Abstract

Understanding the biology underlying the mechanisms and pathways regulating pancreatic β -cell development is necessary to understand the pathology of diabetes mellitus (DM), which is characterized by the progressive reduction in insulin producing β -cell mass. Pluripotent stem cells (PSCs) can potentially offer an unlimited supply of functional β -cells for cellular therapy and disease modeling of DM. Homeobox protein NKX6.1 is a transcription factor (TF) that plays a critical role in pancreatic β -cell function and proliferation. In human pancreatic islet, NKX6.1 expression is exclusive to β -cells and is undetectable in other islet cells. Several reports showed that activation of NKX6.1 in PSC-derived pancreatic progenitors (MPCs), expressing PDX1 ($\text{PDX1}^+/\text{NKX6.1}^+$), warrants their future commitment to monohormonal β -cells. However, further differentiation of MPCs lacking NKX6.1 expression ($\text{PDX1}^+/\text{NKX6.1}^-$) results in an undesirable generation of non-functional polyhormonal β -cells. The importance of NKX6.1 as a crucial regulator in MPC specification into functional β -cells directs attentions to further investigating its mechanism and enhancing NKX6.1 expression as a mean to increase β -cell function and mass. Here, we shed light on the role of NKX6.1 during pancreatic β -cell development and in directing the MPCs to functional monohormonal lineage. Furthermore, we address the transcriptional mechanisms and targets of NKX6.1 as well as its association with diabetes.

KEYWORDS: Diabetes, transcription factor, β -cell mass, pluripotent stem cells, pancreatic progenitors, cell therapy

1. INTRODUCTION

Diabetes mellitus (DM), affecting millions of people worldwide, is a metabolic disease caused by the loss or impaired function of insulin-producing pancreatic β -cells¹. β -cell replacement is a promising strategy for the treatment of diabetes. Transplantation of whole pancreas or isolated islet cells obtained from cadavers have been suggested as an alternative therapeutic approach for diabetes². However, despite successfully reducing hyperglycemia in transplant recipient diabetic patients, there are major limitations in this approach such as the inadequate supply of human pancreata and the necessity for lifelong use of immunosuppressant drugs³. Understanding the molecular mechanisms underlying human pancreas development can potentially provide better strategies for treating DM. Multiple signaling pathways, growth factors, and transcription factors (TFs) are engaged in regulating pancreatic development through orchestrating the balance in differentiation, proliferation, and maturation of endocrine and exocrine cells compartmenting the pancreas⁴. One of the key TFs involved in early and late pancreatic β -cell specification is the homeobox protein Nkx6.1 (NKX6.1)⁴, which is also expressed in nervous system during development and plays a key role in motor neuron specification⁵.

Human pluripotent stem cells (hPSCs) including human embryonic stem cells (hESCs) and human induced PSCs (hiPSCs) have the ability to differentiate into all types of cells, which make them a renewable source for functional insulin-producing cells⁶. Furthermore, they are a promising reference for *in vitro* disease modeling and drug discovery⁷. Step-wise differentiation protocols simulating the human fetal pancreas development have been employed for differentiating hPSCs into insulin producing cells *in vitro*^{8,9}. These studies

indeed successfully reported the generation of functional monohormonal β -cells *in vitro*, i.e. secreting only insulin and can respond adequately to glucose challenge. However, the existing differentiation protocols still require further improvements ⁴. This is mainly due to the small numbers of generated insulin producing cells and their poor efficiency in responding to high levels of glucose ^{8,9}. Pancreatic and duodenal homeobox 1 (PDX1) and NKX6.1 are two main transcription factors (TFs) that are highly expressed in both multipotent pancreatic progenitor cells (MPCs) and functional β -cells. hPSCs-derived MPCs (hPSC-MPCs), co-expressing PDX1 and NKX6.1 (PDX1⁺/NKX6.1⁺) mature into functional β -cells when transplanted into immune-deficient mice and successfully reduced their high glucose blood levels ⁶. On the other hand, MPCs lacking NKX6.1 expression (PDX1⁺/NKX6.1⁻) develop into polyhormonal cells and fail to function properly *in vivo*, indicating that the expression of NKX6.1 has a crucial role in guiding MPC development into β -cells ⁶. Moreover, specification of MPCs into non- β endocrine lineage may require the suppression of NKX6.1.

Collectively, NKX6.1 has an indispensable role in the specification of MPCs into mature functional β -cells. Furthermore, it plays a major part in maintaining the function of adult pancreatic β -cells. In this review, we will thoroughly discuss NKX6.1 expression during different stages of pancreatic development in human and mice, its interaction with other TFs involved in pancreatic β -cell development and its role in the pathogenicity of DM.

2. EXPRESSION OF NKX6.1 DURING PANCREAS DEVELOPMENT

The orchestrated expression of key TFs is mandatory for the development of functional mammalian pancreas. PDX1, NKX6.1, NKX2.2, PAX6, NGN3, ISL1, and NEUROD1 are among the main TFs controlling the chronological development of the distinct types of endocrine cells comprising the islet of Langerhans ⁴. NKX6.1, a homeobox-containing TF, has first been identified and isolated from chromosome 4 of islet and insulinoma cell lines ¹⁰. NKX6.1 is expressed at early stages of pancreatic development as well as in the β -cells, where it is involved in several functions during pancreatic development (Figure 1,2).

During pancreas development, MPCs in the dorsal and ventral buds express PDX1, PTF1A, and NKX6.1 and can differentiate into endocrine and exocrine pancreatic lineages ^{4,11} (Figure 1). Throughout pancreas development, NKX6.1 expression increases in the trunk area of pancreatic epithelium, which later specifies into endocrine lineage ⁴. Nkx6.1 is initially expressed at E9.5 in pancreatic epithelium and continues up to E13, where its expression becomes restricted to β -cells. At E10.5 in mice, Nkx6.1 and Ptf1a are co-expressed in a large percentage of MPCs. By E12.5, Nkx6.1 and Ptf1a make their separate way as Nkx6.1 becomes exclusively confined in the trunk domain of the developing pancreas giving rise to the endocrine lineage, whilst Ptf1a becomes fully committed to exocrine fate originating from the tip domain ¹². Furthermore, few early glucagon (GCG)-expressing cells that do not co-express either PDX1 or NKX6.1 can be detected in the dorsal buds of the developing pancreas ¹³. Some of these early Gcg⁺ cells have a low early insulin (Ins) expression by E11.5 and those Gcg⁺/Ins⁺ cells do not express any Nkx6.1 ¹³. E13.5 marks the emergence of the first Ins-expressing cells that are negative for Gcg (Gcg⁻

/Ins⁺). These cells display a strong expression of both Pdx1 and Nkx6.1¹⁴. The Ins⁺/Gcg⁺ cells and the later appearing single Ins⁺ cells comprise two distinct populations of hormone expressing cells. It has been suggested that the Gcg/Ins co-expressing cells serve as a transition state for the mature β -cells¹⁵. However, this theory has been rejected and instead it has been suggested that the mature β -cells arise from non-hormone expressing pancreatic progenitor cells co-expressing PDX1 and NKX6.1.

Around days E16.5 and E17.5, the first somatostatin (Sst)-expressing cells are observed. Although some of these cells co-express Pdx1, no Sst/Nkx6.1 co-expressing cells have been found at this stage. At E18.5, almost all Sst⁺ cells have Pdx1⁺ nuclei, while Sst⁺/Nkx6.1⁺ cells have not been detected. It is worth noting that after E18.5, the percentage of Pdx1⁺ nuclei in Sst-expressing cells remarkably decrease to 10 – 20%. By E20.5, pancreatic polypeptide (PP)-positive cells are detected¹⁴. Throughout the development of the PP-expressing cells, few cells are positive for Pdx1, but the expression of Nkx6.1 is extremely rare. The above observations provide strong evidence that Nkx6.1 is mainly expressed in β -cell precursors and mature β -cells in adult pancreas of rodents¹⁴. Pancreatic endocrine specifications are not identical in humans and rodents. It has been reported that in mice, the polyhormonal cells appear before the development of monohormonal pancreatic β -cells. In contrast, in humans, the monohormonal β -cells appear prior the appearance of polyhormonal cells during pancreas development^{4,16}.

3. ROLE OF NKX6.1 DURING EARLY PANCREAS DEVELOPMENT

NKX6.1 plays important roles during early and late stages of pancreatic development as well as in mature β -cells. As described above, NKX6.1 expression starts

during MPC stage after PDX1 induction and its expression in PDX1⁺ cells determines pancreatic islet cell fate ^{4,6,17}. In rodents and humans, glucose-responsive monohomonal β -cells originate from MPCs co-expressing PDX1 and NKX6.1 (PDX1⁺/NKX6.1⁺) ^{4,6}. In mice, deletion of *Nkx6.1* prevents the generation of functional monohomonal β -cells; however, it allows the development of polyhormonal β -cells ¹⁸. Also, it has been shown that forced expression of NKX6.1 in PDX1⁺ MPCs rescues pancreatic β -cell development in *NKX6.1* mutant progenitors ¹⁹, highlighting the critical role of NKX6.1 expression at MPC stage in the development of β -cells. However, NKX6.1 ectopic expression in NGN3⁺ cells at the endocrine progenitor (EP) stage is not sufficient to drive EPs to β -cell fate, suggesting that NKX6.1 expression is required before the induction of the endocrine program through NGN3 expression ¹⁹. While previous studies showcased that NGN3 emerges from MPCs that express NKX6.1 (PDX1⁺/NKX6.1⁺) or lack NKX6.1 expression (PDX1⁺/NKX6.1⁻), other studies demonstrated that NGN3 expression can precedes that of NKX6.1 during early pancreatic development ²⁰. It has been reported that the early induction of hormone cells intercept with the development of functional β -cells ²¹. Altogether, the NKX6.1 activation in MPCs prior NGN3 induction and the co-expression of NGN3 and NKX6.1 at the EP stage are crucial for their commitment to the desired functional β -cell lineage ^{4,22}.

Deciding between exocrine and endocrine pancreatic cell fates occurs at early pancreatic progenitor stage and controlled by the balance between NKX6.1 and PTF1A. Previous studies showed that there is an antagonist mechanism between NKX6.1 and PTF1A controlling cell fate determination. PTF1A TF, crucial for exocrine pancreas

development, is detected in early pancreatic progenitors giving rise to endocrine and exocrine fates ²³. *Nkx6.1*-deficient embryos showed a significant high expression of *Ptf1a* and a substantial reduction in *Ngn3*⁺ EPs ²⁴. On the other hand, overexpression of *Nkx6.1* in the MPCs significantly reduces *Ptf1a* expression hence blocking acinar cells generation. Also, overexpression of *Nkx6.1* in acinar cell line leads to a significant reduction in the *Ptf1a* expression. This effect is blocked when *Nkx6.1* binding site in *Ptf1a* is mutated ²⁴. These results provide undeniable proof that *Nkx6.1* directs the choice between endocrine and acinar lineages and that *PTF1A*, a main regulator of acinar gene transcription, is directly regulated by *NKX6.1*. Noticeably, the majority of *PTF1A*⁺ cells in the MPCs lack *NKX6.1* expression, showing that *PTF1A* expression in progenitors is competent to suppress *NKX6.1* ²⁴. Likewise, exogenous *PTF1A* also represses the expression of both *SOX9* and *NGN3* to completely block endocrine cell differentiation ²⁴. This early specification event mediated by cross-antagonism between *NKX6.1* and *PTF1A* may represent an intrinsic mechanism by which the relative numbers of newly-differentiated endocrine versus acinar cells are predetermined during pancreas development ²⁴.

During MPC stage, the co-expression of *NKX6.1* and *SOX9* is crucial for the generation of *NGN3*⁺ EPs that mature into β -cells. In human, the inhibition of *SOX9* expression in fetal islet epithelial cells between weeks 14 and 16 has significantly decreased the mRNA levels of *NKX6.1* and their proliferative capacity ²⁵. Previous studies reported that the level of *NGN3* expression is essential for MPCs to be directed toward the endocrine fate ^{26,27}. This highly suggests that there is an important interaction between *NKX6.1* and *SOX9* during MPC differentiation. However, *Sox9* expression is observed in

embryos lacking the expression of *Nkx6.1* and *Ngn3* indicating that *Sox9* expression is unaffected and is upstream of both ²⁸. It is worth to note that *SOX9* expression significantly declines during EP commitment and acinar cell specification ^{25,28}.

4. ROLE OF NKX6.1 IN MATURE PANCREATIC ISLETS

NKX6.1 has been found to play a crucial role for β -cell homeostasis and insulin secretion. In humans, NKX6.1 has been found to uniquely restricted to β -cells and play a significant role in pancreatic β -cells development ²⁹. NKX6.1 expression starts at 9 weeks of gestation and increases exponentially at 13 weeks only in insulin-producing cells. Studies on human fetal pancreas showed that NKX6.1 expression does not co-localize with SST, PP or amylase during early or adult pancreas development reinforcing the notion of NKX6.1 constraint into insulin producing β -cells ²⁹. NKX6.1 is necessary for the formation and the secretory function of insulin-producing β -cells. A previous study carried out on rodents showed that *Nkx6.1* expression is essential for maintaining pancreatic β -cell identity *in vivo* and its over-expression leads to increased glucose-stimulated insulin secretion (GSIS) ³⁰. Another study reported that *Nkx6.1* is found to directly regulate genes responsible for insulin processing such as *Ero11b* and *Slc30a8*. Moreover, key genes controlling β -cell function, glucose uptake, and metabolism are found to be regulated by *Nkx6.1* expression ³¹. This indicates that *Nkx6.1* is a master transcriptional regulator that mediates multiple crucial β -cell processes.

Furthermore, NKX6.1 plays an essential role in maintaining β -cell identity. It has been found that suppression of *Nkx6.1* in adult mouse β -cells leads to activation of *Ngn3*

expression in β -cells and converts them to Sst-expressing δ -cells ³⁰, indicating a change in β -cell identity due to the absence of *Nkx6.1*. These findings come along with the results obtained from T2D models, in which β -cells are converted into other islet cells ³².

A previous report provided evidence that in mice there are synergetic and compensatory mechanisms between both *Nkx6* TFs, *Nkx6.1* and *Nkx6.2* ³³. In mice, loss of *Nkx6.1* results in defects in β -cells only but loss of *Nkx6.2* shows no defects in pancreatic islets ³³. However, knockout of both TFs, *Nkx6.1* and *Nkx6.2* leads to a reduction in the numbers of α - and β -cells ³³, indicating that the absence of *Nkx6.2* alone can be compensated by *Nkx6.1*, but the *Nkx6.2* cannot compensate the absence of *Nkx6.1*. *Nkx6.1* expression is crucial during the secondary transition of the pancreas development, which is distinguished with high levels of β -cell replication and development ¹⁸ (Figure 1). Mice lacking *Nkx6.1* have a decreased pancreatic β -cell number without any effect on the growth of other pancreatic islet cells ^{18,19}.

Although in human, *NKX6.1* is restricted to β -cells, it is also involved in suppressing α -cell development. It has been believed that gene expression of *GCG*, an α -cell restricted hormone, is not regulated by non- α -cell TFs. However, some reports proposed that, during development, the failure to activate β -cell-specific TFs directs the α -cell phenotype and thus *GCG* gene expression ³⁴. *PDX1* and *PAX4* have been shown to suppress *GCG* gene expression by targeting *PAX6* ^{35,36}. *NKX6.1* drive the β -cell development and maintains its identity through participation in suppression of *GCG* expression ³⁷. Supporting this notion, it has been reported that *NKX6.1* overexpression results in a decrease in the *GCG* mRNA; however, lowering of *NKX6.1* level results in an

increase in the *GCG* mRNA levels. This inhibitory effect of NKX6.1 on *GCG* expression is mainly mediated by targeting PAX6. ChIP analysis reported direct interaction of NKX6.1 with the *GCG* promoter and that NKX6.1 competes with PAX6 for the G1 element of the *GCG* promoter ³⁴.

There are contradictory results regarding the role of NKX6.1 in β -cell proliferation. For example, forced expression of *Nkx6.1* *in vivo* in adult mouse β -cells has no effect on β -cell proliferation ^{31,38}; however, another study showed that overexpression of *Nkx6.1* in cultured islets enhances β -cell proliferation ³⁹. A recent study reported that *Nkx6.1* deletion in mouse model decreases β -cell proliferation through its effect on *Ccnd2* ³⁰. These conflicting results may be due to the difference between *in vivo* and *in vitro* experiments and the change in the expression of some genes, such as *Glut2* after isolating the islets from their niche ⁴⁰. Also, the absence of a positive effect of *Nkx6.1* overexpression on adult mouse islets could be due to the very low rate of β -cell expansion in adult mice. Interestingly, a recent study showed that *Nkx6.1* activity is essential for β -cell expansion postnatal ⁴¹. Inactivation of *Nkx6.1* does not block β -cell proliferation before birth but it does after birth when the animal starts to eat linking *Nkx6.1* role in mediating nutrient-induced β -cell expansion ⁴¹. In line with these findings, the expression of *Glut2* and *Glp1r*, nutrient sensors, are absent in β -cells lacking *Nkx6.1* ⁴¹. During the early postnatal life, a decreased β -cell expansion has been observed in mice lacking *Glut2*, because glucose is important for β -cell proliferation ⁴². Another study demonstrated that the reduction in the intracellular glucose levels associated with *Glut2* deficiency after *Nkx6.1* inactivation leads to a decrease in the proliferative ability of mouse β -cells ³¹, suggesting an essential role of *Nkx6.1* in controlling glucose transport through *Glut2*. However, *Glp1* regulates β -cell

proliferation through a different mechanism⁴³. Therefore, the effect of *Nkx6.1* deficiency on suppressing *Glut2* and *Glp1r* in mouse islets leads to inhibition of β -cell proliferation through two different mechanisms. Forced expression of *Nkx6.1* in adult rat islets leads to an increase in β -cell proliferation by activating cell cycle genes, including cyclins A, B, and E and multiple kinases³⁹. However, a more recent study showed that *Nkx6.1* does not bind to the regulatory region of *Cyclin* genes³¹. It has been reported that *Nkx6.1* directly regulates several essential pancreatic β -cell genes involved in glucose uptake (*Glut2*), glucose metabolism (*G6pc2* and *Pcx*), and insulin biosynthesis (*Ero11b* and *Slc30a8*)³¹. Furthermore, it regulates key transcription factors involved in the development and function of β -cells, including *MafA*, *Mnx1*, *Rfx6*, and *Tle3*³¹ (Figure 3). Moreover, previous studies demonstrated that *Nkx6.1* controls the expression of the nuclear receptor family 4, group A, members 1 and 3 (*Nr4a1* and *Nr4a3*) and *c-Fos*, which are crucial for β -cell proliferation^{44,45}. In neonatal and young mice, it has been found that loss of *Nr4a1* leads to a reduction in the β -cell area⁴⁴. Taken together, these findings indicate that *Nkx6.1* play a critical role in enhancing and maintaining β -cell function through regulating multiple pathways associated with insulin biosynthesis and β -cell development and proliferation (Figure 3).

There are few studies on human islets. Although *Nkx6.1* knockdown impairs β -cell proliferation and GSIS in rat islets³⁷, its overexpression in human islets results in an enhancement in β -cell proliferation without improving GSIS³⁹. The expression and function of some genes described above, such as *GLUT2* are different in human islets; therefore, further functional studies are needed to understand the function of *NKX6.1* and identify the genes regulated by *NKX6.1* in human β -cells.

5. DNA BINDING AND TRANSACTIVATION PROPERTIES OF NKX6.1

Little is known when it comes to binding characteristics, transactivation properties or the specific transcriptional targets of NKX6.1 in human. Previous studies using animal models have provided to a great extent, a better understanding of Nkx6.1 activity⁴⁶. Nkx6.1 utilizes several strategies for recognizing its specific targets. Binding site selection assays have indicated that Nkx6.1 binds to a highly specific DNA sequence comprising of eight base pairs. This sequence harbors a classic 5'TAAT'3 binding core for most homeodomain factors. Furthermore, the conservancy of base pairs flanking the binding core is essential for proper identification by the Nkx6.1 homeodomain. Any changes even as simple as alteration in a single base pair, has a huge impact on reducing the binding affinity. The specificity of flanking sequences may contribute in narrowing down the potential targets of Nkx6.1^{46,47}. Another strategy for NKX6.1 to identify its target is through the binding interference domain (BID). The COOH terminus domain of the homeodomain accounts for the BID of NKX6.1. BID may directly interact with the DNA binding domain. The negatively charged COOH may interrupt the interaction between the positive charges in the DNA binding domain and the phosphate group of the DNA. The BID may provide two important features for Nkx6.1: specificity and regulation. NKX6.1 binds only weakly to DNA *in vitro* when a functioning BID exist. For a proper function of NKX6.1, a modification in the activity of the BID is required. Interactions between NKX6.1 and other proteins that bind nearby or are part of the transcriptional regulation complex could provide relief of interference. As an alternative, certain enzymes like kinases, phosphatases or proteases could regulate the BID activity⁴⁷.

In general, NKX6.1 is marked as a transcriptional repressor of its targets. N-terminus of NKX6.1 has been labeled as the transcriptional repression domain, while the c-terminus (BID) was found to be responsible for positive feedback or transcriptional activation of NKX6.1 promoter. NKX6.1 promoter harbors a sequence similar to the TAAT box and it binds to it to positively self-regulate its own expression ^{46,47}.

6. UPSTREAM AND DOWNSTREAM TARGETS OF NKX6.1 ASSOCIATED WITH β -CELL DEVELOPMENT

Previous reports revealed that there are several NKX6.1 targets associated with multiple functions in β -cells (Figure 4). Nr4a1 and Nr4a3 have been reported as one of the main targets of NKX6.1-mediated β -cell proliferation ⁴⁴. Likewise, c-Fos, is a TF that is regulated by Nkx6.1 expression in rat insulinoma cells. Interestingly Nr4a1 and Nr4a3 have been found to be downstream targets of c-Fos. This implies that the β -cell proliferation induced by Nr4a1 and Nr4a3 is stimulated by Nkx6.1-mediated c-Fos upregulation ⁴⁵. Furthermore, ChIP-Seq analysis showed that Nkx6.1 directly controls the expression of important β -cells and insulin processing genes, including *Glut2*, *G6pc2*, *Pcx*, *Ero1lb*, and *Slc30a8* ³¹. It also controls the expression of TFs of β -cell development, including *Rfx6*, *MafA*, *Mnx1*, and *Tle3* ³¹. A previous study reported that Nkx6.1 controls cell cycle regulators, cyclins and cyclin dependent kinases ³⁹; however, a recent study used ChIP-seq analysis demonstrated that the Cyclin genes are not regulated by Nkx6.1 ³¹. Another target that is associated with NKX6.1-mediated β -cell proliferation is Aurora Kinase A (AURKA). NKX6.1 binds to AURKA promoter and it has been shown that

AURKA is directly induced by the overexpression of Nkx6.1 in rat primary islets that resulted in the degradation of the cell cycle regulator p53⁴⁸.

Furthermore, it has been found that NKX6.1 regulates the expression of hepatocyte nuclear factor 1 α (HNF1 α) that is expressed in both hepatocytes and during pancreas development⁴⁹. HNF1 α is a key determinant of pancreas specification⁴. Although HNF1 α promoter's regulation in hepatocytes has been thoroughly studied, the mechanism by which HNF1 α promoter is regulated during pancreatic development needs further investigations⁵⁰. Transcription is regulated through a TATA-like box and proximal HNF4 α -binding site. The HNF1 α is fully active in hepatocytes but not in INS-1 rat insulinoma cells, providing evidence that its regulation may be controlled by alternative elements in other tissue types. Several TFs specific for β -cells have been screened using transient transfection assays in 3T3 cells with co-transfection of the HNF1 α -luciferase reporter⁴⁹. Binding site mutation analysis showed that (5'-TAAT-3') is a real NKX6.1-binding site and it is used for initiating HNF1 α transcription. NKX6.1 activates HNF1 α in a concentration-dependent manner⁴⁹. Overexpression of NKX6.1 in NIT1 β -cells leads to a marked increase in the expression of endogenous HNF1 α by 3-fold compared to control. On the other hand, knockdown of NKX6.1 using specific siRNA significantly reduces HNF1 α endogenous expression by 80% compared to the control. This provides further evidence that HNF1 α is regulated by NKX6.1⁴⁹.

Little is known about the pathways controlling the expression of NKX6.1 during β -cell development, particularly in human. It has been suggested that PDX1, a known activator of gene expressions, has NKX6.1 as one of its target genes during pancreatic β -

cell development⁵¹ (Figure 4). In *Pdx1*-null mice, the *Nkx6.1* expression is lost in the dorsal pancreatic epithelium. However, the cells expressing *Gcg* in the dorsal pancreas bud in earlier stages still show scanty expression of *Nkx6.1*¹⁷. This means that the *Nkx6.1* production in those *Gcg*/*Nkx6.1* double positive cells are independent of *Pdx1*¹⁷. hPSC Studies investigating the binding sites of PDX1 during human pancreatic development have been mainly examining its role during early MPC stage, which does not express NKX6.1^{52,53}. However, ChIP-seq analysis on primary adult human β -cell reported that NKX6.1 is among the PDX1 binding sites⁵² indicating that PDX1 controls NKX6.1 in human β -cells. Furthermore, NGN3 has been shown to be indirectly inducing the expression of NKX6.1 via activating PAX4. NGN3 has been found to bind to the regulatory region of PAX4 to mediate its expression in endocrine progenitors²⁰. Overexpression or knockdown of SOX9 in fetal human islets has significantly affected NKX6.1 expression and subsequently INS mRNA levels²⁵. This suggests that SOX9 is important for NKX6.1 expression.

Based on the hierarchy of TFs directing pancreatic development in the mice model, *Nkx6.1* lies downstream of *Nkx2.2*⁴. This has been proven when single mutation in *Nkx6.1* did not result in a complete block of β -cell differentiation unlike in *Nkx2.2* mutant embryos¹⁸. This is mainly due to the fact that even though *Nkx6.1* function is impaired, *Nkx2.2* expression is maintained in the *Nkx6.1* mutant pancreas¹⁸. Another study reported that *Nkx6.1* is directly regulated by *Nkx2.2*⁵⁴. This eminently suggests that *Nkx6.1* functions downstream of *Nkx2.2* in mouse β -cell differentiation¹⁸. Of note, in rodents, *Nkx2.2* expression has been detected in the MPCs prior to the development of EPs⁵⁵, while in humans, NKX2.2

has not been found in MPCs of the fetal pancreas and starts to be expressed after endocrine induction ⁴. Taken together, these findings suggest a species difference in the expression and function of NKX6.1 during pancreatic development (Figure 4). NKX2.2 is expressed in both α - and β -cells. In β -cells, NKX2.2 preferentially binds to Arx promoter. The methylation state of Arx promoter might influence this binding specificity via modifications induced by DNMT3A, which is expressed in both α - and β -cells indicating that the preferential recruitment of DNMT3A to Arx promoter reckon on a β -cell specific factor such as NKX6.1. As supporting evidence, NKX6.1 has been found to bind to Arx promoter during β -cell specification ⁵⁶. Further human studies are needed to clarify the relationship between NKX6.1 and other TFs during early human pancreas development.

7. NKX6.1 AND DIABETES MELLITUS

T2D is characterized by impaired insulin sensitivity of insulin target tissues and reduced insulin secretion by pancreatic β -cells. Several lines of evidence suggest that cellular processes defect compromise β -cell function and lead to T2D development ⁶. Moreover, high levels of glucose in blood have been linked with impaired expression of genes that are responsible for β -cell identity ⁵⁷. Talchai et al. described a loss of β -cell features is distinguished by a drop-in insulin production, adoption of progenitor-like features, and conversion of fate into other endocrine cell types in mouse models of T2D, suggesting that loss of the β -cell differentiated state contributes in failure of β -cell in T2D ³². However, whether loss of β -cell functional properties and loss of β -cell identity are

linked during T2D progression remains elusive. The reduced expression in key transcriptional regulators justifies the simultaneous loss of β -cell function and identity³². Mounting evidence suggests that NKX6.1, the β -cell-enriched TF, may have a prominent role in the development of T2D. Genome-wide association studies (GWAS) suggest that T2D is associated with mutations or variants of NKX6.1⁵⁸. Also, decreased expression of NKX6.1 has been shown to be involved the development of T2D in humans and rodents^{32,59}. Moreover, *in vitro* studies in β -cell lines and isolated islets suggest a possible role for NKX6.1 in the regulation of β -cell proliferation as well as of GSIS^{37,39}. A previous study reported that Nkx6.1 is necessary and sufficient to de-differentiate β -cells into immature endocrine precursors in the embryo, supporting the notion that NKX6.1 maintain the differentiated state of adult β -cells³⁰. Together, all these evidences suggest that NKX6.1 is a key regulator of β -cell function and identity in humans and animals.

It has been found that the loss of Nkx6.1 causes rapid-onset diabetes due to defects in insulin biosynthesis and secretion without affecting on β -cell survival³¹. In *NkX6.1*-deficient islets, it has been found that the expression of Zinc transporter Slc30a8 (oxidoreductase Ero1lb) associated with T2D, is dramatically reduced³¹. Furthermore, a severe reduction in the expression of the Pcsk1 (PC1), which converts proinsulin to insulin, is noticed in *NkX6.1*-deficient mouse islets³¹. The observed loss in insulin production and β -cell functional properties is later accompanied by abnormal activation of δ -cell genes in β -cells. Thus, by impairing β -cell function and destabilizing β -cell identity, reduced NKX6.1 levels, as seen in T2D, could contribute to the pathogenesis of T2D³¹.

Furthermore, maturity onset diabetes of the young (MODY), a form of monogenetic

diabetes, is caused by an autosomal dominant mutation in one of several genes involved in pancreas development. MODY3, caused by mutations in the *HNF1 α* gene, is the most prominent form of this disease as it accounts for approximately 70% of MODY cases ⁶⁰. It has been demonstrated that NKX6.1 is a major regulator of HNF1 α and that this regulatory system is unique to β -cells ⁴⁹. This opens the door to study the potential of novel regulatory elements that should be included when screening for mutations affecting HNF1 α expression. NKX6.1, which is uniquely expressed in mature β -cells of the pancreas ²⁹, may implicate a new target for diagnosis of MODY ⁴⁹.

8. USING PLURIPOTENT STEM CELLS TO UNDERSTAND THE ROLE OF NKX6.1 IN β -CELL DEVELOPMENT

hPSCs (hESCs and hiPSCs) have become a solid approach that benefits studies on developmental biology. An outstanding amount of knowledge about pancreas development have been collected using animal models ⁴. However, despite being a very powerful tool in understanding human pancreas, there are some limitations due to differences between mice and human species ⁶¹. The use of primary human β -cells could serve as an alternative approach, nonetheless, being based on isolation of islets from cadaveric organ donors, its scarce availability, and poor maintenance *in vitro* had made it a limited option. Furthermore, it is not a suitable model to study developmental stages of pancreas ⁶. The role of NKX6.1 in β -cell development has been examined with the use of hPSCs. The combination of hPSCs with single cell transcriptome analysis have revealed that β -cell arise from a heterogenous population and subpopulations during differentiation ⁶². However, despite the promising advances of the β -cell differentiation protocols using

hPSCs, there are still many shortcomings in comparison to human primary β -cells^{4,6}. This indicates the urgent need to develop the existing differentiation protocols. The use of hPSCs expressing a fluorescent reporter gene can facilitate the isolation and purification of specific cell types in heterogeneous populations⁶³. Hence, the generation of genetically modified hPSC lines reporting the expression of key β -cells genes including NKX6.1 will improve their differentiation towards functional β -cell lineage. Furthermore, it will also help in characterization and studying the trajectory leading to this fate⁶⁴. Likewise, the use of specific cell surface markers labeling cells of interest is beneficial to purify and isolate the hPSCs-derived ($PDX1^+/NKX6.1^+$) MPCs from the produced heterogeneous population⁶. Surface markers including Glycoprotein 2 (GP2)^{65,66} and CD142⁶⁷ have been identified as markers distinguishing MPCs that give rise to functional β -cells⁶. Similarly, CD49a has been identified as a marker for mature β cells co-expressing NKX6.1 and Insulin⁶². Nonetheless, whether the abovementioned surface markers successfully capture all the cells expressing NKX6.1 at the defined stages remain debatable.

Interestingly enough, the use of hPSCs to study the role of NKX6.1 has unfolded the presence of another pathway by which $NKX6.1^+$ MPCs progress to β -cell lineage. Our recent studies reported the generation of hPSC-derived MPCs, which do not express PDX1 and express high levels of NKX6.1 ($PDX1^-/NKX6.1^+$)^{68,69}. The newly reported population ($PDX1^-/NKX6.1^+$) do not express endocrine markers, CHGA and NGN3 and ductal epithelium marker, Cytokeratin 19⁶⁸. These findings suggest the presence of two distinguished populations of $NKX6.1^+$ MPCs during human pancreas development, in contrast to the idea of the existence of a single $NKX6.1^+$ pancreatic progenitors always co-expressing PDX1⁶⁸. Interestingly, we have recently generated functional β -cells from

PDX1/NKX6.1⁺ MPCs and the generated β -cells co-express PDX1 and C-peptide, indicating that there is another way to generate β -cells without going through PDX1⁺ MPCs (*Memon et al. submitted*). Further hPSC-based studies are needed to understand the mechanism underlying the function of NKX6.1 during human β -cell development.

9. CONCLUSION AND FUTURE PERSPECTIVES

Although NKX6.1 has been reported to have a major role in the differentiation and development of pancreatic β -cells, the exact underlying mechanism remains largely unknown particularly in human islets. In this review, we have summarized the crucial function of NKX6.1 that commences during MPC specification and ends with defining and maintaining the features comprising a functional β -cell. NKX6.1 expression in PDX1⁺ MPCs is critical for driving them towards the right pathway. PDX1⁺/NKX6.1⁺ MPCs are merely the sole precursors that give rise to mature β -cells. At the MPC stage, the antagonistic interaction between NKX6.1 and PTF1A pushes the MPCs to either endocrine or exocrine fate with NKX6.1 favoring the endocrine lineage. In regard to NKX6.1 role in mature β -cells, several studies demonstrated that NKX6.1 is essential for the insulin biosynthesis, β -cell identity, and enhanced proliferation of β -cells. Nkx6.1 enhances β -cell proliferation through its effect on cell proliferation genes, such as *Ccnd2*, *Glut2*, *AURKA*, *c-Fos*, *Nr4a1*, and *Nr4a3*. Furthermore, Nkx6.1 play a key role in β -cell development and function by controlling the expression of key TFs, such as *HNF1a*, *MafA*, *Mnx1*, *Rfx6*, and *Tle3*. Moreover, it plays an essential role in glucose uptake and metabolism and insulin biosynthesis through its effect on *Glut2*, *G6pc2*, *Pcx*, *Ero1lb*, and *Slc30a8* (Figure 3).

Taken together, this indicates that NKX6.1 utilizes many pathways for expanding and maintaining the functional β -cell mass. Since most of the data described here are obtained from animal studies, we cannot apply them to human because there are physiological differences between mice and humans. For example, one of the results obtained from mouse studies showed that Nkx6.1 regulates β -cell proliferation through its effect on Glut2, which is not the main glucose transporter in human β -cells. This indicates that more studies on human islets and hPSC-derived β -cells are needed to understand the exact role of NKX6.1.

The crucial role of NKX6.1 has pushed scientists to further dissect the exact mechanism that this TF employs to restrict the MPC differentiation into the insulin-secreting β -cells. As any TF, NKX6.1 is responsible for regulating the expression of a number of genes by binding to their DNA sequence. Whether this regulation is achieved by repressing or the activation of the target genes, the identification of NKX6.1-targeted genes is an important aspect for better understanding of pancreas development in general and β -cells in particular. Characterizing human NKX6.1 function and downstream targets throughout pancreas organogenesis will provide great insight into the mechanisms through which NKX6.1 regulates the differentiation of MPCs into functioning human pancreatic β -cells. Genetic manipulation by either overexpression or knockdown of NKX6.1 expression is an important tool for the gene function analysis. This approach offers a powerful tool to detect and track the signaling cues controlling MPC's commitment to functional β -cells trajectory oppose to other endocrine cell types. ChIP-Seq assay combined with sequencing can be used for mapping the genomic location of human NKX6.1 and subsequently identify DNA binding sites. Studies carried out in mice models using ChIP-

seq technology have already identified key genes directly and indirectly controlled by NKX6.1 expression. While these studies helped in creating a feasible understanding about NKX6.1 function; however, this cannot be necessarily translated to human model. hPSCs have offered an alternative and a powerful solution for accurate disease modeling of humans. These hPSCs can be differentiated using efficient stepwise differentiation protocols to either MPCs, endocrine precursors or ultimately to β -cells to capture the distinctive downstream targets of NKX6.1 at each stage. ChIP-Seq analysis of NKX6.1 expressing cells during the aforementioned different stages of β -cells development from hPSCs will help in identifying direct NKX6.1 pancreatic targets on a genome-wide scale. Dissecting NKX6.1-mediated governance of the pancreatic β -cell differentiation will undoubtedly provide new insight into the transcriptional mechanisms regulating the differentiation of MPCs into β -cells. Such knowledge will be highly beneficial in optimizing current protocols for differentiating hESC/hiPSCs into functionally-mature insulin⁺ cells. The ultimate goal would be to enrich and produce large amounts of NKX6.1⁺ pancreatic progenitors that in turn leads to adequate amounts of monohormonal, glucose responsive β cells. Moreover, identifying novel surface markers specific for MPCs that are expressing NKX6.1 is advantageous. This will be of great benefit to easily isolate and purify the population of interest for subsequent differentiation or transplantation.

Diabetes pathophysiology involves several factors, including β -cell loss and alterations in β -cell function, identity, and proliferation as a result of defects in the expression of β -cell-specific TFs such as NKX6.1. Thus, discovering treatments sustaining appropriate levels of those TFs in β -cells could be one of the key strategies to treat specific forms of diabetes.
