Abstract

There is currently a lack of pathologic data on the SARS-CoV-2 pneumonia, or COVID-19, from autopsy or biopsy. Two patients who recently underwent lung lobectomies for adenocarcinoma were retrospectively found to have had COVID-19 at the time of surgery. These two cases thus provide important first opportunities to study the pathology of COVID-19. Pathologic examinations revealed that, apart from the tumors, the lungs of both patients exhibited edema, proteinaceous exudate with globules, focal hyperplasia of pneumocytes with only patchy inflammatory cellular infiltration, and multinucleated giant cells. Hyaline membranes were not prominent. Since both patients did not exhibit symptoms of pneumonia at the time of surgery, these changes likely represent an early phase of the lung pathology of COVID-19 pneumonia.

Key words: coronavirus; COVID-19 pneumonia, pathology; SARS-CoV-2

Report

Since December 2020, the outbreak of a novel coronavirus, SARS-CoV-2, infection (COVID-19) that started in Wuhan, Hubei Province, China^[1, 2], has spread to all parts of China, and to Europe and North America. The number of confirmed cases in China has reached 42,700, including 1,017 deaths, as of February 11, 2020. Patients initially present with fever with or without respiratory symptoms, but all patients later develop various degrees of pulmonary abnormalities on chest CT imaging^[1, 3]. Although the vast majority of patients only have a common, mild form of illness, about 15-20% of the patients fall into the severe group, meaning they require assisted oxygenation as part of treatment^[3]. The severe group has a high mortality rate and is associated with older age, underlying diseases such as diabetes, and medical procedures (such as patients who were infected in a hospital setting while receiving surgery for other indications).

Although there have been several studies describing clinical features and characteristic radiographic findings (mainly chest CT scans)^[1, 3], no pathologic studies have been conducted based on autopsies or biopsies. Some of the reasons for the lack of autopsies and biopsies include the suddenness of the outbreak, the vast patient volume in hospitals, shortage of healthcare personnel, and the high rate of transmission, which makes invasive diagnostic procedures less of a clinical priority.

Fortunately and unfortunately, we encountered two patients who underwent surgery for malignancy and were later found to have been infected with SARS-CoV-2. The surgical specimens overlapped in time with the infection, which offered us the necessary specimens to examine the histopathology of COVID-19 pneumonia.

Case Presentation

CASE 1 was a female patient of 84 years of age who was admitted for treatment evaluation of a tumor measuring 1.5 centimeters in the right middle lobe of the lung. The tumor was discovered on chest CT scan at an outside hospital. She had a past medical history of hypertension for 30 years, as well as type 2 diabetes. On Day 6 of hospitalization, an enhanced chest CT was performed that confirmed an irregular solid nodule in the right middle lobe and bilateral ground-glass lesions (GGO). At the time, the significance of the latter findings was unknown. Her general condition was good, with no fever or respiratory symptoms, and clear to auscultation bilaterally. She underwent pre-surgical tests and preparations. On Day 12, a thoracoscopic resection of the right middle lobe was performed without event. On Day 13 (post-op Day 1), a repeat CT showed post-resection changes and bilateral GGO in the lower lobes of the lungs. White blood cell count was $12.49 \times 10^{12}/L$, while lymphocyte count was lowered to $0.4 \times 10^9/L$ and the differential to 5%. There was a slight wheezing sound to auscultation on the right side. On Day 16, the patient developed some difficulty in breath, chest tightness, wheezing, and dry cough. She was diagnosed as “suspicious for viral pneumonia,” with intermittent SpO₂ between 72% and 88%. On Day 24, she was transferred to the special isolation ward due to a pharyngeal swab test positive for the 2019-nCoV. The labs drawn from the day before (Day 23) showed white blood cell $33.52 \times 10^9/L$ ↑ ; neutrophils 89.80% ↑ ; lymphocytes 1.90% ↓ ; eosinophils 0% ↓ ; neutrophil count $30.10 \times 10^9/L$ ↑ ; lymphocyte count $0.65 \times 10^9/L$ ↓ ; monocyte count $2.50 \times 10^9/L$ ↑ ; eosinophil count $0.01 \times 10^9/L$ ↓ ; and basophilic count $0.26 \times 10^9/L$ ↑ .

Despite comprehensive treatment, including antibiotics, assisted oxygenation, and other supportive care, the patient's condition deteriorated. SpO₂ lowered to 62.6% and heart rate to 40 bpm. A do-not-resuscitate (DNR) order was given. She went into coma on Day 27 and died on Day 29. She did not manifest fever during the hospital stay.

Subsequent clinical information confirmed that she was exposed to another patient in the same room who was subsequently found to be infected with the 2019-nCoV.

The right middle lobe resection specimen was delivered to the surgical pathology lab and was processed according to routine biosafety standards. Hematoxylin and eosin stained sections were reviewed. A firm area of 1.5 cm in diameter was identified grossly, which in histology was consistent with typical adenocarcinoma, with half exhibiting the lepidic and half the acinar pattern (not shown). Sections away from the tumor, as shown in **Figure 1**, revealed evident alveolar damages, including alveolar edema and proteinaceous exudates (**Figure 1A**). Prominent inspissated spherical secretions or globules were also noted (**Figure 1B**). There was vascular congestion but only patchy and mild inflammatory infiltration. Granuloma-like nodules consisted of fibrin, inflammatory cells and multinucleated giant cells were shown inside the airspaces (**Figure 1C**). No significant neutrophil infiltration was present in the tissue. There were patchy and severe pneumocyte hyperplasia and interstitial thickening, indicating an ongoing reparative process. Suspected viral inclusions were also noted in some of these cells (**Figure 1D**).

CASE 2 was a male patient of 73 years of age, who presented for elective surgery

for lung cancer. Nine months earlier, a nodule was discovered radiologically in the right lower lobe of the lung during a health checkup. He had a past medical history of hypertension for 20 years, which had been adequately managed. A diagnosis of adenocarcinoma was made in a subsequent needle biopsy. The patient was admitted one week after the biopsy to the Thoracic Tumor ward, where he underwent a right lower lobe lung resection with lymph nodes dissection three days after admission. He recovered well and was discharged on Day 6 post-operationally. A chest CT was performed on post-op Day 2, showing post-operative changes, as well as patchy ground-glass opacity in the right upper lobe. Retrospective re-examination of the images was “suspect for atypical viral pneumonia.” He developed a fever on post-op Day 9 (38.2 C), with dry cough, chest tightness, and muscle pain. A nucleic acid test for 2019-nCoV came back as positive. Other labs were significant for lowered lymphocyte count. He was re-admitted to the Infectious Disease ward. A repeat chest CT scan showed additional foci of ground-glass opacifications (GGO) in the bilateral upper lobes, consistent with viral pneumonia. Tests for influenza virus and other infectious agents were negative. He underwent treatment for NCP. He gradually recovered and was discharged after twenty days of treatment in the Infectious Disease ward.

Upon pathologic examination of the resected lobectomy specimen, a 1.2 cm grey white nodule adjacent to the pleura was identified, which was poorly demarcated from the adjacent non-tumor lung parenchyma. Histopathologic diagnosis of the tumor was that of adenocarcinoma, pT1bN0 (28 lymph nodes all negative). The resection margins were negative as well. Histologically, the surrounding lung parenchyma showed patchy

but evident proteinaceous and fibrin exudate (**Figure 2A**). There were diffuse thickening of alveolar walls (**Figure 2B**), focal small organization (not shown) and interstitial fibroblastic hyperplasia (**Figure 2C, arrow**), indicating varying degrees of proliferative phase. Focally, abundant polymorphonuclear cells and macrophages infiltrating the airspaces were also present (**Figure 2D**).

Discussion

To our knowledge, the pathologic findings reported here represent the first for SARS-CoV-2 pneumonia. Thus far, no autopsies had been performed on patients with COVID-19. Data on lung biopsies performed for the NCP is similarly lacking.

The two cases reported here represent “accidental” sampling of the COVID-19, in which surgeries were performed for tumors in the lungs at a time when the superimposed infections were not recognized. These provided the first opportunities for studying the pathology of NCP. Meanwhile, these two incidences typify a common scenario during the earlier phase of the 2019-nCoV outbreak, during which a significant number of healthcare providers became infected in hospitals in Wuhan, and patients in the same room were cross-infected, as they were exposed to unknown transmission sources.

For **CASE 1**, the surgery was performed six days after the CT findings of early GGO signs, meaning the pathologic changes of the non-tumor lung parenchyma indeed represent at least the peripheral part of NCP, as the imaging changes were more prominent towards the lower lobes. For **CASE 2**, as recognized later on, that patient was put in the same room with patients who were positive for SARS-CoV-2 infection (the

status of infection was not known to anyone at the time, of course). He developed early lung lesions on a chest CT performed to evaluate the result of surgery. However, due to a lack of sufficient knowledge about the new infection, the lesions were recognized only retrospectively as representing COVID-19 pneumonia.

Although patient #1 was never febrile, her CBC profile, especially from post-op Day 1, showed high WBC counts and lymphocytopenia, which is consistent with COVID-19. This may be a good clue for early diagnosis in the future. **CASE 2** developed a fever a few days after the CT findings, suggesting a delay in symptom development in these patients. During the earlier days of the outbreak, there had been limitations in both capacity and turnaround time for the nucleic acid test, which had further caused delay in confirming the diagnosis of COVID-19^[4].

The differential diagnoses of COVID-19 pneumonia might include, but are not limited to, acute or chronic pneumonia resulting from other infections. Comprehensive clinical analyses of the epidemical status, CT scan, and nucleic acid test can easily exclude such possibilities. As for the original SARS, SARS-CoV-19 shares high genetic homology with SARS-CoV. Notably, the International Committee on Taxonomy of Viruses (ICTV) recently renamed the 2019-nCoV to SARS-CoV-2 and the disease as COVID-19. Compared with pathological findings in a cohort of autopsy cases of SARS, the two cases presented here also exhibited exudative and proliferative phase acute lung injury such as edema, inflammatory infiltrate, pneumocyte hyperplasia, and organization, but without obvious hyaline membrane formation and other chronic process such as squamous metaplasia and postmortem changes^[5-7]. Of note, pathologic changes seen in

our two cases proceeded the development of clinical symptoms, and likely represent an earlier phase of the disease. Future studies in autopsies may add to the current findings of more advanced changes.

It would be beneficial if RT-PCR and/or immunohistochemical stains could be performed on these two cases to further confirm the presence of the virus associated with the pneumonia. Unfortunately, these tests are currently under development, and adaptation to tissue specimens is not yet available. Nevertheless, we believe it is imperative to report the findings of routine histopathology for better understanding of the mechanism by which the SARS-CoV-2 causes lung injury in the unfortunate tens and thousands of patients in Wuhan and worldwide.
