at dip>45. Vs2 velocities Vs2 fastest velocities are in the direction of Y for 03SA1 at any dip while
377 they are highly variable for the sample 04STE. Girdles with maxima characterize Vs2 in 06P1 and 08VP3,
378 producing highly heterogeneous distribution at different dip.

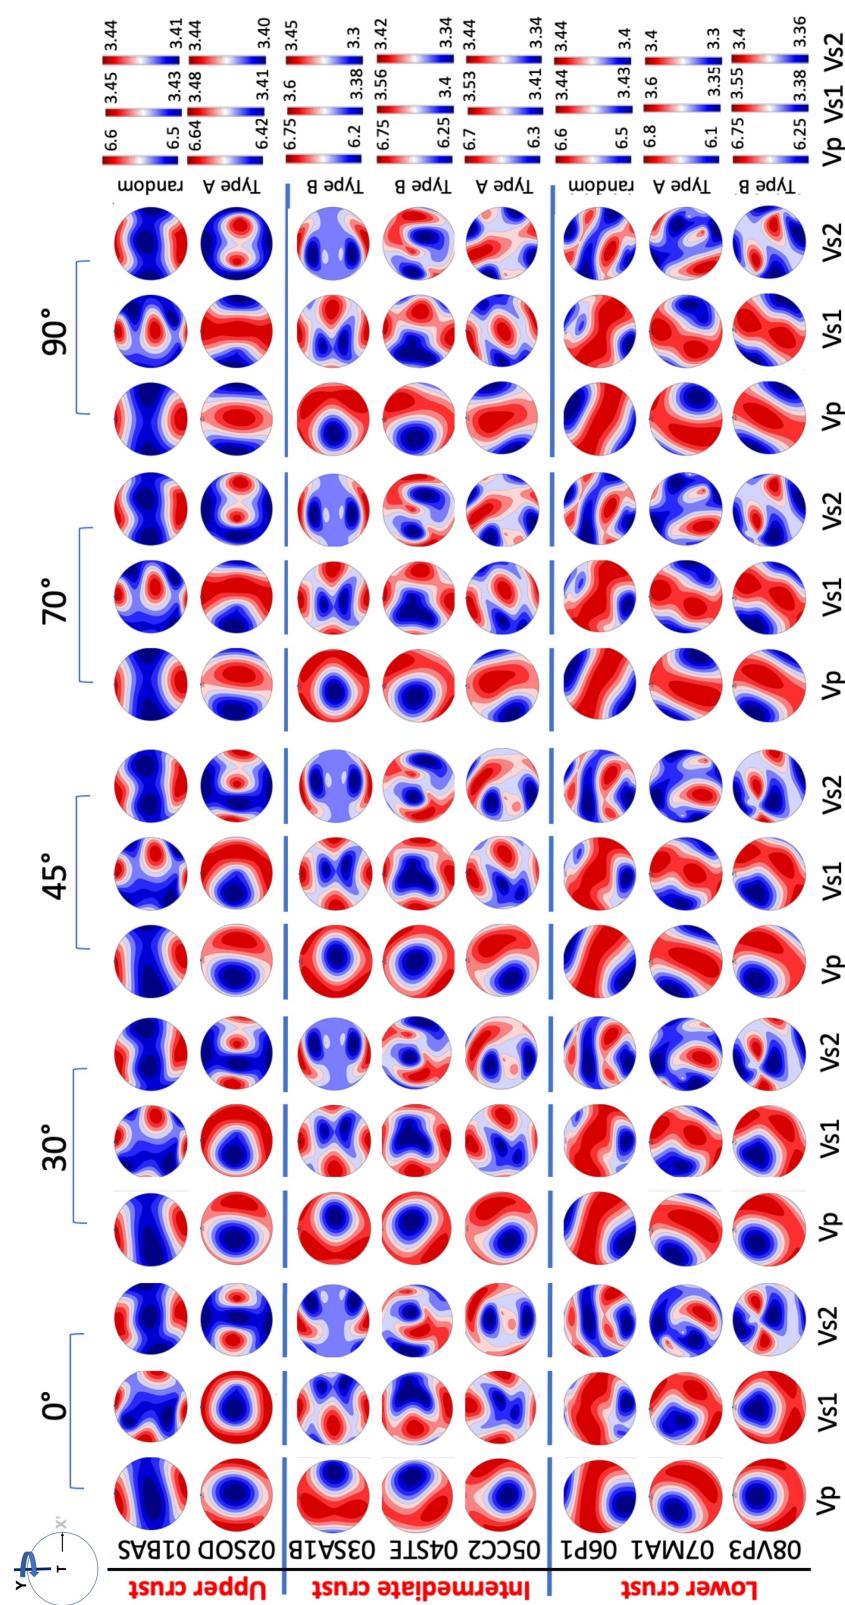

Figure 8. Pole Figures representing the P- and S- (S1 and S2) seismic velocities for calcite at different depth and dipping angle of the main macroscopic fabric plane (e.g. shear plane or stratification). X' correspond to the horizontal component of the X fabric axis while T correspond to the normal to the horizontal surface.

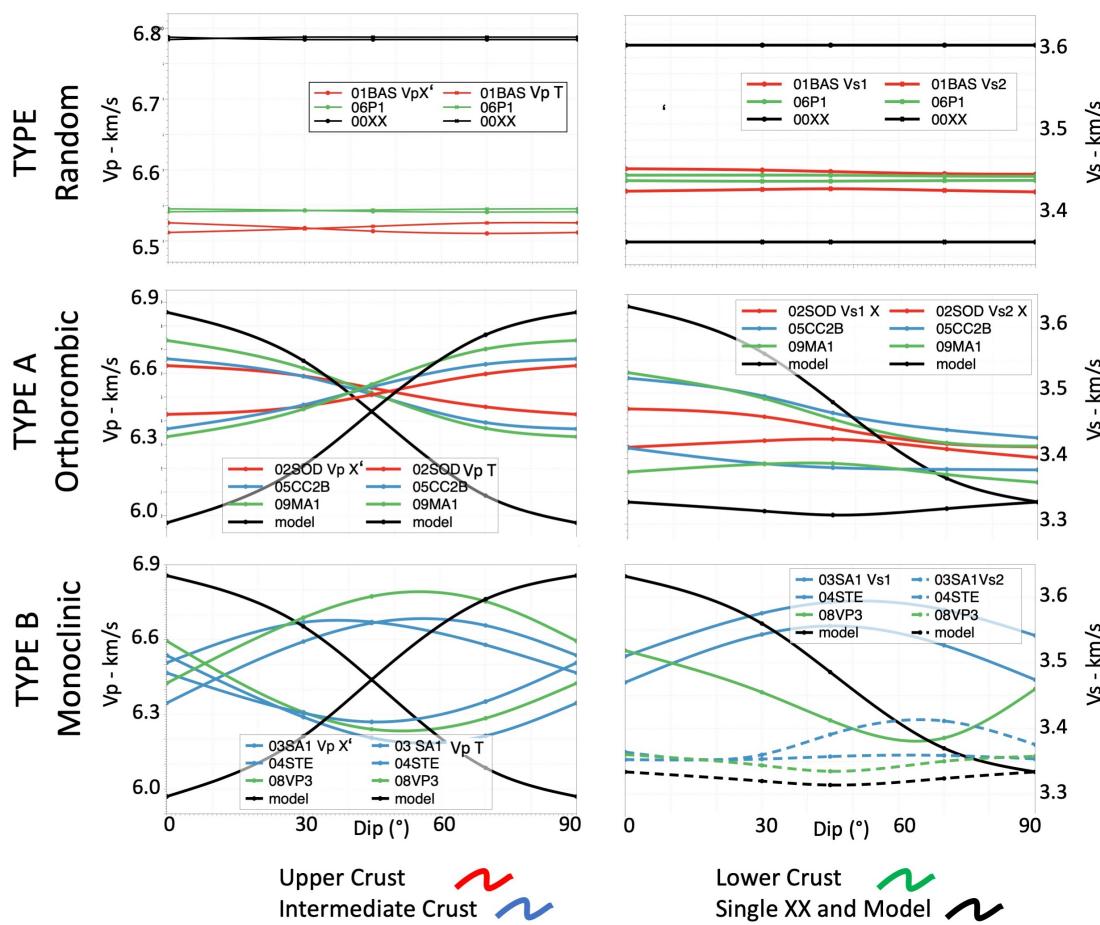

Figure 9. Vp components propagating horizontally (X' component) and vertically (T component) - Vs1 and Vs2 horizontal component (of X)X'. See text for explanation

379 In the Type B distribution, the lower crust sample 08VP3 displays an opposite trend to the intermediate
 380 crust samples 03SA1 and 04STE. In particular, while for the intermediate crust samples the horizontal
 381 Vp and Vs1 values increase from 0 to 45-50 degrees and then decrease approaching vertical dipping,
 382 the lower crustal sample 08VP3 starts decreasing and then, at about 60 degrees dip, increases. These
 383 heterogeneities also occur for vertical Vp and Vs2 components. The Vp vertical component closely mirrors
 384 the Vp horizontal, while the Vs2 components are less sensitive to the dip variation, being in a smaller
 385 interval, generally < 0.1 km/s.

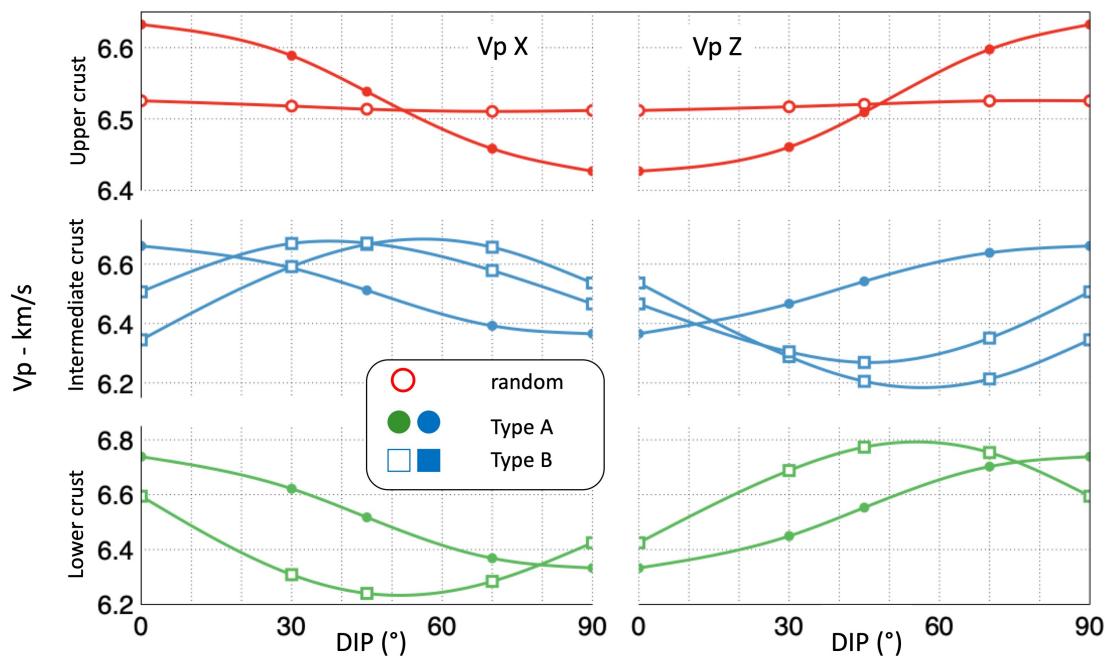

Figure 10. Vp crustal section. upper crust = red, intermediate crust = blue, lower crust = green. Texture types: A = hollow circle; A = full circle; B = hollow square

386 Figure 10 represents the Vp velocities at different depths, at varying dip. From 0 to 15 degrees dipping
 387 of the shear planes, as those generally developed along the flat part of thrust systems [9], the Type A
 388 textures produce higher Vp velocities propagating horizontally, parallel to X' component (Figure 8) and
 389 slower parallel to the normal to the topographic surface (T component in Figure 8). This setting does not
 390 change with depth, while the fastest Vp velocities are recorded at depth (i.e., lower crust). This pattern is
 391 reversed at different dip angles: upper crust at 50 degrees, intermediate crust between 20 and 30 degrees,
 392 and the lower crust at 80 degrees. At intermediate crust conditions, this flip may correspond to the
 393 evolution of the thrust system from flats to ramps. The change of dip correspond to a substantial increase
 394 of Vp velocities parallel to X', from 6.4 to 6.7 km/s. At the same depths, it corresponds a decrease parallel
 395 to T for rocks having a Type B texture pattern. Oppositely, at depth, both Type A and B produce an overall
 396 decrease of horizontally propagating velocities, from 6.8 to 6.3 km/s and from 6.6 to 6.2 km/s, respectively.
 397 Type B reaches its minimum at 50 degrees and then increases slowly approaching vertical dips. In general,
 398 steep dipping shear zones, as those in transtensional or transpressional systems (e.g., positive and negative
 399 flower structures), will produce slower or at maximum equal Vp velocities propagating horizontally (X')
 400 than shear zone within the same system but with lower dipping angles (Figure 10). Figure 11 represents
 401 the evolution of Vp seismic velocities (vertical component T) with depth at changing dip angles. Figure
 402 11 also reports the predicted P-wave velocities in the continental crust as modeled by Lloyd et al. (2011)
 403 [23] for 'rock recipes'. Vertical red boxes correspond to Vp ranges for middle to lower crust proposed by
 404 Rudnick & Fountain (1995)[117]. Two aspects arise from this image. Firstly, carbonate rock may overlap
 405 with average rock types or 'recipes' at various depth in the continental crust. Large discrepancies to these
 406 overlapping may arise by the dipping of the shear planes. At similar depths, Vp velocities may differ of
 407 about 0.3-0.5 km/s, only due to different dipping. Secondly, a specific pattern is reproduced by Type A
 408 texture, at any depth. Type A texture shows is characterized by an increase of Vp velocities as the dipping
 409 angle increases. This pattern is reproduced at the three different depths our samples represent. Moreover,
 410 Types B displays more variability in the way seismic velocities change with dipping of the shear plane.

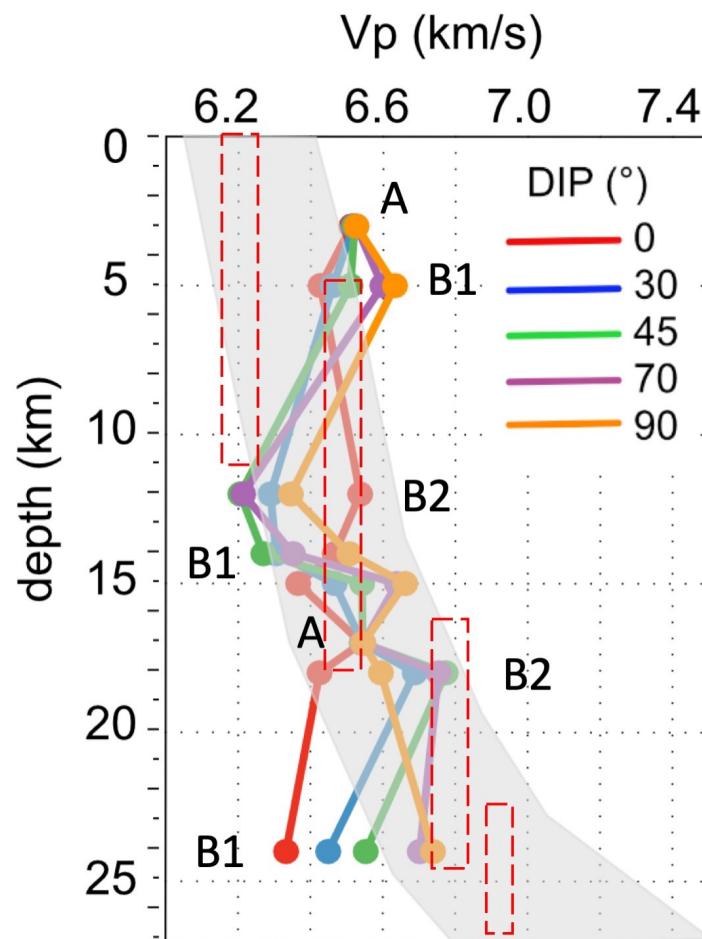

Figure 11. P-wave velocity propagating vertically (T component of Figure 8) crustal profile based on the data presented in this work for carbonate rocks at different depth and dip angle of the shear plane. Grey area correspond to the predicted P-wave velocities in the continental crust as modeled by Lloyd et al. (2011) [23]. Vertical red boxes correspond to Vp ranges for middle to lower crust Rudnick & Fountain (1995)[117]. A, A, and B texture Types described in the text.

411 6. Conclusions

- 412 • Eight samples of limestones and marbles were studied by neutron diffraction. We collected Texture
413 of naturally deformed calcite at different depths in the crust, from upper to lower crust.
- 414 • Different Texture patterns were recognized, from random to strongly textured (Type B); the latter,
415 with orthorhombic (Type A) or monoclinic (Type B) symmetries. Seismic anisotropies were calculated
416 using the Orientation Distribution Function to homogenize the elastic tensor of calcite.
- 417 • A wide variability of seismic anisotropies arise from the various textural types, crustal positions and
418 dipping of the shear planes.
- 419 • These results may be valuably used to guess geometry of shear zones at upper to depth for carbonate
420 rocks or at deeper crustal levels where thick carbonatic horizons are involved localizing deformation
421 (Figure 11).
- 422 • This work suggests that at depth, even for carbonate rocks, there is an important overlapping between
423 different rock types in term of their seismic properties (Figure 11); unambiguous determination of
424 geological information from natural seismic must consider the orientation of the macroscopic fabric,

425 shear foliation, lineation, or any fabric associated with texture playing a role in developing seismic
426 anisotropies [24,84].

- 427 • More work still needs to be done to include other parameters influencing seismic anisotropies, intrinsic and extrinsic, to build a database of natural rocks properties [5-7,13,23].
- 428 • Lastly, texture types may produce unique seismic velocities pattern. For example, Type A (Figure 11)
429 produce a unique pattern at any depth, characterized by an increase of Vp velocities (e.g., 6.3 to 6.8
430 at 20-25km depth) as the dipping angle increases. Future studies may show if these singular pattern
431 might be used to better constrain the interpretation of seismic profiles.

433 **Author Contributions:** All authors participated in the preparation of this manuscript. M.Z. conducted sample
434 collection, collaborated neutron experiments, data analysis and prepared the first version of the manuscript. D.C.
435 worked on neutron experiments and data analysis. B.O. worked on neutron experiments and data analysis

436 **Funding:** Neutron experiments were funded by ILL (www.ill.eu)

437 **Acknowledgments:** Two anonymous reviewers are greatly thanked for their help to produce the present form

438 **Conflicts of Interest:** The authors declare no conflict of interest.
