Abstract: GM2 gangliosidoses are a group of pathologies characterized by GM2 ganglioside accumulation into the lysosome due to mutations on the genes encoding for the β -hexosaminidases subunits or the GM2 activator protein. Three GM2 gangliosidoses have been described: Tay-Sachs disease, Sandhoff disease, and the AB variant. Central nervous system dysfunction is the main characteristic of GM2 gangliosidoses patients that include neurodevelopment alterations, neuroinflammation, and neuronal apoptosis. Currently, there is not approved therapy for GM2 gangliosidoses, but different therapeutic strategies have been studied including hematopoietic stem cell transplantation, enzyme replacement therapy, substrate reduction therapy, pharmacological chaperones, and gene therapy. The blood-brain barrier represents a challenge for the development of therapeutic agents for these disorders. In this sense, alternative routes of administration (e.g. intrathecal or intracerebroventricular) have been evaluated, as well as the design of fusion peptides that allow the protein transport from the brain capillaries to the central nervous system. In this review, we outline the current knowledge about clinical and physiopathological findings of GM2 gangliosidoses, as well as the ongoing proposals to overcome some limitations of the traditional alternatives by using novel strategies such as molecular Trojan horses or advanced tools of genome editing.

Keywords: Lysosomal Storage Disorders; GM2 gangliosidoses; Tay-Sachs disease; Sandhoff disease; β -Hexosaminidases; Therapeutic alternatives

1. Introduction

Gangliosides are a group of glycosphingolipids mainly located in the neuronal cell membrane and that are responsible of several pivotal biological functions for the correct functioning of the central nervous system (CNS) [1]. About 5% of all brain gangliosides correspond to GM2 gangliosides [2, 3]. In normal conditions, GM2 gangliosides are catabolized by the lysosomal hydrolases β -hexosaminidases (Hex, EC 3.2.1.52) through the hydrolysis of the N-acetylgalactosamine residues [4]. Hex are a subset of isozymes formed by the dimerization of α and β subunits: HexA ($\alpha\beta$), HexB ($\beta\beta$) and HexS ($\alpha\alpha$). In addition, GM2 gangliosides degradation involves the GM2 activator protein (GM2-AP), which present the gangliosides to α subunit of HexA [1]. Mutations in the genes encoding for α (HEXA), β (HEXB) or GM2-AP (GM2A) proteins affect the lysosomal degradation of GM2 ganglioside and other glycolipids, causing their accumulation into the lysosome and the GM2 gangliosidoses Tay-

Sachs (TSD, OMIM #272800), Sandhoff (SD, OMIM #268800), or GM2-activator protein deficiency (AB variant; OMIM #272750), respectively [4]. Upon the GM2 ganglioside accumulation, several cytotoxic effects take place mainly in neurons, which frequently cause neuronal death [5]. Individuals with GM2 gangliosidoses have a progressive neurological impairment including motor deficits, progressive weakness, hypotonia, decreased responsiveness, vision deterioration, and seizures [6]. Unlike TSD patients, SD patients may present systemic manifestations as organomegalies [7, 8]. The diagnosis for these disorders begins with recognition of the clinical characteristics, which is followed by the measurement of the enzymatic activity that can be confirmed by mutation analysis [9, 10].

Both the understanding of physiopathology and the development of therapies for GM2 gangliosidoses have benefited from the different animal models available for these disorders. These animal models include mice, cats, and sheep, which mimics some of the biochemical and physiological characteristics of GM2 gangliosidoses [11]. An ideal TSD mouse model was recently developed through a combined deficiency of HexA and Neu3, which mimics the neuropathological and clinical abnormalities of classical early-onset TSD patients and may provide a valuable tool for treatments development for this condition [12].

Several therapeutic approaches have been evaluated for GM2 gangliosidoses, including enzyme replacement therapy, hematopoietic stem cell transplantation, pharmacological chaperones, substrate reduction therapy, and gene therapy. Nevertheless, currently there is not an approved therapy for these disorders. The efficacy of the therapeutic approaches is affected, among others things, by the blood brain barrier (BBB) that limits the access of intravenous therapeutic agents to the CNS [13]. In this sense, strategies involving chimeric recombinant enzymes, direct brain injection, or the development of vehicles to target proteins to the brain have shown promising advantages respect to conventional administration strategies [14]. Likewise, the development of novel gene editing tools, as CRISPR/Cas9, has supposed a new horizon to the treatment of the lysosomal storage disorders including the GM2 gangliosidoses [15]. In this paper, we provide a critical review about physiopathology features and diagnosis of these diseases as well as a major up to date about the development of therapies for GM2 gangliosidoses.

2. Gangliosides: Structure and physiological role.

Gangliosides are complex glycolipids composed of a ceramide linked to a glycan with at least one sialic acid [2]. Currently, over 180 gangliosides have been identified in vertebrates [2, 16]. In humans, GM3 ganglioside is predominantly in peripheral tissues such as liver, adipose tissue, aorta, and platelets [17]; whereas GM1, GD1a, GD1b, GT1b, and GQ1b are the major gangliosides in human brain (~95%) [18]. The remaining 5% of brain gangliosides corresponds to other gangliosides among which GM2 is found [2, 3, 19]. Gangliosides are distributed in caveolae-rich microdomains of the plasma membrane [16, 20, 21], where they perform crucial functions such as membrane organization [21], neuronal differentiation [20, 22], cell adhesion [23], signal transduction [24], inflammation [3], and neurite outgrowth [22, 25], among others.

The *novo* biosynthesis of gangliosides starts with the formation of ceramide in the cytoplasmic side of rough endoplasmic reticulum (RER) and that ends in the *trans*-Golgi network through the sequential addition of carbohydrates in a process catalyzed by several glycosyltransferases to generate lactosylceramide [1, 26]. Subsequently, the LacCer- α -2-3 sialyltransferase adds sialic acid to form GM3 gangliosides and other precursor gangliosides [26]. This GM3 ganglioside acts as precursor for the synthesis of more complex gangliosides like GM2, by the action of β -1,4-N-acetylgalactosaminyl transferase (GM2/GD2 synthase), which transfers the N-acetylgalactosamine residue to the GM3 structure [4, 26, 27]. GM1 and GD1a gangliosides differ from GM2 by the number and type of monosaccharides presents, as well as by the number of sialic acid residues.

3. β -Hexosaminidases: Synthesis, transport, and catalytic functions.

β -hexosaminidases are dimeric lysosomal enzymes composed by α and/or β subunits to form HexA ($\alpha\beta$), HexB ($\beta\beta$), and HexS ($\alpha\alpha$) isoforms [4]. Genes of α (*HEXA*) and β (*HEXB*) subunits are located in chromosome 15q23 and 5q13.3, respectively [4]. Fourteen exons and thirteen introns are

described for both genes which share a 60% of identity, suggesting a common ancestor [28]. Early studies using pulse and chase analysis showed that Hex are synthesized as long precursors of 67 (α) and 63 (β) kDa that are proteolytically processed to 54 and 52 kDa peptides, respectively [29, 30]. The β subunit suffers further proteolysis to obtain a mature form of 29 kDa and other smaller peptides that remain linked by disulfide bonds [29]. Two major cleavages points for α precursors have been identified: 1) alanine 22 that allows removing the signal peptide (22 a.a.) into the ER and 2) lysine 86 that is followed by lysosomal exopeptidase-mediated trimming of three amino acids to give the mature form of α subunit into the lysosome [28, 31]. For β precursors, cleavages points are found in valine 42 that removes signal peptide (42 a.a.) and alanine 45 [32]. Furthermore, the mature subunit is nicked internally in the valine 48, threonine 122, and lysine 315, which remain joined through disulfide bonds [32].

Post-translational modifications of Hex, as N-glycosylations and phosphorylations, are carried out during the ER-Golgi traffic of the proteins [33]. For α chains, asparagine (Asn) 115, 157, and 295 have been identified as putative N-glycosylation sites [34]; whereas Asn 84, 142, 190, and 327 have been described for β chains [34, 35]. Additionally, early studies suggested that terminal mannoses present on Asn84, Asn115, and Asn295 N-glycosylations must be phosphorylated to be recognized by the mannose-6 phosphate receptor (M6PR) [33]. After these modifications take place, the subunits are dimerized to obtain the active enzymes [33]. Although it is not clear the organelle in which Hex are dimerized; some authors suggest that this process is carried out into the *trans*-Golgi network (TGN) before being targeted to the endosome-lysosome pathway [36-38]. These enzymes can also reach the extracellular compartment through sorting from TGN, which can be then taken up by neighbouring or secreting cells through fluid-membrane endocytosis [4]. The uptake of these enzymes by neighbouring cells constitutes the cross-correction mechanism that is the base of the main therapeutic strategies for lysosomal storage diseases (LSDs). In addition, the HexA has also been identified on the plasma membrane of *in vitro* cultured fibroblasts, which has shown activity against the GM2 ganglioside [39]. However, the *in vivo* physiological role of this membrane-bound enzyme and the transport mechanism from TGN it is not completely understood yet.

Substrate degradation requires the dimerization of HexA and HexB. Noteworthy, only HexA can hydrolyze the N-acetylgalactosamine present in GM2 ganglioside; while both HexA and HexB hydrolyze a variety of substrates including glycosaminoglycans, glycolipids, and glycoproteins [4, 33, 40, 41]. In addition, the hydrolysis of galactose in the GM1 ganglioside structure is necessary for the catalytic activity of the HexA on the GM2 ganglioside (Figure 1) [38]. For the HexA, two active sites have been described, one on each α and β subunits (Figure 2) [33, 42]. Glutamate 323 and 355 in the α and β subunits, respectively, act as general residues that allow the protonation of the glycosidic oxygen atom; whereas aspartate 322 and 354 in the α and β subunit, respectively, contribute to the necessary stabilization during the nucleophilic attack to the N-acetylgalactosamine [33, 42]. In addition, it has been proposed that arginine 424 of the α subunit form hydrogen bonds with the carboxylate group of the sialic acid; whereas aspartate 452 in the β subunit would repeal the sialic acid binding [33, 42]. This fact may explain the differences in the affinities of the natural and artificial substrates for HexA and HexB [40]. In contrast to globoside degradation by HexB, the GM2 ganglioside degradation requires a the GM2-AP mediation [43]. GM2-AP is considered as a lipid transporter protein that removes the GM2 ganglioside from the endosome membranes derived from the plasma membrane internalized during caveolae-mediated endocytosis [1]. *In vitro* approaches have predicted that GM2-AP simultaneous interactions between the GM2 ganglioside and the α subunit of HexA are necessary for the hydrolysis of N-acetylgalactosamine residue [1, 44].

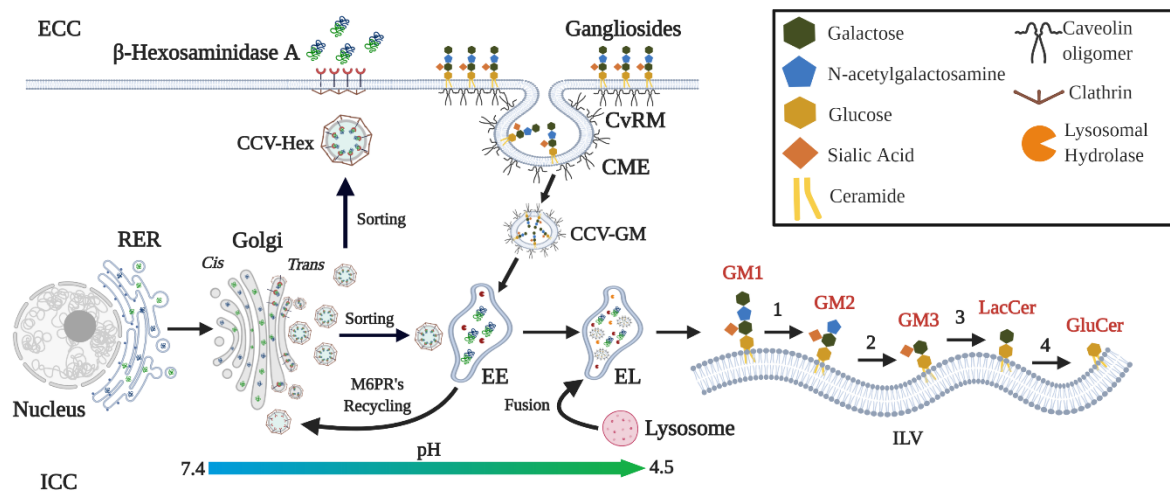

Figure 1. M6PR-dependent transport of β -Hexosaminidase A and ganglioside degradation. α and β subunits of Hex are synthesized in the rough endoplasmic reticulum (RER) and transported to the *Cis*-Golgi network. In this compartment, Hex is subject to N-glycosylations and phosphorylations from *Cis*-Golgi network to the *Trans*-Golgi network [33]. Monomers are dimerized in the *Trans*-Golgi network and coupled to mannose-6 phosphate receptors (M6PR) [33, 37]. New vesicles are sorted to both early endosomes (EE) and to the secretory pathway, where can be uptake by neighbour cells through M6PR [37, 45]. Hexosaminidases are dissociated from the M6PR in the EE; which allows the M6PR recycling to the *Trans*-Golgi network by both clathrin-dependent and independent mechanisms [37]. On the other side, gangliosides are placed in caveolae-rich microdomains (CvRM), and in the turnover of the plasma membrane undergo caveolae-mediated endocytosis (CME) [1, 38]. New caveosomes containing gangliosides (CCV-GM) reach the EE and further fusion events result in a late endosome, which can be fused with the lysosome to give rise to the endo-lysosome (EL, pH: 4.5) [37]. Gangliosides degradation starts with the hydrolysis of the galactose of the GM1 ganglioside to generate GM2 ganglioside which are harboured on intralysosomal vesicles (ILV)[1]. GM2 interacts with HexA through a GM2AP-mediated mechanism to removes the N-acetylgalactosamine residues [38]. Additional reactions implied in the ganglioside degradation to glucosylceramide (GluCer) are shown. The enzymes of each reaction are as follow: **1 and 4:** β -Galactosidase/GM2AP, **2:** β -Hexosaminidase A/GM2AP, and **3:** Neuraminidase. **LacCer:** Lactoceramide. **ECC:** Extracellular compartment. **ICC:** Intracellular compartment.

4. Mutations of β -Hexosaminidases A and B, and GM2 activator protein.

According to *The Human Gene Mutation Database*, currently, 181, 103, and 9 mutations have been reported for *HEXA*, *HEXB* and *GM2A* genes, respectively, including missense/nonsense, splicing, small deletion and indels, and gross deletions (Figure 3) [46–48]. Although the type and frequency of mutations have been linked to the demographic origin of the patients, for *HEXA* the most representative mutation is the transition c.533G>A that changes arginine by histidine (p.R178H) and affects the catalytic site of the α subunit, altering its function and stability [49–52]. In the case of *HEXB*; a frequent mutation is c.445+1G>A, which occurs in a conserved intronic site that promotes a complete loss of a canonical splice donor site [53, 54]. Finally, mutations in *GM2A* are extremely rare and only 9 mutations have been described on 11 patients [48, 55]. Figure 3 show some of the most common mutations on *HEXA*, *HEXB*, and *GM2A* genes.

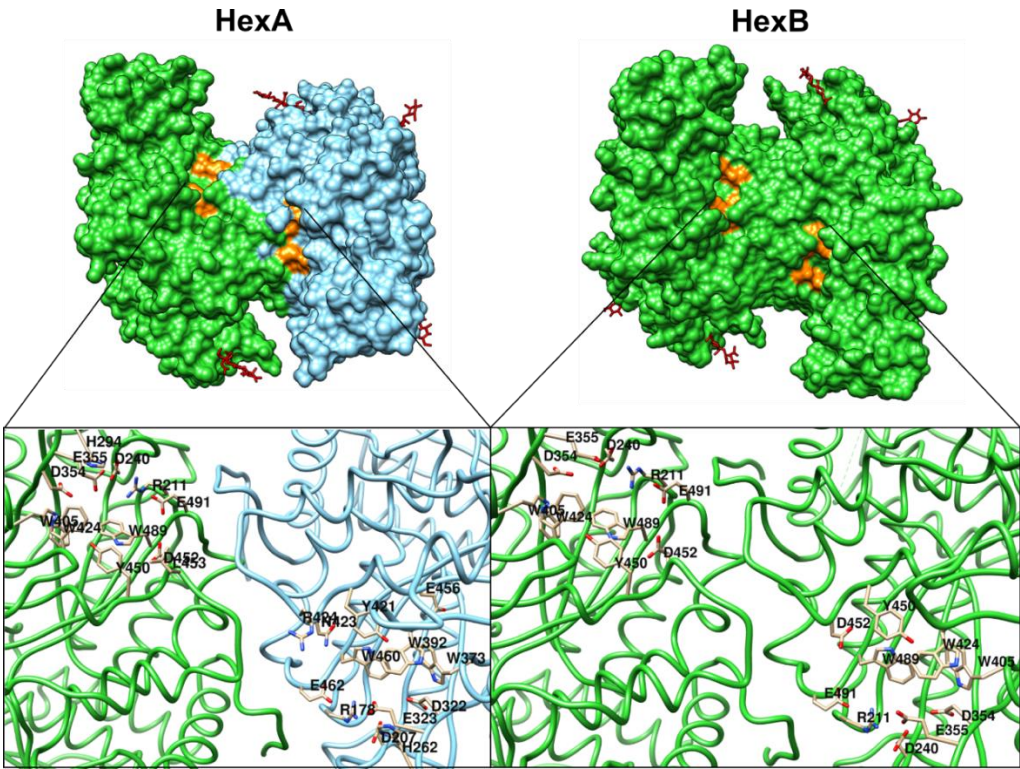

Figure 2. Structure of HexA and HexB. HexA (PDB 2gjx) isolated from human placenta, while HexB (PDB 1o7a) was recombinantly expressed in insect cells. α - and β -subunits are colored in light blue and green, respectively. N-glycans and active sites are colored in red and orange, respectively. The residues present in the active site of each subunit are also shown.

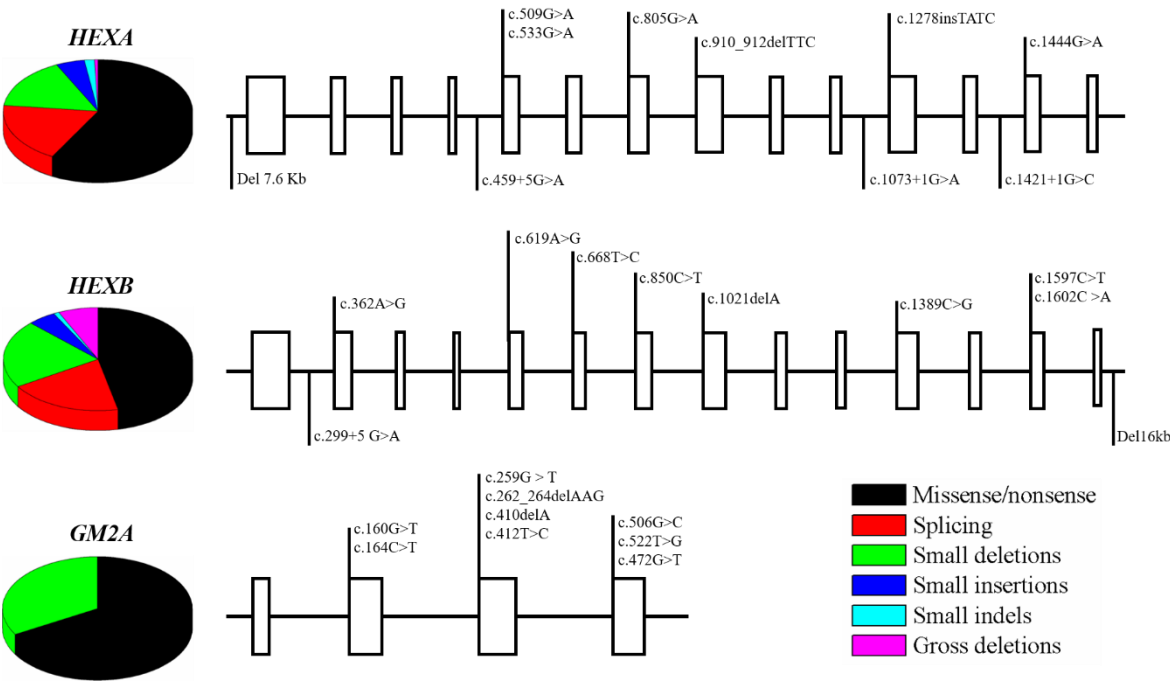

Figure 3. Common mutations on *HEXA*, *HEXB*, and *GM2A* genes. The figure shows some of the most common mutations identified on *HEXA*, *HEXB*, and *GM2A*, as well as their distribution throughout the gene. Mutations can be found either on exons (boxes), introns, and the 5' and 3'UTRs. 14 exons and 13 introns are represented to *HEXA* and *HEXB*, whereas 4 exons and 3 introns are shown for *GM2A*. This figure was made according to the reviewed in [48, 52–57].

Table 1. Main neurological features in GM2 gangliosidosis.

Disease	Affected gene	Affected protein	Accumulated substrate*	Common findings			Ref
				Onset	Symptoms	Neuroimaging	
TSD	HEXA	HexA	GM2 Ganglioside	Infantile Acute	Seizures, axial hypotonia, cherry-red spot, regression in developmental milestones, exaggerated startle response	Bilateral thalamic involvement, brain atrophy, hypomyelination	[56, 58, 59]
SD	HEXB	HexA, HexB	GM2 Ganglioside, Globoside	Juvenile Subacute	Ataxia, myoclonus, motor regression, psychotic episodes, intellectual disability, progressive clumsiness	Cerebellar atrophy	[50, 60]
AB variant	GM2A	GM2AP	GM2 Ganglioside	Adult Chronic	Dysphagia, muscle atrophy, cerebellar ataxia, dysarthric speech, manic depression, muscle weakness, psychotic episodes	Severe cerebellar atrophy, hypodensity of the thalamus	[4, 6, 57]

TSD: Tay-Sachs disease **SD:** Sandhoff disease. ***Note:** β -Hexosaminidases can hydrolyse molecules with N-acetyl-hexosamines residues such as glycosaminoglycans (GAGs). Accumulation of partially degraded GAGs has also been reported. For more detail please see [61, 62].

5. Clinical presentations and biochemical correlations of GM2 gangliosidoses

Although TSD, SD, and AB variant are a consequence of mutations in different genes, the neurological compromise is similar among these three disorders [1]. Classical neurological findings are associated to the clinical onset as follows: 1) *acute*: seizures, hypotonia, regression in developmental milestones [59], 2) *subacute*: motor regression, psychotic episodes, intellectual disability [50], and 3) *chronic*: dysphagia, cerebellar ataxia, muscle weakness, and manic depression [6]. In Table 1 we summarized these neurological findings of GM2 gangliosidoses. In addition, it is important to highlight that SD patients may present systemic manifestations such as cardiomegaly, hepatosplenomegaly, macroglossia, and skeletal abnormalities [7, 8], as a consequence of the impaired HexB activity, which also contribute to the degradation of several glycosaminoglycans like keratan sulfate and chondroitin sulfate [61, 63].

5.1. Diagnosis of GM2 gangliosidoses.

The diagnostic of GM2 gangliosidoses patients begins with recognition of the clinical characteristics of these disorders (Table 1) [7-9, 60]. Diagnosis is also favored by neuroimaging characterized by hyperdensity of basal ganglia, which can be accompanied by other changes in white matter and sometimes prominent, but non-specific, cerebellar atrophy [9].

The specific diagnosis requires the determination of HexA and HexB activities by using artificial substrates. For instance, the use of 4-methylumbelliferyl-N-acetylglucosaminide (MUG) allows to measure the activity of both HexA and HexB, while a sulfated substrate (MUGS) is used to specifically measure the HexA activity [9]. Despite Hex activity can be assessed on biological fluids, cells, tissues, and dried blood spots (DBS) [10], the diagnosis gold standard is the measurement of the enzyme activity in leukocytes, fibroblasts, or chorionic villi [10]. Nevertheless, the β -hexosaminidase activity assay does not allow the identification of asymptomatic carriers or the diagnosis of patients with deficiency on the GM2 activator protein, for who molecular diagnosis is required [9]. Molecular diagnosis by sequencing the *HEXA*, *HEXB*, and *GM2A* genes allows to confirm the diagnosis of all GM2 gangliosidoses subtypes.

The heterogeneity of onset correlates inversely with the residual catabolic activity of Hex [1, 64]. Whereas patients with the acute presentation have absent or very low (<5%) enzyme activity, patients with subacute or chronic onset may have enzyme activities between 5 and 10% [4, 63, 65]. In this sense, it has been proposed that a 10% of wild-type enzyme activity may avoid the disease, based on early studies describing GM2 ganglioside degradation with activities between 10 and 15% [66], and pseudo-deficiencies reported in healthy individuals [1, 4]. Nevertheless, some pathogenic mutations in both TSD and SD may lead to enzyme activities around 15% of wild type levels [56, 58]. In this sense, it has been proposed that a therapeutic benefit of any of the treatment alternatives for GM2 gangliosidoses may reach enzyme activities higher than 15% of the wild type levels. Recent findings in this interesting topic will be discussed in detail later.

6. Physiopathology of GM2 gangliosidoses

As a consequence of mutations on Hex subunits or the GM2 activator protein, GM2 gangliosides are accumulated into lysosomes [1, 4]. Although it is not completely understood yet, early evidence using animal models of SD showed the presence of autoantibodies against GM2 gangliosides in serum and CNS [67]. This finding may suggest that GM2 ganglioside accumulation could promote the disruption of the lysosome and the release of the ganglioside, as has been described for some mucopolysaccharidoses (MPS) [68]. Since the lysosome has a pivotal function in the degradation of several macromolecules and organelles [69-71], its impairment will affect the cellular homeostasis with a negative impact on the global tissue physiology. Here we described the current findings of the physiopathology of these disorders, which are summarized in the Figure 4.

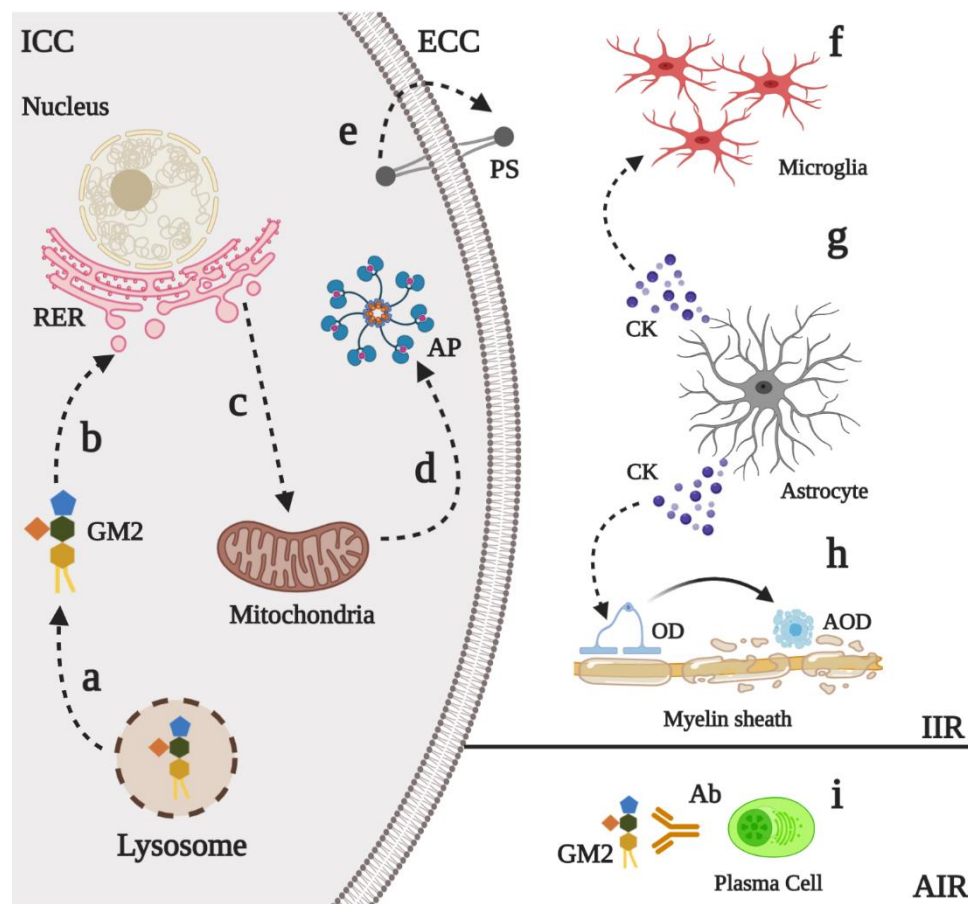

Figure 4. Physiopathological events in GM2 gangliosidosis. Innate (IIR) and adaptive (AIR) immune response have been described in GM2 gangliosidosis. Upon the impaired of lysosomal degradation of the GM2 ganglioside, this can be released into the cytoplasm (a) where its sialic acid can interact with the rough endoplasmic reticulum (RER) (b). Sustained stress into RER induces the activation of proapoptotic proteins like CHOP (c) that promotes mitochondrial-mediated apoptosis (d). In early apoptosis states, the phosphatidylserine (PS) is externalized (e), which promotes the recruitment of several proinflammatory cells such as microglia (f). Astroglial cells have also been reported in the GM2 gangliosidosis (g). The release of several astrocyte-derived cytokines (CK), such as CCL2 and CXCL10, increases the recruitment of microglia and the apoptosis in myelinating oligodendrocytes (AOD), which induces neuron demyelination (h). Finally, auto antibodies (Ab) against GM2 ganglioside seem to contribute to the pathophysiology of the GM2 gangliosidosis (i), although the precise mechanism of its release has not been described. ECC: Extracellular compartment, ICC: Intracellular compartment, AP: Apoptosome, OD: Oligodendrocyte.

6.1. Neurodevelopment Process.

The use of a cerebral SD organoid model, generated from patient-derived iPS cells, has been an interesting approximation to the discovery of novel implications of GM2 accumulation [72]. In this context, recent findings have described that impaired Hex activity promotes an increase in the size of the cerebral organoids, which was corrected after transduction of *HEXA* and *HEXB* cDNAs by using adeno-associated virus (AAV) vectors [73]. In agreement with these results, and using *HEXB* deficient zebrafish embryos, Kuil *et al.*, 2019 found an increase in the lysosomal speckles in radial glia [74], which are progenitor cells able to differentiate into neurons, astrocytes, and oligodendrocytes [75]. At 5 days postfertilization, the authors also found reduction in the spherical form of lysosome within microglia, in addition to an abnormal locomotor activity [74]. Nevertheless, an increase in the apoptosis rate was not reported in these studies [73, 74]. Together, these results are evidence of the cellular and functional consequences of GM2 ganglioside accumulation in the maturing of the

nervous system. These findings also support the fact that the impairment of these cellular processes could have an impact on the acute symptoms of SD, as has been previously identified [76].

6.2. Neural Death and Neuroinflammation.

Neural death has been proposed as an important mechanism in the physiopathology of the GM2 gangliosidosis [4]. Early studies of brain and spinal-cord from autopsy samples of TSD and SD patients revealed an increase in the *in-situ* DNA end-labeling, suggesting that apoptosis could contribute to the neurodegenerative process in these patients [77]. Similar findings were later described in SD animal models [78] and TSD mouse model (*HEXA*^{-/-}/*NEU*^{-/-}) [12], showing a marked reduction in neuronal density [79]. Although the precise pathway that explains the increase of neural apoptosis has not been completely resolved, recently findings have shown that GM2 ganglioside can induce endoplasmic reticulum stress [5, 80]. It has been also proposed that GM2 ganglioside, but not asialo-GM2 ganglioside, promotes neurite atrophy and cell death through PERK-mediated apoptosis with downstream CHOP activation [5], which is an inductor of mitochondrial apoptosis [81]. These results suggest that the sialic acid on the GM2 ganglioside may have proapoptotic properties. Nevertheless, the use of a PERK inhibitor did not completely abolish the apoptosis, suggesting that further mechanisms in the neuronal death in GM2 gangliosidosis could be involved [5].

Given the typical mechanism of early apoptosis such as phosphatidylserine externalization on the surface of the neuron [82, 83], it has been suggested that the characteristic microgliosis and infiltration observed in patients and animal models may be the response to the neuronal death [4, 78, 84]. Early studies conducted by Jeyakumar *et al.*, 2003 using a SD (*HEXB*^{-/-}) mouse model, showed that as the disease progresses and symptoms such as head tremor, motor dysfunction, and hind limb paralysis appear, there is an increase in the immunoreactivity for the Major Histocompatibility Complex type II in brain stem and thalamus, as well as an increase in the proinflammatory cytokines TNF α and IL1 β [85]. These findings suggest that innate immune activation of the CNS could be produced, at least in part, in response to the neuronal death. Although authors reported similar findings on the TSD (*HEXA*^{-/-}) mouse model, cytokines levels were not increased, which can be explained by the fact that neuraminidase/sialidase can transfer GM2 to GA, which can be processed by HexB; thus bypassing the HexA defect [11, 12].

Despite microglial activation and proliferation have been extensively reported in TSD and SD models [84, 86], astrogliosis can also play an important role in GM2 gangliosidosis even in asymptomatic states of the disease [87, 88]. In this regard, Ogawa *et al.*, 2017 showed in SD mice that astrocytes are activated by an FcR γ -dependent mechanism [88]. Upon activation, astrocyte secretes the chemokines CCL2 and CXCL10, which correlates with a robust microglial activation and the invasion of peripheral immune cells. This astrocytes activation could lead to degeneration and death of myelinating oligodendrocytes, promoting active demyelination [89, 90], which is frequently observed in infantile forms of GM2 gangliosidosis [4, 91, 92]. Together, these findings highlight the pivotal interplay between microglia and astrocytes in the inflammatory response observed in GM2 gangliosidosis, which could be the functional consequence of neuronal injury due to GM2 ganglioside accumulation and that may contribute to the neurodegenerative process.

7. Current proposals for the treatment of GM2 gangliosidosis

Several approaches have been tested for the development of specific treatments for GM2 gangliosidosis, which are summarized in Figure 5 [93-95]. These strategies range from traditional enzyme replacement therapy alternatives to novel biotechnological tools such as CRISPR/Cas9 and prime editing, with promising results both *in vitro* and *in vivo*. Although some of these developments have been translated to clinical trials [96-99] (Table 2), there is not an approved treatment for TSD, SD, or AB variant yet. In this section, we review the current proposals and advances in therapeutics for GM2 gangliosidosis.

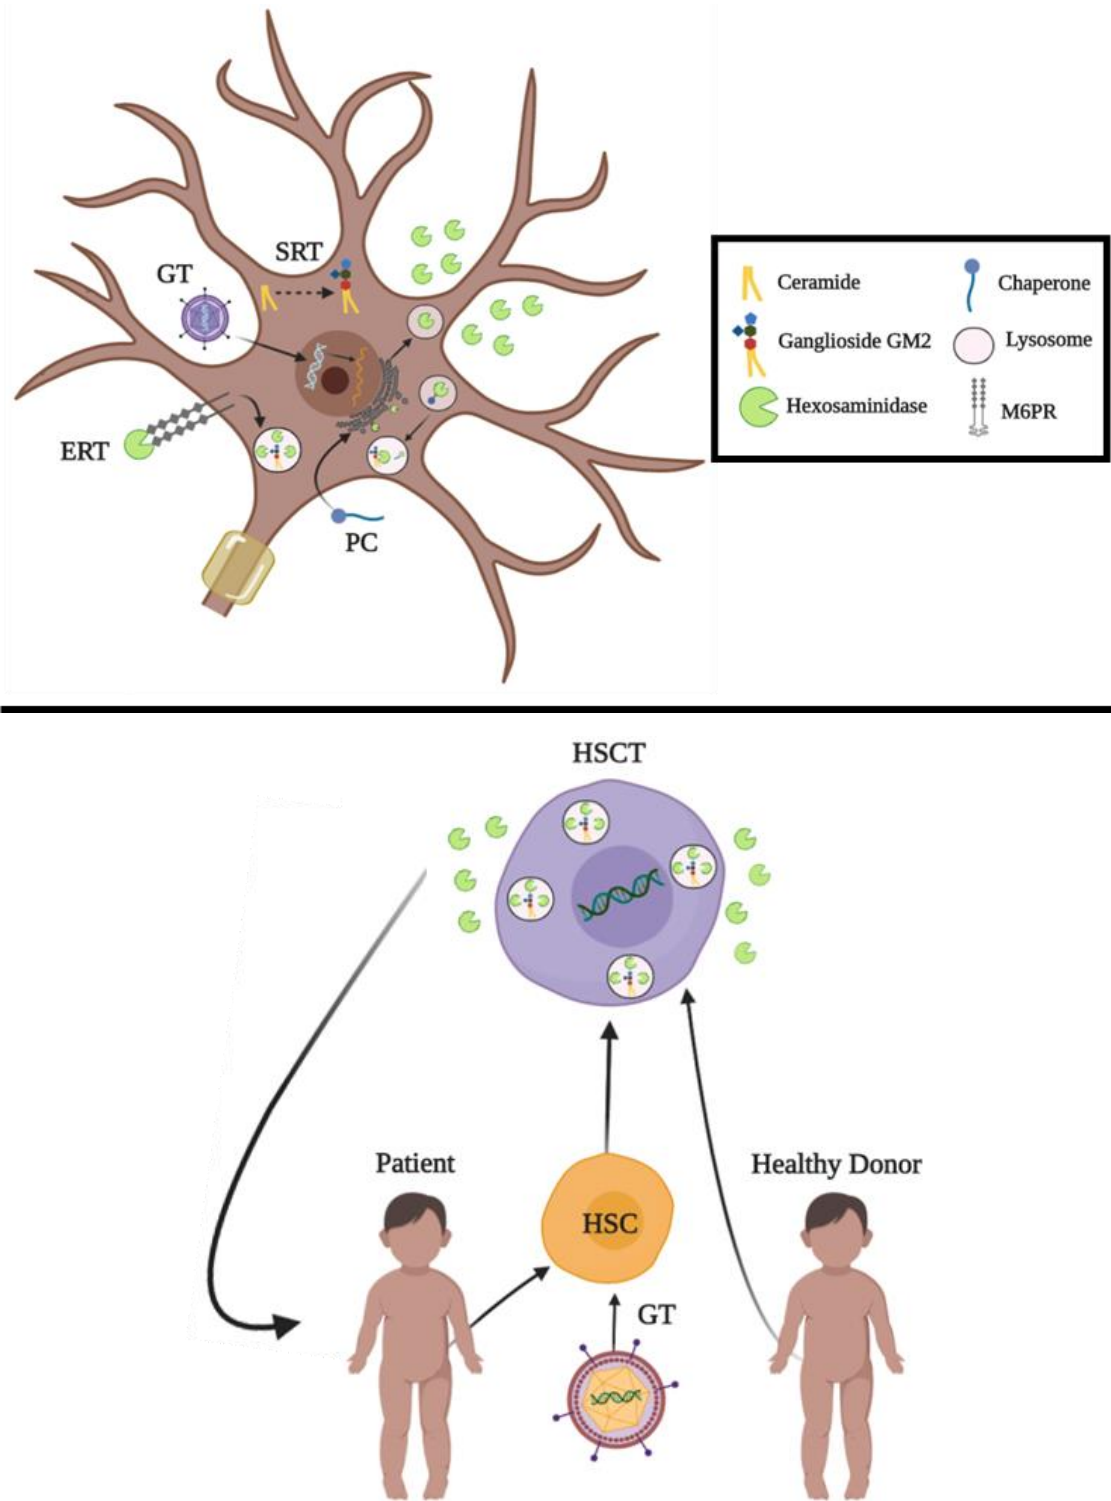

Figure 5. Therapeutic alternatives for GM2 gangliosidosis. The figure shows current proposals for *in vivo* (upper) and *ex vivo* (lower) approaches. Extracellular Hex represents exocytosis of the enzyme upon its translation, which supports the cross-correction hypothesis. **GT:** Gene Therapy. **SRT:** Substrate Reduction Therapy. **PC:** Pharmacological Chaperones. **ERT:** Enzyme Replacement Therapy. **HSCT:** Hematopoietic Stem Cell Transplantation. **HSC:** Hematopoietic Stem Cell.

7.1. Enzyme replacement therapy.

Enzyme replacement therapy (ERT) is a therapeutic alternative conceived in 1964 by Christian de Duve in which the lysosomal enzymes can be uptake through endocytosis and delivered to the lysosomes [14]. ERT is possible due to the cell uptake of mannosylated enzymes via specialized mannose receptors and currently it has been approved for Gaucher, Fabry, and Pompe diseases, late infantile neuronal ceroid lipofuscinosis type II, acid lipase deficiency, alpha-mannosidosis, and MPS type I, II, IVA, VI, and VII [93, 100].

In the case of GM2 gangliosidoses, early studies carried out by Johnson *et al.*, 1973 using intravenous administration of HexA in a patient with SD showed that the enzyme was presented in liver but not in the cerebrospinal fluid or brain parenchyma, suggesting that enzyme was unable to cross the BBB [101]. To overcome these limitations, promising strategies to enable that exogenous lysosomal enzymes can cross the BBB include the development of fusion proteins, also known as molecular Trojan horses [14]. These fused proteins are recombinant chimeric enzymes fused to a monoclonal antibody (MAb) that recognize either the human insulin receptor (HIR) or the transferrin receptor (TfR), and which allow the passage of the BBB through a receptor-mediated endocytosis [102]. In this field, several studies using non-human primates have shown that intravenous administration of HIRMAb fused to α -iduronidase [103], iduronate-2-sulphatase [104], sulphamidase [105], α -N-acetylglucosaminidase [106] can cross the BBB without side effects. Although these approaches have not been evaluated in animal models of GM2 gangliosidoses, recently Boado *et al.*, 2019 showed that an HexA fused to HIRMAb has a similar activity to the non-fused enzyme (2.464 ± 109 mU/mg vs 2.557 ± 187 mU/mg, respectively), suggesting that use of molecular Trojan horses could be an alternative to treat GM2 gangliosidoses [102].

The use of several routes like direct injection into the cerebrospinal fluid and intrathecal or intracerebroventricular (ICV) injections have shown potential therapeutic effects for some LSDs with CNS compromise [14, 107, 108]. In this sense, it has been reported the ICV administration to SD mice of recombinant HexA produced in Chinese hamster ovary (CHO) cells or the yeast *Ogataea minuta*, with or without modifications on the N-glycans [4, 109, 110]. The results showed significant increase on the enzyme activity levels in several brain regions and in the life span, as well as a reduction on the levels of GM2 and GA2 gangliosides and the MIP-1 α chemokine [4, 109, 110]. Similarly, Matsuoka *et al.*, 2011 evaluated the ICV administration of a chimeric HexB enzyme, which contain a β -subunits with six point mutations and a partial sequence from the α -subunit that allows the binding of charged substrates and GM2AP [111]. This approach, led to a significant reduction of GM2 ganglioside in the brain and cerebellum, and a 2-fold increase in Hex activity. Noteworthy, a marked reduction of GM2 ganglioside was also observed in liver; which could have a significant impact on the disease, since hepatosplenomegaly is a common clinical finding of SD patients [92]. Together, these results suggest that ICV ERT is a potential strategy for the treatment of GM2 gangliosidoses and that N-glycans modifications may have a positive effect on enzyme uptake, biodistribution, and substrates reduction throughout the brain.

Although most of the enzymes used for ERT are produced in CHO cells, recombinant Hex produced in the yeast *O. minuta* and *Pichia pastoris* have also been evaluated [110, 112, 113]. In this sense, recombinant HexA and HexB produced in the methylotrophic yeast *Pichia pastoris* GS115 have shown high pH and serum stability [112]. In addition, these enzymes are internalized by an M6PR-dependent mechanism without the need of further modifications of the N-glycans [114], unlike that reported for the recombinant HexA produced in *O. minuta* [110]. *In vitro* evaluation of recombinant HexA produced in *P. pastoris* showed normalized lipid accumulation in neural stem cells, showing the potential of this enzyme in the development of an ERT for GM2 gangliosidoses [115]. Recent efforts to allows the delivery of these recombinant Hex to CNS involved their conjugation with nanoparticles [116].

7.2. Hematopoietic Stem Cell Transplantation.

Since Hex can be exported to the extracellular space [37, 45] and cross-correct neighboring cells through a M6PR-mediated mechanism [4, 117], the administration of hematopoietic stem cells (HSC), could provide sufficient amounts of the deficient enzyme in a natural or engineered-dependent

manner [117, 118]. Allogeneic HSC transplantation (HSCT) can be performed from bone marrow (BM), umbilical cord (UC), or peripheral blood after a myeloablative regimen [119]. This strategy has been successfully performed in other LSDs, such as MPS I [120, 121], MPS II [122], and Gaucher type 1 and 2 [123].

For GM2 gangliosidosis a limited number of patients have been subject to HSCT. In this regard, Jacobs *et al.*, 2005, used allogeneic BM transplantation to treat a 3 years-old asymptomatic child with subacute TSD. The results showed an increase in leukocytes HexA activity without prevention of the neurodegenerative events of the disease [124]. Later, in a single-center study, five children with infantile TSD were subjected to unrelated UC transplantation. After treatment, the survival was extended in 2 cases with an arrest on the neurodegenerative process, without improvement in motor skills [125].

Recently, Ornaghi *et al.*, 2020 used lentiviral vectors carrying both α - and β -subunits to transduce HSC isolated from healthy donors, as well as neural stem cells and murine HSC, showing an increase of up to 2-fold in the total Hex activity [126]. In addition, physiological functions of these stem cells, such as proliferation, self-renewal, or multipotency, remain unchanged, suggesting that *ex vivo* gene therapy could be an interesting option for the treatment of GM2 gangliosidosis [126]. Nevertheless, a common challenge in allogeneic HSCT is the graft-versus-host disease (GVHD) [127]. In fact, studies in patients with inborn errors of metabolism have shown up to 10% of acute GVHD [125]. In order to overcome this limitation, recent developments using hypoinmunogenic human stem cells have opened a new horizon for the HSCT, avoiding the events of GVHD through evasion of both cellular and humoral immune response [128, 129]. However, this approach has not been applied to GM2 gangliosidosis yet. Likewise, an attractive alternative for the treatment of GM2 gangliosidosis could be the use of autologous HSCT, in which the mutations are corrected thorough gene therapy in hematopoietic precursors isolated from the patients [118, 130].

7.3. Pharmacological chaperones.

Pharmacological chaperones (PCs) are small molecules that bind to target protein stabilizing the native conformation or promoting the correct folding of misfolded and unfolded proteins [131, 132]. PCs bind with high affinity and selectivity to the target protein into the ER and later dissociated into the lysosome as a consequence of the acidic pH and the presence of the natural substrate, which competes with the PC for the active site [133, 134]. Since most of the PC described so far act as competitive inhibitors [135], it has been proposed the use of allosteric sites to identify non-inhibitory PC [133]. In addition, PCs have a mutation-dependent activity, which limits the number of patients that may respond to the treatment [133, 134]. PC must not be confused with chemical chaperones like dimethyl sulfoxide (DMSO), which can also bind to and stabilize some proteins but with less selectivity and greater toxicity [136].

In a screening of 1040 FDA-approved drugs, Maegawa *et al.*, 2007 found that pyrimethamine (PYR) was the most promising PC for HexA since it induced an up to 3-fold increase in enzyme activity on TSD fibroblasts [137, 138]. PYR is a drug used in the treatment of cerebral toxoplasmosis and complicated malaria, which targets folic acid synthesis and can cross the BBB [139]. Nevertheless, clinical trials with PYR showed an increase in enzyme activity but with a limited impact on the CNS manifestations of the disease [4, 98, 140].

To identify potential PCs for GM2 gangliosidosis, an *in silico* analysis of iminosugar inhibitors that bind to the active site of HexA was carried out [141]. Throughout molecular docking and dynamics simulations, the pyrrolidine DMDP amide was predicted as the strongest competitive inhibitor of HexA. DMDP amide improved the intracellular activity of HexA up to 14.8-fold in TSD fibroblasts patients, reaching up to 43% of wild-type levels [141]. These results suggest that iminosugars could be an interesting therapeutic alternative for GM2 gangliosidosis, as has been previously described for other LSDs [133, 135].

Another potential strategy reported to increase the folding of mutant Hex is the use of progranulin (PGRN). This is a glycoprotein secreted by epithelial, neuronal, and immune cells that is involved in a variety of physiological processes and diseases such as early embryogenesis, cell

proliferation, immune and neurodegenerative diseases, inflammation processes, wound healing, and tissue repair [142, 143]. Jian *et al.*, 2016 showed that the heat shock protein 70 associates with the lysosomal enzyme β -glucocerebrosidase (GCase) in the ER/Golgi apparatus by a PGRN-dependent manner, avoiding the aggregation of the GCase [143]. Since PGRN could be considered as a co-chaperone, it was evaluated to increase the HexA activity in fibroblasts from TSD patients. The results showed that the G and E domains of the PGRN bind to HexA, increasing the enzyme activity and lysosomal delivery, and leading to a GM2 reduction in TSD fibroblasts [142].

7.4. Substrate reduction therapy.

Substrate reduction therapy (SRT) is a therapeutic strategy based on the partial inhibition of an enzyme involved in the synthesis of the accumulating substrate [144]. One of the molecules that have been evaluated for this purpose is N-butyldeoxynojirimycin (NB-DNJ), also termed Miglustat or Zavesca [145]. This is an iminosugar that inhibits the glucosylceramide synthase (GCS), which catabolize the first step of glycosphingolipid synthesis like glucosylceramide (Gaucher disease) [146], sphingomyelin (Niemann-Pick type C) [147], GM1 (GM1 gangliosidosis) [148] and GM2 gangliosides [149]. Miglustat is an oral drug able to cross the BBB, slowing the accumulation of gangliosides in neurons, and delaying the progression of neurological symptoms [144]. Miglustat has been evaluated in murine models of SD [150] and TSD [151] with promissory results regarding ganglioside storage reduction, the decrease of neurological symptoms, and the extension of lifespan. Subsequent studies evaluated the effect of miglustat in five patients with juvenile GM2 gangliosidosis in advanced disease stage over a period of 24 months, without improvement on the neurological impairment [152]. Likewise, Masciullo *et al.*, 2010 showed that a 3-years treatment with miglustat on an adult with chronic SD, did not arrest the neurodegeneration [153]. In this sense, implementation of miglustat in early disease stages should be assessed, to understand the therapy efficacy during early intervention.

Ashe *et al.*, 2011 evaluated the molecule Genz-529468, which has an IC_{50} 250-fold greater than miglustat [154]. Genz-529468 was administered to SD mice and the results were compared with miglustat-treated mice. The effect of each drug on brain GM2 levels was opposite. In this sense, whereas Genz-529468 increased GM2 levels to about 120% of untreated mice; miglustat decreased the GM2 levels to about 90% of untreated mice. However, levels of other brain glycosphingolipids, specially GL1, were dramatically increased with both inhibitors. The authors also reported similar results for both drugs in terms of the delayed loss of motor function and extended of the lifespan. In addition, mice treated with miglustat and Genz-529468 showed lower microglia activation and astrogliosis, and delay of neuronal apoptosis. These findings suggest that the use of inhibitors of GCS could improve the clinical outcomes due, at least in part, to their anti-inflammatory properties [4, 155].

Finally, Arthur *et al* 2013 reported the evaluation of EtDO-PIP2, a GCS inhibitor, on juvenile SD mice [156]. The intraperitoneal administration of EtDO-PIP2 to SD mice reduced the total content of brain and liver gangliosides, suggesting that it could be an interesting alternative for the treatment of ganglioside storage diseases with CNS manifestations.

7.5. Gene therapy.

Since GM2 gangliosidosis are monogenic diseases, the delivery of a functional gene should correct the genetic defect and lead to a normal physiological development [94]. In recent years, several strategies based on gene therapy have been developed for LSDs, including GM2 gangliosidosis [94, 95, 157, 158], which will be discussed below.

Usually, gene therapy uses recombinant viral vectors to deliver transgenes into specific tissues, from which the adeno-associated virus (AAV)-derived vectors have gained great attention during the last years [4]. Nevertheless, AAV can induce an immune response that can limit the efficacy of the therapy [159]. Therefore, new viral vectors have been engineered to modify the viral capsid and reduce the immune response [160, 161].

Several papers have described a variety of studies of gene therapy applied to the brain of small and larger animal models of GM2 gangliosidosis, mostly using AAV vectors [4]. Early gene therapy

studies for GM2 gangliosidoses were based on the intracranial co-administration of AAV1 or AAVrh8 vectors carrying the α and β subunits on SD mice [162, 163] or cats [84, 164–166]. These results showed a wide distribution of the enzyme through the brain, a significant increase in the life span, the reduction of GM2 ganglioside levels, and an improvement on motor functions [84, 162–166]. Moreover, treated SD cats showed an increase on the myelin-enriched cerebroside and a decrease in the microglial activation, suggesting an attenuation of the neuroinflammation [84, 165], which is an important physiopathology feature observed in GM2 patients [78, 85, 89]. As an alternative to the multi-vector injections, a self-complementary AAV9.47 vector was evaluated, which encoded for a hybrid μ subunit (HexM) that combine the α -subunit active site, the stable β -subunit interface, and unique areas of each subunit necessary for the interaction with the GM2AP [40, 163]. The results showed that HexM was able to reduce the GM2 ganglioside storage in thalamus, hypothalamus, and hippocampus; and led to an improvement on animal behavior [163].

During the last years, gene therapy studies for GM2 gangliosidoses have been included the evaluation on larger animal models and the design of bicistronic vectors. For instance, Golebiowski *et al.* 2017 evaluated the effect of an the intracranial administration of AAVrh8 vectors carrying the cynomolgus macaques Hex subunits (α and β) on non-human primates [167]. Although supraphysiological Hex activity levels were achieved in CNS; most of the treated animals showed altered neurological function represented by ataxia, general weakness, and lethargy; as well as histopathological findings suggestive of neurotoxicity [167]. These findings suggest a response not only against vector but also to the supraphysiological levels of Hex, which contrasts to the results observed in other species such as mice or cats. These aspects could be better resolved with similar preclinical testing but using validated non-human primates' models for GM2 gangliosidoses to understand the real therapeutic effect on species close to human.

Recently, Gray-Edwards *et al.*, 2018 used AAVrh8 vectors carrying the α and/or β subunits to evaluate the therapeutic effect of an intracranial injection in a TSD sheep model [86]. The treated TSD sheep achieved wild type or even supraphysiological levels of HexA activity and a decrease in disease progress. In addition, treated TSD sheep showed a normalization of accumulated gangliosides in most areas of the brain, except cerebellum and spinal cord where the storage did not change. Noteworthy, neuroinflammation was also attenuated after the treatment [86].

Novel approaches using bicistronic vectors have been developed [168]. As a proof-of-concept the bicistronic ssAAV9-HexBP2A-HexA vector was evaluated, which has a short P2A linker and the cDNA of *HEXA* and *HEXB* genes under the control of the chicken β -actin promoter [169]. A single administration of the vector into neonatal SD mice allowed a 56% extension of the lifespan compared to untreated animals. In addition, this vector allowed a significant increase in the enzyme activity and the reduction of GM2 gangliosides levels both in brain and serum [169]. Using similar bicistronic vector but with a bidirectional promoter to drive the transgene expression in opposite directions of the *HEXA* and *HEXB* subunits, recently Lahey *et al.*, 2020 found an increase the survival from 138 for untreated SD mice to more than 600 days in a dose-dependent manner after of IV administration of the vectors [41]. Improvement in the motor, strength, and coordination tests for treated animal to similar values observed in wild type mice was also observed. These promising findings were accompanied by increased levels of HexA and HexB enzyme activity in liver and CNS; as well as reduction in GM2 ganglioside storage in cerebrum, cerebellum, brain stem, and spinal cord of SD mice; which was correlated with a significant reduction of microglial activation in brain [41]. Finally, similar observations were reported for bicistronic lentiviral vectors carrying murine or human cDNAs encoding for the α - and β -subunits linked by a P2A linker. These lentiviral vectors led to a Hex activity up to 5-fold higher than wild-type levels in murine neurons and human stem progenitor cells, as well as a 30–60% reduction of GM2 storage. Similarly, in SD fibroblasts the total Hex and HexA activity increased in a 8:1 ratio, respectively [126].

7.6. CRISPR/Cas9-based gene therapy

Three major genome editing tools have been developed: zinc finger nucleases (ZFN), transcription activator-like effector nucleases (TALEN), and more recently, clustered regularly

interspaced short palindrome repeats/Cas9 (CRISPR/Cas9) [170, 171]. CRISPR/Cas9 uses an RNA-guide nuclease (sgRNA-Cas9) to induce double-strand breaks (DSB) into a specific locus of the genome [172, 173]. DSB can be repaired either through non-homologous end joining (NHEJ) or homologous direct repair (HDR) pathways [15]. On the first case, upon the DSB and on absence of a DNA template, the cellular repair machinery recruits several effectors such as Ku70/80, DNA-PKcs, Artemis, and DNA ligase IV that promote the binding of non-homologous ends in an error-prone mechanism. Through this mechanism is possible to induce deletions or insertions leading to insertional inactivation [174]. This approach is used to knock-out target genes, and has been used to generate *in vitro* and *in vivo* models of GM2 gangliosidosis [40, 73, 74]. DSB can also be repaired through the HDR pathway mechanism by using an exogenous DNA fragment as template (donor DNA), to mediate the insertion of the therapeutic DNA fragment on a specific locus (Figure 6) [171, 174, 175].

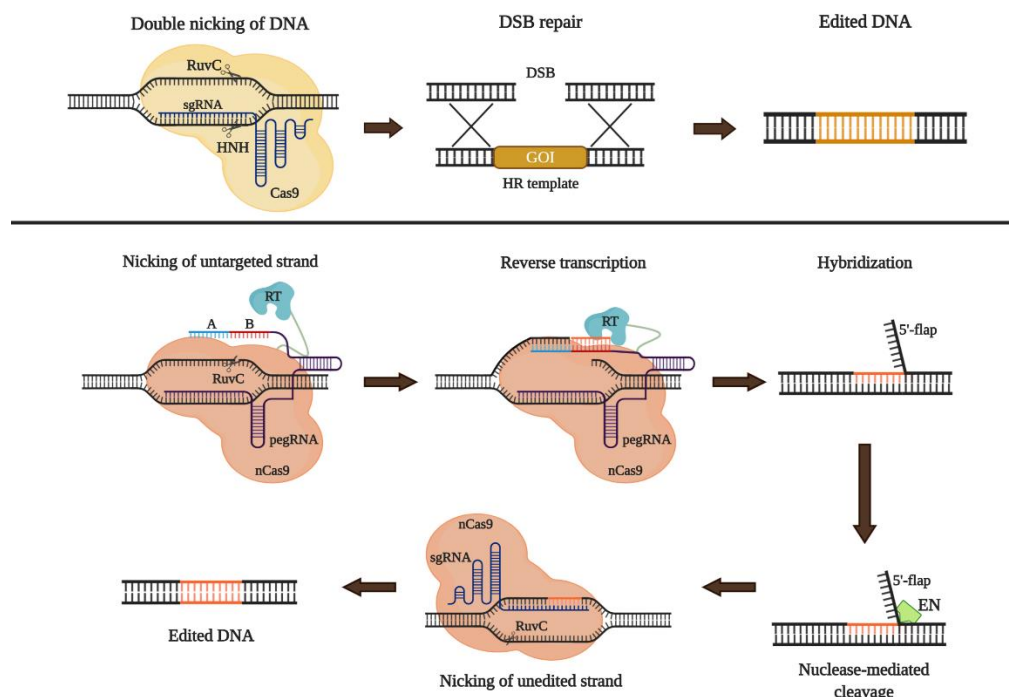

Figure 6. Approaches for genome editing using CRISPR/Cas9. The upper panel shows the classical strategy of knock-in using a ribonucleoprotein complex (sgRNA-guide Cas9) to guide to Cas9 to the target DNA and cut the double-strand (DSB). After the DSB, repair machinery is activated. In the presence of a donor sequence (**HR template**), homologous recombination is favored. To promote the recombination event of a gene of interest (**GOI**), the HR template must be flanked by homologous recombination arms which are complementary to the 5' and 3'-ends of the sequence into the gene that will be subject of edition. Typically, between 100-150bp and 400-800bp are suitable for small (< 50bp) and large (>100) insertions, respectively [176, 177]. In the lower panel, *Prime Editing* (PE) is represented. PE uses a nickase Cas9 (nCas9-H840A) fused to reverse transcriptase (**RT**) and a guide RNA (**pegRNA**) which is engineered with a sequence in the 5'-end. 20 nucleotides guide to nCas9 to the target DNA and a sequence in the 3'-end with a primer-binding site (**A**) as well as an RT template (**B**) that could be between 7 to 12 nucleotides [178]. Upon reverse transcription, newly synthesized strand hybridizes to the unedited strand (US) forming a mismatch and a **5'-flap** strand which is removed by exonucleases (**EN**) like EXO1 [179]. The mismatch is resolved with the introduction of a new nCas9 coupled to a simple sgRNA which guide to nCas9 to the edited strand (ES), about 50 bp from the pegRNA-mediated nick, to cut the US and use the sequence of the ES as a template for repair de simple cut [178]. In both cases upper and lower panels, newly edited DNA is successfully obtained with different efficiencies.

Although the punctual correction of each mutation could be interesting, in pathologies with hundreds of mutations, like GM2 gangliosidoses, this approach is not suitable. As a consequence, the knock-in strategy using safe harbors to introduce the cDNA into the genome draws more attention [180, 181]. Ou *et al.*, 2020 recently used the albumin locus for the intravenous administration of two AAV8 vectors: one carrying a promoterless HexM cDNA, and other one carrying the Cas9 gene and the gRNA [182]. This approach allowed the constitutive expression of the HexM under the control of the albumin promoter. Four-months post-treatment, the enzyme activity increased in plasma, heart, liver, spleen, and brain, compared to untreated SD mice. This increase in the HexM activity correlated with the decrease of the GM2 ganglioside in liver, heart, and spleen. On the other hand, neither a decrease of GM2 ganglioside in the brain nor positive changes on behavioural tests (fear conditioning and pole test) were observed as a result of the treatment [182]. Despite the above, a significant improvement motor function was observed in treated SD mice compared to untreated animals suggesting a slight therapeutic effect on the CNS. Overall, these results show that although this strategy must be optimized, the insertion of HexM gene into hepatocytes is an alternative to reach supraphysiological levels of the enzyme, particularly in the brain, where typical strategies such as ERT fails due to the inability to cross the BBB [13]. Since new epitopes can be generate from HexM, immune tolerance regimens must be also considered [41].

Despite HDR is the main approach used in CRISPR/Cas9-mediated genome editing, novel strategy without DBS or donor DNA, termed prime editing, was recently described [96, 183]. This tool uses a nickase Cas9 (H840A) fused to reverse transcriptase (RT) and a short engineered RNA sequence (prime editing guide RNA-pegRNA) [178]. The pegRNA is designed to function as a guide of Cas9 to the target DNA and serve as the template for a RT-mediated retrotranscription, avoiding the need of a DNA donor [183, 184]. An additional sgRNA-Cas9 is necessary to nicking the unedited strand and promotes the final correction using the edited strand as a template, in a process that occurs only after the edition and avoiding the generation of DSB [178, 184] (Figure 6). Using this strategy, Anzalone *et al.*, 2019 recreated in HEK293T cells a 4-bp insertion in *HEXA* gene (1278+TATC), which is associated with TSD, with high efficiency (31%) and low indels (0.8%). The cells were then correct using the prime editing strategy, thorough the evaluation of 43 pegRNA and three sgRNA. Nineteen pegRNAs showed edition efficiencies higher than 20% and lower indels 0.32% [178], suggesting that this novel strategy could be a new therapeutic approach for the treatment of GM2 gangliosidoses without the need of DSB or donor template.

8. Conclusions and Perspectives

During the last years significant advances have been done to understand the physiopathology and natural history of GM2 gangliosidoses. For instance, natural history programs have allowed to identify the shared and specific manifestations of each disease and phenotype (infantile/acute, juvenile/subacute, and adult/chronic), which represent valuable information to improve the diagnosis and patients follow up. However, important efforts still need to be done in order to include a wider number of patients with different genetic backgrounds, since most of the studies have been carried out in specific populations (e.g. clinicaltrials.gov NCT01869270, NCT02851862, NCT00668187, NCT03333200, and NCT00029965).

On the other hand, although gangliosides remain as the main compounds responsible for neuron homeostasis alteration, neuroinflammation and demyelination have also shown to play an important role in disease progression. In addition, the presence of anti-ganglioside autoantibodies, progressive accumulation of α -synuclein, and impaired autophagy, are elements that have been also associated with the disease process [4]. In this sense, as observed in other LSDs [185], it is possible that a single therapeutic strategy would not be enough to treat GM2 gangliosidoses patients and that the co-administration of different therapies may be required. Noteworthy, different therapeutic strategies, including ERT, gene therapy, pharmacological chaperones, HSCT, and substrate reduction therapy, have shown promising results and some of them have reached clinical phases (Table 2). In addition, the National Tay-Sachs, and Allied Diseases (<https://ntsad.org/>) announced the beginning of gene therapy clinical trials for GM2 gangliosidoses. Although the use of CRISPR/Cas9 is still on its initial

stages, the first pre-clinical studies have shown the potential of this tool in the design of novel gene therapy strategies.

Finally, epigenetics should be also considered in GM2 gangliosidoses. Although the role of epigenetic mechanisms in lysosomal diseases has not been well established, it has been proposed that these mechanisms may contribute to the clinical heterogeneity observed in these disorders [186]. However, to the best of our knowledge, no studies on this field has been performed for GM2 gangliosidoses. The understanding of the epigenetic alterations observed in GM2 gangliosidoses patients may represent an opportunity to the develop of novel treatment alternatives [187].

Table 2. Clinical trials for GM2 gangliosidoses reported at Clinicaltrials.gov by June 2020.

Therapy	NCT Number	Intervention	Status	Phase	Country
Pharmacological Chaperone	NCT00679744	Pyrimethamine	Withdrawn	Phase 1	USA
	NCT01102686	Pyrimethamine	Completed	Phase 1/2	Canada
Substrate Reduction Therapy	NCT00418847	Miglustat	Completed	Phase 2	Canada
	NCT03822013	Miglustat	Recruiting	Phase 3	Iran
	NCT00672022	Miglustat	Completed	Phase 3	USA
	NCT04221451	Venglustat	Recruiting	Phase 3	USA
	NCT02030015	Miglustat and ketogenic diet	Recruiting	Phase 4	USA
	NCT01372228	Enriched hematopoietic stem cell infusion	Active, not recruiting	Phase 1/2	USA
HSCT	NCT00176904	Chemotherapy and hematopoietic cell transplantation	Completed	Phase 1/2	USA
	NCT01626092	Chemotherapy, total body irradiation with marrow boosting and Hematopoietic stem cell transplantation	Completed	Phase 1/2	USA
	NCT00383448	Chemotherapy, total body irradiation and Hematopoietic stem cell transplantation	Completed	Phase 2	USA
	NCT02254863	UBC-derived oligodendrocyte-like cells	Recruiting	Phase 1	USA
Umbilical Cord Blood Transplantation (UBC)	NCT01003912	Fetal UCB transplantation	Withdrawn	Phase 1	USA

	NCT00654433	UBC cells expressing high levels of the intracellular enzyme aldehyde dehydrogenase	Terminated	Phase 3	USA
Cerebellar ataxia treatment	NCT03759665	N-Acetyl-L- Leucine	Recruiting	Phase 2	USA

Author Contributions: A.F.L., E.B.F., D.S.G, R.G., O.Y.E., and D.A.S wrote the original draft. A.F.L., C.J.A.D., A.J.E.M, reviewed and edited the manuscript. All authors contributed to the literature analysis. All authors have read and approved the final manuscript.

Funding: C.J.A-D and A.J.E.M are supported by the Ministry of Science, Technology and Innovation, Colombia (Grant ID 120380763212 – PPTA # 8352) and by the Pontificia Universidad Javeriana (PPTA # 8275). A.F.L. received a doctoral scholarship from Pontificia Universidad Javeriana. D.S.G., R.G., and D.A.S received a young researcher fellowship (Contract 829-2018 – PPTA #8728 and #8729) from the Ministry of Science, Technology and Innovation, Colombia.

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the review.

Abbreviations

AAV	Adeno-associated virus
Ab	Antibodies
AIR	Adaptative immune response
AOD	Apoptotic oligodendrocytes
AP	Apoptosis
BBB	Blood brain barrier
Cas9	CRISPR associated protein 9
CK	Cytokines
CNS	Central Nervous System
CRISPR	Clustered Regularly Interspaced Short Palindromic Repeats
DMSO	Dimethyl sulfoxide
DOAJ	Directory of open access journals
DSB	Double-strand break
ECC	Extracellular compartment
EE	Early endosome
ERT	Enzyme Replacement Therapy
FDA	Food and Drug Administration
GAG	Glycosaminoglycans
GCS	Glucosylceramide synthase
GluCer	Glucosylceramide
GM2-AP	GM2-activator protein
GT	Gene therapy
GVHD	Graft-versus-host disease
HDR	Homologous direct repair
Hex	Hexosaminidase
HLA	human leukocyte antigen
HSCT	Hematopoietic Stem Cell Transplantation

ICC	Intracellular compartment
IIR	Innate immune response
iPS	Induced pluripotent stem
LacCer	Lactoceramide
LD	Linear dichroism
LSD	Lysosomal Storage Disorders
M6PR	Mannose-6 phosphate receptor
MDPI	Multidisciplinary Digital Publishing Institute
MPS	Mucopolysaccharidosis
MUG	4-methylumbelliferyl-N-acetylglucosaminide
MUGS	4-methylumbelliferyl-beta-D-N-acetyl-glucosamine-6-sulfate
NHEJ	Non-homologous end joining
OD	Oligodendrocytes
PC	Pharmacological Chaperones
PGRN	Progranulin
PS	Phosphatidylserine
PYR	Pyrimethamine
RER	Rough endoplasmic reticulum
SD	Sandhoff disease
SRT	Substrate Reduction Therapy
TGN	Trans-Golgi network
TSD	Tay-Sachs disease
