Abstract: The field of Cooperative Intelligent Transport Systems and more specifically Pedestrians to Vehicles (P2V) could be characterized as quite challenging, since there is broad research area to be studied, with direct positive results to society.P2V is a type of Cooperative Intelligent Transport System, within the group of Early Warning Collision/Safety System. In this article, we examine the research and applications carried out so far within the field of Pedestrians to Vehicles Cooperative Transport Systems by leveraging the information coming from VRU's smartphones. Moreover, extensive literature review has been carried out in the fields of VRUs Outdoor Localisation via smartphones and VRUs Next Step/Movement Prediction, that are closely related to P2V applications and research. We identify gaps that exist in these fields that could be improved/extended/enhanced or newly developed, while we address the future research objectives and methodologies that could support the improvement/development of those gaps. We also propose a P2V security framework that combines prediction and communication capabilities in order to avoid accidents between pedestrians and vehicles.

**Keywords:** Cooperative Intelligent Transport Systems (CITS); Vehicle to Pedestrian (V2P); Vulnerable Road Users (VRU); GPS; Smartphones; Inertial Measurement Units Sensors

# 1. Introduction

Vulnerable Road Users, VRU, is a collective term used to describe cyclists, motorcyclists, moped riders and pedestrians. More specifically, in one of the studies presented, the number of accidents were predicted under the acceptance that no further successful measures including ITS solutions were to be introduced within Road Transport Systems. For these studies, the Community Road Accident database, CARE, was used. CARE is a European Commission database resource comprising detailed data of individual accidents, from the EU Member States. According to this research, during the period 2002-2012, there was a significant decline in the number of accidents overall. However, the decline in VRUs accidents is much less recorded, with bicycle and pedestrian casualties remaining relatively constant. This research predicted that the number of bicycle accidents were expected to increase, while by 2030 the number of VRUs accidents will be almost comparable to those of car accidents, since there is a significant decreasing rate of those accidents [1]. Due to the fact that the number of fatalities remains high and despite the recent advances in traffic safety, the United Nations have set as one of the first priorities, to halve the number of deaths and injuries from road traffic

accidents by 2020 [2], while the European Commission aims at reducing the number of fatalities in road transport to nearly zero by 2050. In this context, Cooperative Intelligent Transport Systems, could play a significant role, since they utilize the coordination between different traffic agents such vehicles and vulnerable road users. In such a scenario, vehicles and VRUs could exchange information in order to prevent dangerous traffic situations. This type of connectivity is even more important via the market penetration of vehicular communication systems and the increasing use of smartphones worldwide. More specifically smartphones could play a vital role in the development of Pedestrian To Vehicle communication safety systems. By 2020, 6.1 billion smartphone users are expected globally. This equals 70% of the world's population, showing the potential of this new information source[3], while in last quarter of 2018 the total number of mobile subscriptions was around 5.9 billion[4]. Smart devices, with their included sensors and user interface, can provide information about the current movement state (velocity, acceleration, and heading) and the position and characteristics of their users, such as age, gender, habits. On the other hand, sensors installed on vehicles, could also provide information about vehicle's current position, direction, speed but also driver's intensions. The concept of Cooperative Intelligent Transportation Systems, C-ITS, is to combine measurements and information from vehicles, pedestrians, and local infrastructure within a limited geographical area. Current applications within this area of interest are collision avoidance systems, emergency vehicle warning systems and traffic mitigation [5].

The contributions of the paper are three-fold:

- A comprehensive review of current state of the art outdoor localization methods via smartphones is conducted.
- In addition, Vehicle to Pedestrians (V2P) Systems systems and methods for Next Move/Step Prediction are presented and analyzed
- Finally, a framework Prediction Communication P2V is proposed.

The rest of this paper is organised as follows. Section 2 provides an overview of related work in the domain of Cooperative Intelligent Transportation Systems (CITS). Section 3 describes several Vehicle to Pedestrians (V2P) Systems. Section 4 describes VRUs outdoor localization methods via smartphones. Section 5 presents VRU's Next Move/Step Prediction current implementations. Section 6 provides a general overview of the Prediction Communication P2V proposed FrameWork. Finally, Section 7 summarises our findings and concludes our work.

#### 60 2. CITS Overview

50

70

The development of Global Navigation Satellite Systems (GNSS) along with the adoption of mobile internet allow the rapid rise of Co-operative Intelligent Transportation Systems (C-ITS). Improvement of traffic conditions and safety levels on road networks, either urban or highways, are the main goals of those systems. C-ITS technologies that are based-on smartphones may contribute to real time vehicle data collection and in traffic safety and sustainability issues. The information content is characterized by the spatial scope that could be utilized and the time period the information remains valid [6]. Table 1 summarizes the relationship between those two dimensions, lifetime validity and current spatial validity.

| Explicit Lifetime                           | Local Validity (km) |
|---|---------------------|
| 0-30 [s] Accident Warning                   | 0.1                 |
| 31 [s] - 10 [min] Emergency Vehicle Warning | 1                   |
| 0 [min] - Work Zone warning                 | 5                   |

Table 1. C-ITS information lifetime and local validity

• Advanced Transportation Management Systems (ATMS): ATMSs aim in reducing traffic congestion instances especially in urban environments by optimizing efficiency of usage of

existing infrastructures. The optimum solutions that those systems try to find, both in urban freeways and surface streets, are based on the blending of state-of-the-art sensing, communication, and data-processing technologies. [7]

- Advanced Traveller Information System (ATIS): Travellers' travel choices are mainly mainly based on the knowlede that they gain from previous experience when travelling through areas of a city. With the use of Advanced travel information systems (ATIS), which are designed to provide real time information about available travel alternatives based on the current situation on the roads, travellers can take better travel choices. Using this technology, experience of travellers is combined with descriptive, prescriptive and feedback information. Descriptive information is mainly the information about prevailing conditions such as current or predicted travel times. This information can be provided either pre-trip or en-route through message signs or on-board devices. On the other hand, prescriptive information provides travellers the 'best' alternative e.g. the route with the shortest distance, total travel time or most eco-friendly [8,9].
- Advanced Vehicle Control & Safety System (AVCSS): These systems apply advanced technologies both in vehicles and roads to assist drivers to better control vehicles and consequently reduce traffic accidents. The main services included in the AVCSS, are longitudinal collision avoidance, lateral collision avoidance, intersection collision avoidance, vision Enhancement for crash avoidance, safety readiness and pre-crash restraint deployment [10]
- Advanced Public Transportation System (APTS): Advanced public transportation systems (APTS)
  can be used for the improvement of both traffic efficiency of operation and safety of public
  transportation users. Those systems combine transportation management and information
  technologies to public transit systems. Some of the most well known APTs are real-time passenger
  information systems, automatic vehicle location systems and bus arrival notification systems [7]
- Commercial Vehicle Operation (CVO): Intelligent Transport Systems, ITS, are used in commercial
  vehicle operations to help improve vehicle safety while on the same time can enhance the
  communication between motor carriers and respective regulatory agencies. Some applications of
  ITS are the following:
  - Safety Information Exchange Systems: These systems can expedite the collection, distribution and retrieval of safety information.
  - Electronic Screening Systems: They can be used for automated inspection of vehicles.
  - Electronic Credentialing Systems: They can be used for electronic submission to systems, processing, approval, invoicing, payment of tolls, and even tax filing [11]

Figure 1 illustrates all the different vehicle communication types within C-ITS.

## 3. Vehicle to Pedestrians (V2P) Systems - Developments

Although pedestrians are among vulnerable road users that are involved in fatal accidents [12], previous research on road safety in VANETs is mainly focused on vehicle to vehicle accidents. By incorporating pedestrians as active players into VANETs with the use of their smartphones

4 of 15

as communicating nodes, enables the deployment of novel safety applications such as vehicle to pedestrian (V2P) collision avoidance [13].

The use of mobile devices is increasing by vulnerable road users and drivers, while current mobile solutions do not consider any risks when traffic has to be considered [14]. For that reason, safe related to the use of mobile devices is important, especially within urban environment where traffic is of high density [15]. According to [16], the introduction of autonomous vehicles, is an opportunity to reduce accidents rates due to human errors, since driver's intervention will not be required. However, the factor of trust is vital in adopting autonomous, since the road users that will closely interact autonomous vehicles, will have to assess and verify autonomous vehicles' reliability and effectiveness as far as vulnerable road user's safety.

During the last 10 years, a significant research in the field of the CITS, and more specifically in the field of Pedestrian to Vehicle and vice versa. In all of the cases, smartphones sensors were used in order pedestrian's information such as position and heading to be transmitted to surrounding vehicles. As far as vehicles information, this was provided either from smartphones existing within the vehicle, already installed sensors such as GPS, while in some cases, laptops having installed the required network cards, such as external WiFi, were placed to the vehicle's dashboard. Most of the authors, apart from smartphone's GPS, used data coming from smartphone's accelerometer, gyroscope, magnetometer. According to the results provided, GPS localization inaccuracies were pinpointed, while in the case where they tried to predict pedestrian's next moves/short path, they pointed out the difficulties related to this process. It has to be mentioned that the majority of the authors tried to tackle, Non-Line of Sight and blind spots, where the driver's view is limited to due to buildings, vehicles and other obstacles. Tables II and III summarise in a chronological order, the most representing research carried out per year from 2008-2018 within the field of P2V.

## 4. VRUs outdoor localization via smartphones

According to the above, Cooperative Intelligent Transport Systems are about to play a significant role in the traffic safety, since the objective of the United Nations is to halve the numbers of deaths and accidents from traffic accidents by 2020 [2]. According to the above research, within a vehicular network scenario, vehicles and vulnerable road users can exchange information such as position,

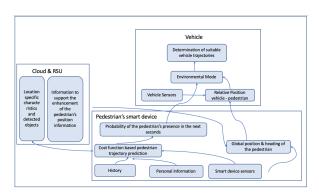

Figure 2. Real-Time Localization of a Person Using Smart Phone

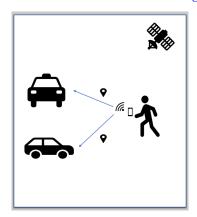

Figure 3. WiFi Safe Basic Idea

speed, heading in order to prevent accidents. The increasing use of smartphones sets them as one of the most suitable candidates for serving this communication but for providing vulnerable road user's information. Vulnerable road user's real time accurate position is a vital factor for the success of these systems, because the most accurate real time positioning measurements the better information will be provided for VRU's trajectory and heading. Within the research, there have been so far 3 position correction methods; differential GPS, smartphone sensors data fusion and multi satellite systems.

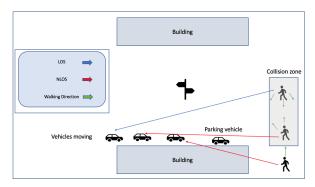

Figure 4. WiFi Dangerous Scenarios

## 4.1. GPS / Assisted GPS / Differential GPS

145

GPS is the most common global positioning technology, used in to determine a three-dimensional ground location of any object. Although GPS when embedded in vehicle navigation devices, has been proved to be efficient, it has a number of shortcomings when used in pedestrian location-based services, LBS [2].GPS' main drawback is low performance within 'urban canyons', places where direct line of sight to the GPS satellites are obstructed from nearby buildings. In those situations signals can reach the receiver after being reflected, usually many times, from nearby surfaces, known as multi-path signals [2], [17]. The situation is even worse for pedestrians positioned on the pavement, close to tall buildings that obstruct the signals.

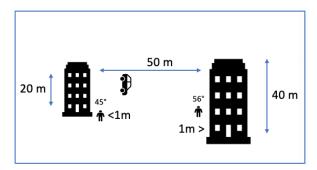

Figure 5. View of Sky (angle in degrees) based on Proximity to Buildings

While in vehicles the GPS antennae is mounted in a place having a clear sky view, in pedestrians' cases smartphones are possibly based in bags or pockets. having as a result sign deterioration. Moreover, GPS doesn't provide any ways to calculate VRU's heading, which is essential for CITS targeting to VRU's safety. Due to these reasons, additional services and sensors are required/already being used to improve VRU's tracking [2]. Through the introduction of assisted GPS (A-GPS), the GPS receivers are allowed to retrieve information from network resources in order to combine them with the information received from the satellites and thus improve location accuracy. Such systems are especially useful when the receiver are not easily reachable from satellite signals [18]. GPS-enabled smartphones are typically accurate to within a 4.9 m radius under open sky [19]. As mentioned in [19] the best positional accuracy achieved was between 1 and 5 m (average error) under open sky conditions. In contrast, commercial grade receivers with differential correction typically result in a positional error of less than 1 m [19]. Differential GPS, DGPS, is an enhancement to GPS, providing improved location accuracy from 1 to 3 m in the case of ideal implementations. DGPS combines the signals received from the satelites with thos received from fixed ground-based reference stations in order to fix positioning errors. Proper digital correction signals are transmitted to all ground-based transmitters which are called rovers. DGPS relies on two stations; one is base station and next is a rover [20]. In a work developed in 2015, wheeled mobile robots were autonomously navigated and controlled. This incorporated self-localization, recovery and path planning [21]. The DGPS technique

was used to develop the autonomous path following, while the Extender Kalman Filter was applied to optimize robot's trajectory.

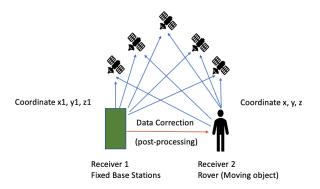

Figure 6. How DGPS works

## 4.2. Multi Satellite Systems

In 2015, a four-system positioning model was developed by taking advantage the available GNSS,BeiDou, Galileo, GLONASS and GPS. According to the test results, the addition of BeiDou, Galileo and GLONASS systems to the standard GPS-only processing significantly shortened the convergence time and improved the positioning accuracy [22]. These results proved that combining GPS, BeiDou, GLONASS and Galileo present the highest accuracy. The time required to achieve the desired accuracy is: several minutes for accuracy less than 10 cm, around 30 minutes for accuracy better than 5 cm and few hours to reach mm level accuracy. Therefore, it is proved that the fusion of multiple GNSS except from increasing the number of observed satellites also optimizes spatial geometry parameters and thus improves convergence, accuracy, continuity and reliability of object positioning [22]. In another project carried out in 2016 [20], the authors applied a DGNSS correction project method to a commercial smartphone, while the accuracy results produced from their research are summarized in Table IV.

| Assessment Method | GPS - DGPS | Glonass - DGPS | Multi GNSS - DGNSS |
|-------------------|------------|----------------|--------------------|
| RMS (m)           | 0.42       | 0.64           | 0.41               |
| Mean (m)          | 0.46       | 0.44           | 0.30               |

Table 4. Analysis results of position accuracy for GPS, multi-GNSS, and differential methods

It was thus proved that by ntegrating GLONASS into the GPS positioning system scientits can improve root-mean- square, RMS, and mean value of errors by 18%. The RMS result for standalone GPS error has been improved to 0.42 m by applying a differential technique, and the performance of Differential GNSS, DGNSS, is better (by approximately 15%) than that of Differential GPS, DGPS.

# 4.3. Inertal Navigation Systems Smartphones Sensors Data Fusion

Over the last year has been carried out a significant research on the use of motion sensors, accelerometers, and rotation sensors, in order to calculate, via the use of dead reckoning the position, the orientation and the velocity of a moving object without the aid of external systems. These sensors are usually supplemented by barometers and magnetometers. The systems that use these sensors are known as inertial navigation systems, INS. For outdoor environments, the combination of GPS and INS is commonly used to overcome the long-term drift of INS and the short outage of GPS [23]. In [24], a step detection algorithm was introduced using one shoe-mounted accelerometer. The result of the detection algorithm was robust in several walking conditions such as walking velocity, walking type, inclination. Step length was estimated via the use of neural network. The proposed neural network

8 of 15

estimated the step lengths of a pedestrian well irrespective of walking frequency, inclination with accuracy of 98% of distance travelled. In 2009, a research was carried out comparing several algorithms for a pedestrian's step detection, stride length, heading and position information, by using inertial sensors, accelerometers, gyroscopes and magnetometers, attached to a person's foot [25]. The stride length results produced from the estimation algorithms, Weiberg [26] and [25] are presented in table V.

The authors of the research implemented and tested 3 different positioning algorithms. Two of them were based on the accumulation of the estimated stride lengths, along the horizontal orientation of the foot, while the third algorithm was based on the results of the ZUPT algorithm1. After a study of more than 30 test trajectories (outdoor an indoor), the error between the final position estimation and the starting point, in the majority of the cases were between 5 to 15 meters [24]. In 2013, another research was carried out, where GPS and low cost INS were integrated in order to enhance pedestrian's outdoor navigation enhanced by surrounding buildings [27]. The authors pinpointed that the ZUPT method, still produces heading errors, so they developed an algorithm by using the layout of the surrounding buildings and smoothing the errors produced by the ZUPT algorithm using Extends Kalman Filter. The results showed the estimated position accuracy was below 5.3 m in 40 min walk and about 0.15% of the total distance [27]. Figures 9 and 10 depict this system. In 2013, a system named SmartLoc was presented, estimating car's location and travel distance by leveraging inertial sensors embedded in smartphones, GPS signals and automatically detected landmarks such as bridge, traffic, lights and driving patterns such as turning, uphill, downhill, from inertial sensor data to improve the localization accuracy when the GPS signal was weak. The authors tested the system within the city of Chicago and an Android smartphone mounted to the car's windshield. The authors drove for over 100 different road segments in downtown Chicago ranging from 1km to 10km and over 30km in highway. The system's evaluation indicates the improvement in localization accuracy compared to GPS, since the error was around 20m for 90% of travel time while the mean error of GPS was 42.2 m. The system also proved that can also reduce the energy consumption by at least 10% for localization, if GPS is periodically being turned off when its signal weak, without sacrificing localization accuracy [28]. The authors in [23], pinpointed that it is necessary to map am object's position onto a spatial map, in order to develop a robust navigation system. The authors of this work, integrated GPS signals and data coming from INS, while they applied Kalman Filter and map matching, in order to identify the right trajectory and to improve the matching navigation accuracy. Kalman Filter was used to fuse the data coming from the sensors, such as accelerometer and gyroscope, while the map matching algorithm was used in order to reduce the GPS positioning errors. For the testing purposes, GPS receiver and MEMs2 IMU3 were mounted on a motorcycle, while the tests performed in Tainan City. In [29], authors presented a system, named APT, for outdoor pedestrians with smartphones. This system was using a robust dead reckoning algorithm and error tolerant algorithm for map matching. In the case user is walking with the smartphone, the dead reckoning algorithm monitors user's steps and walking direction, while the user's position is being updated according to the map matching algorithm. In case the pedestrian's location cannot be determined due to several available route, GPS is being used to eliminate ambiguity. Hence, the main purpose of GPS is to help distinguish between distant routes, therefore GPS is used not often. The map information stores all possible routes of the user, and when a new step or turn is being recorded by the dead reckoning algorithm, the map matching algorithm updates pedestrian's location. Figure 7 depicts the system's flow, while Figures 11 and 12 present a more detailed insight of this solution.

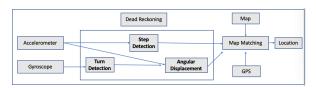

Figure 7. APT's Flow Chart

9 of 15

The authors tested the system within Sunken Garden in Williamsburh, US, by using anchor points as vertices and route segments as edges, while the ground truth of the anchor points were manually found from the Google Map. The test results proved that the system produced overall less errors than GPS location accuracy, without however performing extremely better than pure GPS. In 2014, there was another research, were a pedestrian dead reckoning algorithm was introduced by using data coming from smartphone's sensors [30]. The proposed algorithm consists of step detection, stride length and heading estimation. The system's architecture is depicted in Figure 8:

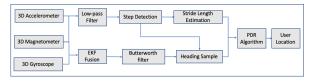

Figure 8. A pedestrian dead reckoning algorithm

For the estimation of stride length, a Back Propagation Neural Network was developed, while Extended Kalman Filter was applied to determine user's direction. The integration of gyroscope, accelerometer and magnetometer can improve user's heading precision while the Extended Kalman Filter was uses to merge all the sensor's information in order to acquire accurate information on attitude angles. During testing, a commercial smartphone and data produced from its sensors, accelerometer, magnetometer and gyroscope were collected. For the stride length estimation, data from 5 different persons with different heights in order to examine the performance of stride length algorithm. As far as the heading estimation test a building's corridors were used to assess the performance of the heading estimation algorithm, while for the trace tracking an actual walking trace was used. The results of stride length estimation were good enough; an average standard deviation of 0.03 m for each person was achieved. As far as the heading estimation results, there weren't satisfactory, while the trace tracking error, on average was 5.83 for 10 different measurements coming from 10 different people. The authors pointed out that the optimization of the heading estimation algorithm could be an interesting work in the future. In 2017, another research was published, where a smartphone-based algorithm, integrating PDR/GPS/Bluetooth for pedestrian outdoor/indoor was proposed [31]. The authors pinpointed that sensors installed in smartphones are unstable due to the interference of external magnetic, large scale iron and steel equipment. For that reason, they proposed an algorithm utilising data from gyroscope and magnetometer, to improve the accuracy of heading direction. The following figure illustrates the system's design.

As far as the outdoor data fusion part, the following figure illustrates it

For the tests, the authors used a commercial smartphone and 2 people participated in the tests. During the experiment, the smart- phone is held in hand and the x-axis of the phone is along the forward direction [31]. The best outdoor localization results produced where 5 m per 100 of walking distance, while the heading direction algorithm produced localization results with error of 3 m in 70% of the test period. The authors pointed out that in their research, they didn't consider the change in height. In 2018, another research was published presenting a Hybrid Location Estimation solution, combining GPS, Pedestrian Dead Reckoning and a Cell-id based Trilateration algorithm, CbT,[32]. The proposed model involves two parts. The first, it is the static part, where user's position is obtained through any of the GPS, Wi-Fi or Cell-id. The second, the dynamic part, is where user's trajectory projection is generated via a PDR system. The following figure depicts the proposed solution, while the figure after illustrates the proposed PDR.

The system was tested in a commercial smartphone, and the experiments conducted within the campus of Madras Institute of Technology, Anna University, Chennai, both in indoor and outdoor environments . According to the authors, the accuracy of the HLE system in the case of obtaining GPS followed by PDR system is 10-15 meters, while the accuracy for CbT, followed by PDR system is 17-25 meters. The system's execution time, running on the smartphone, was 0.14 s.

# 5. VRU's Next Move/Step Prediction

In [33], the authors developed a system, installed on a mobile phone running on the operating system Symbian 60, to predict together the intended and the future route, of a pedestrian. The authors collected GPS data, from 14 participants, and run several experiments to test the system's performance. The system, firstly detects, the places where the person may depart from or go, by using a clustering algorithm named Forward- Backward Matching, FBM. Afterwards, trajectories based on a space partitioning method, where abstracted and from them the movement patterns were extracted, by applying a Continuous Route Pattern Mining., These extracted movement patterns were organized in couples of origin-destination. The prediction part was made by using a decision tree created from the movement patterns. The experimental results showed that this approach achieved around 80% and 60% accuracy in destination prediction and 1-step prediction, respectively, and resulted in an average deviation of approximately 60 m in continuous future route prediction. The authors pinpointed the weaknesses of their research since they were based only to movement data. They suggested that they could use in the future information such as time of day, day of the week and traffic conditions. Figure 13, illustrates the prediction system's architecture

In [34], the authors presented a method to predict pedestrian's next move by applying a mixed Markov-Chain Model, MMM, but also comparing the results against a Hidden Markon Model, HMM, and a Markov Model. The authors used 10 datasets generated by a simulator creating data from 1337 pedestrians. The prediction rates for the 3 different models applied are summarized in Figure 14.

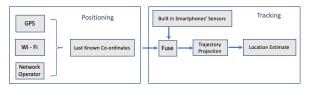

Figure 11. Hybrid Location Estimation Solution

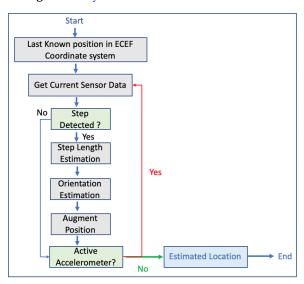

Figure 12. Hybrid Location Estimation PDR

In [35], the authors applied a neural network model to predict a pedestrian's step size within an indoor environment, by using data coming from an accelerometer. The neural network was enhanced from the application of a genetic algorithm. The authors pointed out the weaknesses of their research, since more sensors' data could/should be used. In [36], the authors pointed out that pedestrian path prediction is an important part of vehicle safety system assisting in preventing possible V2P. They focused, on developing a pedestrian path prediction system, based on pedestrian positioning information recorded by smartphone devices. The authors developed two neural networks for this work leveraging information such as GPS, heading and velocity recorded by smartphones. The first neural network model was invariant to the pedestrians' walking location and GPS noise, while the second neural network was time series neural network. The performance of those two neural networks was compared against a prediction based on dead reckoning. For the tests, 2 pedestrian participated and the walking trips were recorded (average walking trip 850 seconds). The results showed that the dead reckoning method makes accurate prediction when the prediction time is less than 0.5 seconds, but makes large prediction errors when the prediction time is more than 0.5 seconds. The neural networks, performed better in cross training, meaning training trips from one pedestrian and test trip from a different pedestrian. The authors, pointed out that future research is needed for predicting within very short period of time such as >0.5 sec and < 2 sec. In [34], the authors implemented a convolutional neural network in order to detect starting movement transitions between waiting and moving of cyclists, as early as possible by using a smart device. Data of 49 cyclists were gathered during an experiment at a public intersection with bicycle lanes and walkways. The ground truth was generated from a wide-angle stereo camera and visual inspection. Their results produced a F-14 score of 97% and an average delay of 783 ms.

#### 6. The Prediction and Communication P2V Proposed Framework

According to the above, so far there has been a significant research and progress of smartphone outdoor localisation and communication between pedestrians and vehicles. Also, the upcoming

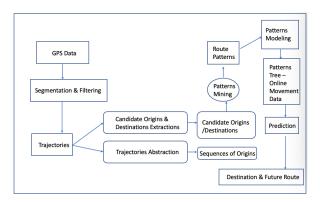

Figure 13. A Prediction System Architecture

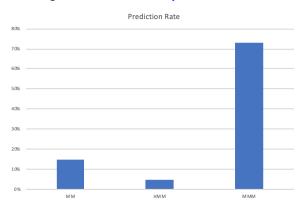

Figure 14. MMM vs HMM vs MM step prediction rates

integration of more than one GNSS, GPS, GLONASS, Galileo will further improve smartphone's and consequently pedestrian's outdoor localisation. For instance, there are a couple of smartphones that are using Galileo such as Phone 8 Plus, iPhone 8, iPhone 10/X, Samsung S8, S Samsung 8+, Samsung Note 8, Huawei P10 plus, Huawei Mate 9 pro, Huawei P10, Huawei Mate 10 Pro, Huawei Mate 9.

However, in the field of predicting pedestrians' next move and short path, there is a room for improvement, and this is a field where this papers focus on. This is a field, where the majority of the current research has mentioned that should be improved in order to develop more accurate P2V systems, since the localization part is getting improved, while also efficient communication between vehicles and pedestrians has been already achieved. Based on this initial analysis we propose a framework that combines prediction and communication capabilities in order to avoid accidents between pedestrians and vehicles especially in cases where the driver doesn't have a visual contact with the pedestrian due to obstacles.

The suggested prediction/communication framework consists of the following stages which are illustrated in Figure 15:

 Mobile phone of each passenger collects and fuses data coming from sensors such as accelerometer, magnetometer, gyroscope, compass, GPS, Wi-Fi, barometer ,if available,and heart rate sensor.

345

- Current and historical fused data is used in order to predict the next movement/next short path of the pedestrian
- The pedestrians are classified whether their movement and their continuous movement would lead them to a possible risk within the next seconds (maximum 10 seconds)
- Only the medium risk and high risk classified pedestrians' information, is communicated to all neighbors such as bicycles or cars or both.
- Based on this information cars can take the appropriate decisions in order to avoid possible accidents

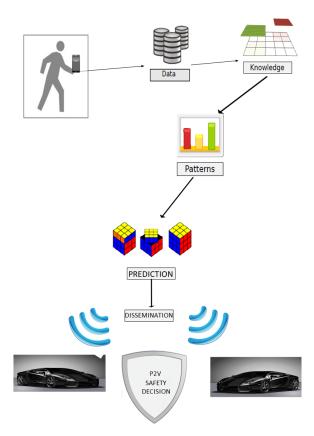

Figure 15. Proposed P2V Framework

Our research path for implementing this framework is the following:

- Analyse the feasibility of existing prediction models for meeting the specific requirements of our framework
- To measure their efficiency and accuracy
  - Testing different data mining techniques such as Mean Absolute Error, Root Mean Squared Error, Mean Absolute Percentage Error, Mean Absolute Scaled Error. The models will be evaluated in terms the accuracy, precision and recall results.
  - Using specific simulator environments like Veins[37], in order to integrate the models into a simulated environment where the communication of different entities will be incorporated as well

Our research is expected to contribute to the field of real time series prediction by applying state of the art methodologies in order to improve P2V safety via smartphones. To the best of our knowledge it is the first time the Long Short Term Neural Networks, will be used to predict in real time pedestrian's next move/short path, with data coming only from pedestrians' smartphones' sensors data.

### 7. Conclusion

360

According to the World Health Organization, from 2007 till 2015, approximately 1.25 million people have died each year in traffic accidents worldwide, while half of these deaths were pedestrians, cyclists or motorcyclists (VRUs). The World Health Organization has predicted that by 2030, these traffic accidents will be the seventh cause of death. Cooperative Intelligent Transport Systems, and more specifically collision avoidance systems could play a vital role in mitigating this phenomenon. On the other hand, due to the increasing use of smartphones, industry and research have paid a lot of attention to the development of a specific type of collision avoidance system, P2V. It has been identified

that the positioning accuracy provided by the integration of multiple GNSS within smartphones, the development of dead reckoning algorithms by processing data coming from smartphones' IMS sensors, and the use of proper communication techniques, P2V could play a significant role in minimizing these kind accidents. However, according to the literature, there is a room for improvement in predicting VRUs next move/next short path. The current article proposes Prediction Communication P2V framework that can provide enhanced road safety to VRUs.
