Impact of use of gastric-acid suppressants and oral anticancer agents on survival outcomes: a systematic review and meta-analysis

Gastric acid suppressants versus no gastric acid suppressants

Abstract: We performed a systematic review and meta-analysis to evaluate the role of gastric acid suppressant use on outcomes of tyrosine kinase inhibitors (TKIs) and oral chemotherapy. We identified all researches evaluating the effect of GAS use on patients receiving oral chemotherapy or TKIs for solid tumors. The pooled hazard ratios (HRs) and 95% confidence interval (95% CI) for overall survival (OS) and progression-free survival (PFS) were calculated with fixed-effects or random-effects model. The study population included n=16 retrospective studies and 372,418 patients. Series concerned gastrointestinal tract tumors (n=5 studies), renal cell carcinomas (RCC, n=3 studies), non-small cell lung cancers (NSCLC, n=5 studies), and soft tissue sarcomas or mixed histologies solid tumors in n=3 studies. The pooled HRs for OS and PFS were 1.31 (95% CI: 1.20–1.43; P<0.01) and 1.3 (95%CI 1.07-1.57; P<0.01) for GAS and no GAS users, respectively. Only studies of EGFR mutated NSCLC patients receiving TKIs and those with colorectal cancer receiving oral chemotherapy showed a significant correlation between GAS and poor survival. Our study supports the evidence of a possible negative impact of concomitant GAS therapy on survival outcomes of patients receiving oral anti-cancer drugs.

Keywords: gastric acid suppressant; chemotherapy; tyrosine kinase inhibitors; proton pump inhibitors

1. Introduction

Oral chemotherapy has historically been part of therapeutic regimens for the treatment of cancer [1-3]. Over the last years, new oral anti-cancer agents acting as multi-tyrosine kinase inhibitors (TKIs) has dramatically changed prognosis and thereby became standard treatment for several types of tumors [4-9]. TKIs targeting the epidermal growth factor receptor (EGFR) (e.g. gefitinib, erlotinib, afatinib, osimertinib) are currently approved for treatment of EGFR mutant non-small cell lung carcinoma (NSCLC), and multi-targeted TKIs (e.g. sunitinib, axitinib, sorafenib, pazopanib) for the treatment of renal cell carcinoma (RCC). Moreover, plenty of new TKIs are currently being tested in clinical trials in several types of solid tumors. The use of oral drugs has a positive impact on patients' quality of life for the convenience of self-administration; however, there is a significant risk of drug-drug interactions. The diffusion of these drugs often parallels that of

gastric acid suppressants (GAS), such as proton pump inhibitors (PPI) or histamine-2 receptor antagonists (H2RA), GAS commonly represent part of the complex drug regimen of an average oncologic patient, with an estimated rate of 50% inappropriate PPIs prescriptions, both in hospital and ambulatory settings [10]. Because of the oral administration and pH-dependent solubility of chemotherapy and TKIs, concerns have been raised on the possible effect of co-administering drugs which raise gastric pH [11,12]. Chronic acid suppression can reduce the effectiveness of drugs that require an acidic pH for their absorption [13]. Retrospective data suggest that TKIs plasma concentration is decreased in patients receiving concomitant GAS therapy with subsequent poorer oncologic outcomes [14,15], however pooled analyses of patients enrolled in clinical trials have shown inconsistent results [16,17].

The aim of our meta-analysis is to define whether concomitant use of GAS therapy (either PPI or H2RA) in patients receiving treatment with oral anti-cancer agents (i.e. chemotherapy or TKIs) is associated with survival outcomes.

2. Results

A total of 353 potentially eligible records were identified in the electronic databases. After exclusion of n=337 not pertinent papers, n=16 were selected for inclusion in quantitative analysis (n=372,418 patients included, with 12% of patients receiving concomitant GAS therapy) [16-31]. The search results and characteristics of the included studies are presented in figure 1 and tables 1-2.

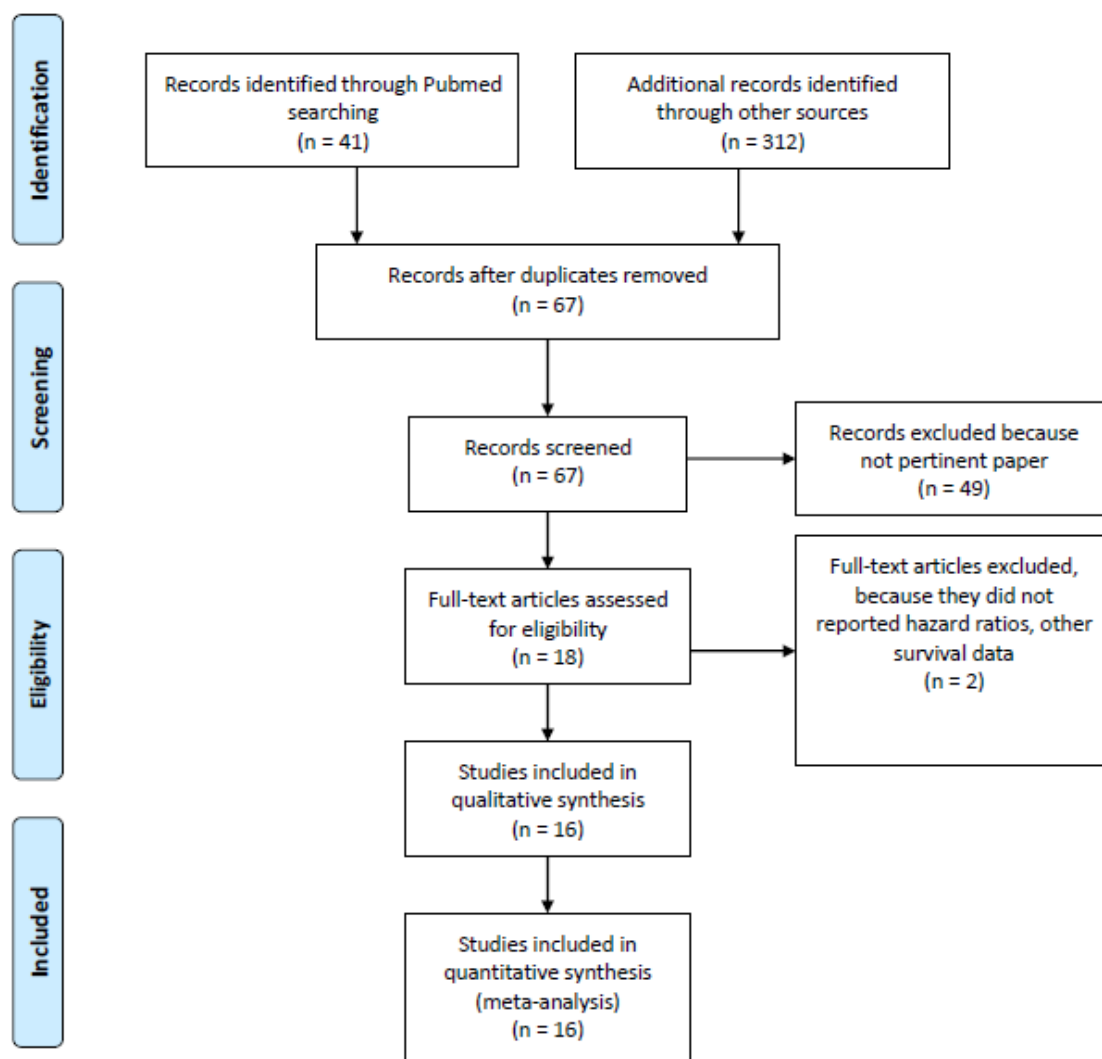

Figure 1. Flow diagram of included studies.

* when both uni and multivariate analyses were performed, HR results of multivariate analyses are reported. **Legend:** CI, confidence interval; GAS, gastric acid suppressants; HR, hazard ratio; NA, not available; NA, not determined; NOS, Newcastle-Ottawa Scale; MVA, multivariate analysis; ORR, overall response rate; OS, overall survival; PFS, progression free survival; UVA, univariate analysis.

All studies were retrospective except for a pooled analysis of phase 2-3 studies by Lalani et al. and a secondary analysis of a randomized prospective trial by Chu et al. Oncologic treatment consisted in oral TKIs in n=11 studies, while in n=4 studies patients received oral chemotherapy (i.e. capecitabine); one study did not include information regarding the type of study drugs. Oncologic diagnoses were cancers of the gastrointestinal tract (GI, n=5 studies), RCC (n=3 studies), NSCLC (n=5 studies), and soft tissue sarcomas or mixed histologies solid tumors in n=3 studies. Quality according to NOS scale was moderate (range 5-8; median 6).

2.1. Overall survival and progression-free survival with GAS vs no GAS

N=15 studies reported data on OS. Because the heterogeneity test showed a high level of heterogeneity ($I^2=68\%$, $P<0.01$) among studies, a random-effects model was used for the analysis. OS of patients receiving concomitant GAS therapy was significantly worse (HR =1.31, 95% CI: 1.20–1.43; $P<0.01$; Figure 2) compared to those of patients not receiving GAS. Similarly, the use of GAS reduced PFS in n=13 studies (HR=1.3, 95%CI 1.07-1.57; $P<0.007$; Figure 3), which reported data on PFS. Heterogeneity was high ($I^2=74\%$), so a random effect model was used.

Figure 2. Forest plot for overall survival of the analyzed studies.

Figure 3. Forest plot for progression free survival of the analyzed studies.

2.2. Subgroup analysis

In a separate analysis of studies involving patients treated with TKIs, the use of concomitant GAS was similarly associated to poorer OS (HR=1.35, 95%CI 1.16-1.56; $P<0.01$). Similarly, capecitabine assumption with GAS resulted in increased mortality (HR=1.37, 95%CI 1.1-1.7; $P<0.01$). We also searched for a distinct correlation of concomitant GAS in different tumor types: only studies of EGFR mutated NSCLC patients receiving TKIs and either PPIs or H2RAs and those with GI cancers receiving all PPIs and oral chemotherapy retained a significant correlation between GAS and poor survival (HR=1.47, 95%CI 1.27-1.71; $P<0.01$ and HR=1.3, 95%CI 1.02-1.66; $P=0.04$), while in case of renal cell carcinoma the correlation between GAS assumption and reduced survival was missing. In patients with lung cancer on anti-EGFR, regression between H2RA and HR for OS was not significant, so the contribution of H2RA does not seem relevant for the final outcome.

In some studies, both PPIs and H2RAs were administered. After exclusion of these studies, $n=7$ publications included only patients taking PPIs and HR for OS was similar to the whole population (HR=1.22, 95%CI 1.09-1.36; $P<0.01$). In studies that reported median follow up ($n=6$), OS was still poorer in patients taking GAS (HR=1.29, 95%CI 1.27-1.31; $P<0.01$).

2.3. Overall response rate

In few studies with data available, PPIs did not influence ORR (OR=0.89, 95%CI 0.53-1.47; $P=0.64$, figure 4).

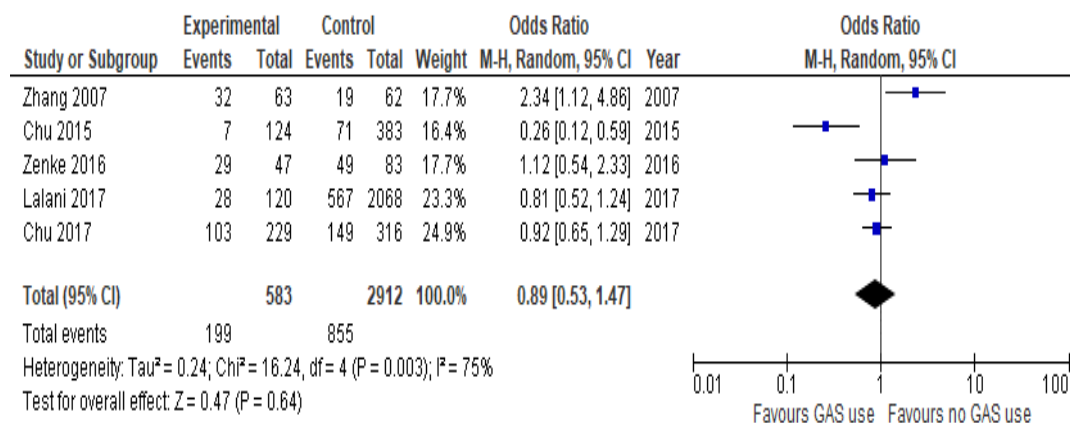

Figure 4. Forest plot for overall response rate of the analyzed studies.

2.4. Publication bias

A funnel plot was used to assess publication bias in the studies evaluating OS with concomitant GAS versus no GAS therapy in cancer patients. No publication bias was detected. Also Egger's test was not significant ($P=0.39$) (Figure 5).

Figure 5. Funnel plot for publication bias in overall survival analysis.

3. Discussion

This is the first meta-analysis exploring the role of concomitant GAS therapy during oral anti-cancer agents for treatment of solid tumors. According to our results, GAS therapy seems to negatively impact on OS and PFS, while it has no impact on ORR.

GAS, and above all PPIs are among the most commonly prescribed drugs worldwide. Their principal application is treatment of gastroesophageal inflammatory syndromes, such as gastroesophageal reflux disease, esophagitis, and peptic ulcer disease [32]. Given to their mild toxicity profile, the use of PPIs has spread over the last 20 years, and we are now facing an overuse in patients with benign conditions or not needing this specific therapy. Recently, various studies have related PPIs use to increased incidence of respiratory tract and *Clostridium difficile* infections, mainly related to an altered commensal intestinal microbiome, as a consequence of raised gastric pH and bacterial overgrowth [33].

The clinical impact of concomitant use of GAS therapy and oral anti-cancer agents remains controversial. Numerous pharmacokinetic studies have addressed this question, showing a possible detrimental effect of GAS on oral anti-cancer drugs' absorption. However, this phenomenon varies according not only to the drugs analyzed, but depends also on specific drug-drug interactions differing among drugs of the same class [11,12,34,35]. As an example, Egorin et al. showed that PPIs may significantly decrease dasatinib plasmatic levels, while they do not impact on imatinib levels [34]. A similar effect was shown in a small series of patients using concomitant GAS and erlotinib [11], but was not confirmed by data of patients included in the BR.21 trial database [35]. This retrospective analysis on clinical outcomes of patients receiving concomitant GAS and erlotinib showed no differences in plasma drug levels and survival outcomes compared with patients who did not take concomitant GAS [35]. However, the pH-dependent absorption of erlotinib was confirmed in a randomized pharmacokinetic study, which demonstrated that concomitant Cola intake led to a clinically relevant increase in erlotinib bioavailability during esomeprazole treatment due to a temporarily lowered intragastric pH [36]. Analyses on the pharmacokinetics of different TKIs showed that afatinib is highly soluble throughout the physiologic pH range and may therefore have fewer interactions with GAS, compared with gefitinib or erlotinib [37]. A similar effect was observed for osimertinib, which plasmatic levels were not determined by food or PPIs co-administration [12]. With our meta-analysis, we reported a significant correlation between GAS and poor survival only for the NSCLC and CRC subgroups, while there was no significant impact on

survival when RCC series were considered. A possible explanation may be found in the difference between oral TKIs used in NSCLCs and RCCs. Indeed, TKIs used in lung cancer own anti-EGFR activity (gefitinib and erlotinib), while TKIs used in RCCs have mainly anti-vascular endothelial growth factor (VEGF) properties (sunitinib, sorafenib, axitinib and pazopanib). Moreover, our results are consistent with findings of a previous pooled analysis of metastatic RCC patients treated in phase II and III trials. Indeed, OS results were similar between PPIs and non-PPIs users in case of anti-VEGF TKIs use [16].

Two are the main concerns related to alterations in pharmacokinetics during concomitant GAS therapy. The first is that combined use of PPIs and TKIs may increase the treatment-related adverse events (AEs) of both drugs. Although intuitive, also this mechanism is controversial: in a recent report from Cho et al., concomitant GAS therapy increased gefitinib-induced hepatotoxicity [38]. However, another case series of patients treated with gefitinib and erlotinib did not show differences in the incidence of cutaneous AEs and diarrhea, when comparing patients receiving concomitant GAS to those who did not [30]. Similar reports of patients undergoing concomitant capecitabine and PPIs showed that rates of treatment discontinuation and/or dose reduction due to toxicities was comparable to that of patients not receiving GAS therapy [20,29].

The second important issue lies in the potential reduced absorption and subsequent compromised anti-cancer drug effect. Reports from the Literature on this topic mainly consist of case series, reporting heterogeneous data in terms of patients' populations, anti-cancer drugs (chemotherapy, TKIs), GAS therapy (PPIs, H2RA, or both), and outcomes (survival vs response vs AEs incidence). Our meta-analysis confirmed that concomitant GAS can have a negative impact on PFS and OS, however without significant effects on ORR. One of the possible reasons for the worse survival outcomes is that patients requiring GAS are older and have various comorbidities (e.g. cardiovascular disease requiring aspirin and therefore PPIs therapy). Another theory is that concomitant GAS therapy reduces serum levels of anti-cancer drugs under the therapeutic threshold, thus increasing the risk for distant metastasis and disease progression. Although previous studies show that TKIs are effective even at low serum levels, it is recognized that the cerebrospinal fluid penetration rate of first-generation TKIs is only around 2% [39]. Thus, the concomitant use of drugs reducing gastric absorption of TKIs may further reduce their serum levels to an insufficient plasmatic concentration [40].

Our meta-analysis has some intrinsic limitations. First of all, patients taking PPIs may have an intrinsic poor performance status and/or chronic conditions that require continuous GAS. Secondly, use of PPIs was not offered with a randomized design so that patients treated with PPIs may have suffered from concomitant gastritis/dyspepsia and/or may have taken steroids for supportive care, consequently needing chronic GAS therapy. Thirdly, there is uncertainty regarding the correct administration of PPIs straightly before the antitumoral treatment. Finally, other pharmacological interactions (e.g. with the CYP3A4 citochrome) may have reduced plasmatic concentration of anti-EGFR agents.

4. Materials and Methods

This study followed the Meta-analysis Of Observational Studies in Epidemiology (MOOSE) group guidelines and checklist [41] (Fig. 1, Tab. 3).

Table 3. MOOSE Checklist for Meta-analyses of Observational Studies.

Item No	Recommendation	Reported on Page No
Reporting of background should include

4.1. Data extraction and quality assessment

A protocol was defined prior to the search including the population criteria, description of oncologic treatments, comparisons, and outcomes of interest. A systematic Literature search was performed using the PubMed (MEDLINE), EMBASE and The Cochrane Library. The search was performed comprehensively using several databases from each one's earliest start until 1st August 2019. We sought to identify all English language researches evaluating the effect of GAS use on outcome of patients receiving concomitant oral chemotherapy or TKIs for solid tumors. For the process of evidence acquisition, Literature was queried using the following terms [MeSH]: "gastric acid suppressant" OR "proton pump inhibitors", and "chemotherapy" or "tyrosine kinase inhibitors" AND "carcinoma" or "cancer" AND "survival". References of included studies were hand-searched in order to identify potentially relevant adjunctive papers. For each study we extracted the following information, if available: number of patients, baseline patients' characteristics, data regarding oncologic treatments, progression-free (PFS) or recurrence-free (RFS) survivals and overall survival (OS) or the corresponding HRs, and overall response rates (ORRs) in the 2 arms.

Two independent reviewers (AI and FP) evaluated all studies in order to verify the inclusion criteria. Studies selection was conducted with a two-phase screening. First level screening excluded titles and abstracts meeting the following criteria: a) case reports, letters, comments, and reviews not reporting original data; b) in vivo and/or in vitro studies; c) studies involving fewer than 10 patients; and d) language publication other than English. Studies matching inclusion criteria were obtained in the complete form and reviewed in full-text version for an advanced assessment. Second level full-text screening was performed in order to include studies with the following criteria: (1) studies involving patients with solid tumors receiving oral chemotherapy or TKIs; (2) studies reporting outcomes of patients receiving concomitant GAS therapy compared to those who did not; (3) information regarding HRs or survival curves for OS and/or PFS and/or ORRs for patients using GAS compared to those who did not. Differences of opinion were resolved by agreement between the reviewers. Study quality was independently evaluated using the Newcastle-Ottawa Quality Assessment scale for case-control studies [42]. Disagreement was also resolved by consultation and consensus.

4.2. Statistical analysis

The primary outcome of interest was OS. The secondary endpoints were PFS and ORR. The HRs and 95% CIs from each study were either extracted directly from original papers or calculated using Kaplan-Meier curves based on the method of Tierney et al [43]. Random effects models with inverse variance weighting were calculated using Review Manager (RevMan 5.3, The Nordic Cochrane Center, Copenhagen, Denmark). The heterogeneity of the underlying population was assessed using the Q-statistic and I² test. For the interpretation, I² values greater than 50 % were considered to be heterogeneous [44]. Publication bias was assessed by visually evaluating a funnel plot (Begg's and Egger's test, Fig. 4).

5. Conclusions

The use of GAS during cancer therapy with capecitabine or TKIs should be offered with caution because it may result in a reduction of anticancer treatment and finally may significantly affect therapeutic outcomes. In our meta-analysis, we observed a significantly worse OS and PFS in patients receiving GAS during cancer treatment with anti-EGFR TKIs or capecitabine-based regimens in GI cancers and NSCLC. In conclusion, except for clear clinical reasons (concomitant use of steroids/non-steroidal anti-inflammatory drugs, severe gastroesophageal reflux disease/gastritis/peptic ulcer) GAS should be avoided during treatment with oral anticancer drugs for solid tumors.
