**Abstract:** We present the hardware of a cheap multi-sensor magnetometric setup, where a relatively large set of magnetic field components is measured in several positions by calibrated magnetoresistive detectors. The setup is developed with the scope of mapping the (inhomogeneous) field generated by a known magnetic source, which is measured as superimposed to the (homogeneous) geomagnetic field. The final goal is to use the data produced by this hardware to reconstruct position and orientation of the magnetic source with respect to the sensor frame, simultaneously with the orientation of the frame with respect to the environmental field. Possible applications of the setup are shortly discussed, together with a synthetic description of the data elaboration and analysis.

**Keywords:** Tracking; Magnetic tracker; Magnetoresistor; Magnetic Sensor; Sensor Array; Microcontroller; Eye Motion.

## Introduction

Magnetic field measurements can be performed with a variety of sensors, whose sensitivity, robustness, dynamic range, linearity, reliability, speed, simplicity, and cost range in very broad intervals. The state-of-art sensors in terms of sensitivity are based on the superconductor quantum interference devices (SQUIDs) that surpass the sensitivity level of  $1\text{fT}/\sqrt{\text{Hz}}$ . The main drawback of SQUIDs is the need of cryogenics. Optical atomic magnetometry constitutes another technology that in some implementations – particularly in the so called Spin-Exchange-Relaxation-Free (SERF)– may compete with SQUIDs in terms of sensitivity. It enables also the construction of relatively simple and robust sensors with sensitivity at the  $\text{pT}/\sqrt{\text{Hz}}$  level and below, including miniaturized devices, and implementations with a high-frequency response. Optical atomic magnetometers (OAMs) do not require cryogenics. On the other hand, they are based on spectroscopy in high quality vapour cells and commonly lighted with laser sources, both features making them expensive and not easily integrable in solid state devices. When these extreme performances are not required, fluxgate technology offers an eligible alternative, on the basis of which different grades of sensors are produced with a rather wide range of sensitivities and costs. When sensitivities of the order of  $\text{nT}/\sqrt{\text{Hz}}$  are sufficient, beside low cost fluxgate sensors, the solid-state technology offers nowadays extremely cheap and easy-use devices based on the magnetoresistive effects. The magnetoresistive effect (discovered and formerly studied by lord Kelvin [1,2]) in its giant [3], tunnel [4], and anisotropic [5] occurrences is profitably used to measure fields of several tens of micro Tesla, i.e. of the order of the geomagnetic field, with typical sensitivities in the  $\text{nT}/\sqrt{\text{Hz}}$  range and bandwidth extending up to kHz, or –depending on the implementation– to

MHz and beyond [6]. Devices based on magnetoresistance (MR) with sensitivity levels attaining the  $\text{pT}/\sqrt{\text{Hz}}$  above 1 kHz have been reported [7]. The magnetoresistive sensors (similarly to SQUIDs and fluxgates, and in contrast to typical OAM magnetometers) are vectorial in nature, i.e. respond to single components of the magnetic field: an assembly of three orthogonally oriented sensors enables a complete measurement of the magnetic field vector. Other popular solid state sensors are based on the Hall effect, their sensitivity and accuracy is worse than MR and they are more commonly used to roughly estimate (or rather just to detect) relatively strong fields. A synthetic, rough overview of the available technologies and of the accessible bandwidth and sensitivity intervals for magnetometric measurements is provided in Fig.1

The success of MR technology is also related to its easy integration with silicon-based electronic devices. Integrated circuits (ICs) containing one or more magnetoresistive elements became recently very popular, and their cost decreased by order of magnitudes in the last decade thanks to large-scale production: nowadays two- or three-axis devices are widely used as sensors for electronic compasses, such as those contained in smartphones and drones. Other applications of these cheap sensors include virtual and augmented realities, navigation, non-destructive evaluation, and various industrial activities [6,8,9]. Modern MR ICs contain not only magnetoresistive sensors but also signal conditioning and DAQ electronics, together with special reset circuits that facilitate the MR use and improve reliability and reproducibility of their response, as well as circuitry for digital data transfer.

We concentrated our attention on a family of ICs designed for inter-integrated-circuit ( $I^2C$ ) protocol transmission of 3D magnetic data, which allow for an acquisition and data transfer rate as fast as 200 readings (3 data per read) per second. Due to the typical presence of a single sensor per user, in most cases these ICs have a static, not reconfigurable  $I^2C$  address. Some devices have indeed reconfigurable address. In the case of the IC used in our prototypes, two address configuration pins (for a maximum of four chips per bus) are available. This limitation leads, when a sensor array is needed, to develop control-interface circuits with a parallelized architecture. At a cost of the obviously heavier circuitry, such an approach brings the second (but not secondary) advantage of accelerating the data acquisition and making it simultaneous all over the sensor set.

The aim of our work is to acquire at a relatively high rate (hundreds samples per second) magnetometric data sets that can be elaborated to reconstruct the position of magnetic field sources, i.e. to track their spatial co-ordinates and the angles of their orientation. In the frequent case of a simple source like a magnetic dipole [10–12], the tracking procedure does provide three spatial coordinates and three components of the magnetic dipole. As soon as the measurement is performed in an external field (such as the geomagnetic field, which can be assumed homogeneous over the volume of the sensor frame), three more field components have to be worked out, that is a total of  $6 + 3 = 9$  tracking data to be extracted per measurement. These 9 data contain redundant information in the case of repeated measurements, because both the modulus of the dipole moment and the modulus of the ambient field can be assumed constant. In other terms, rotations of the dipole around its direction and rotations of the sensors around the ambient field do not cause field variations: those rotations correspond to *blind co-ordinates*. In other terms, in the assumption that the intensity of the magnetic source and/or of the environmental field are constant, the number of freedom degrees (and hence of the fit parameters) would be reduced from 9 down to 8 or 7.

The information about the two blind co-ordinates could be retrieved by using a non-dipolar source (e.g. a set of two rigidly connected dipoles) and complementing the environmental magnetic field with a measure of the gravitational field. In this paper, we will not address these possible improvements. The use of non punctual sources, with the introduction of multipolar terms that break the dipole-symmetry has been successfully attempted and reported in the literature [13].

Similarly, the system could be used to track two or more dipolar sources arbitrarily located with respect to each other [14,15]. In this case, the enhancement in the source degrees of freedom would require more computing resources and an increase of the minimum number of sensors.

The capability of tracking objects with adequately fast time response is a challenging and intriguing achievement, with important implications in several research and application areas. In particular, tracking methods based on magnetometric measurements offer a minimally invasive methodology and has been studied/proposed in a variety of applications, including medical diagnostics [16] tracking of vehicles [17], biology [18], and robotics [19].

Further possible applications may arise in diverse other areas, also depending on the precision and the speed that can be achieved, like body part tracking (such as eye, tongue, hand, finger), human-computer interfaces, virtual and augmented reality, etc..

Several approaches have been proposed to face the inverse problem of reconstructing the field source parameters from the field measurement (see e.g. ref. [20] and references therein). Depending on the application, required accuracy, precision, robustness and speed of the tracking procedure may change, and different methodologies can be applied.

## 1. Setup overview

We have designed and built an interface circuit capable of operating arrays made of up to eight three-axis MR sensors, which can be variously disposed and grouped in the space. A picture of a sensor array and interface electronics is shown in Fig.2. A PCB hosting micro-controller, eeprom memories, internal and external supply circuitry and USB interface is connected to two sensor boards, which can host 4+4 or 5+3 IC sensors (as in the case shown in that figure). Each sensor has a dedicated I<sup>2</sup>C bus for communicating with the micro-controller. The latter may send commands (and receive data) simultaneously to (from) the eight sensors. The data can be either immediately transmitted to the computer or stored into an eeprom memory for successive download. The second option is used in the calibration procedure (see Sec.4 below). Details of the available functionalities and consequent possible operations are provided in the next sections. These are designed in view of producing fast (real time) tracking devices with a high throughput rate (hundred trackings per second) and precision (submillimetric spatial and 2 degree angular resolutions).

## 2. Sensor specifications

The Isentek IC 8308 [21] is a three axis magnetometer based on anisotropic magnetoresistance effect, whose main characteristics are reported in Tab.1. The chip implements reset, temperature compensation and analog-to-digital conversion circuitry, and communicates through an I<sup>2</sup>C port. Both on-demand and continuous data outputs can be queried. The maximum data acquisition rate is 200 Sa/s, and different kinds of internal filters can be activated to improve the the S/N ratio at expense of the actual bandwidth. Sensitivity and offset have non-negligible deviations from ideality so that a calibration is necessary (see Sec.4). These parameters may also change with time and (slightly) with temperature, so that an adequate measurement accuracy can be kept at the cost of repeated calibrations. It is worth noting that the temperature compensation circuitry helps reducing this problem since the effects of typical daily environmental temperature drifts can be neglected. In our implementation, a temperature sensor has been included, so that the user knows both the temperature at which the calibration data were collected and the current temperature: when the deviation exceeds a threshold level, an alert is provided, making a new calibration advisable. A data-consistency analysis is also available to point out the need of recalibrating the unit, as discussed at the end of Sec.4.

**Table 1.** The IC IST 8308 main features and characteristics.

Parameter	Value	Units
sensitivity drift with temperature	0.023	°C
sensitivity drift with temperature	0.023	% / °C
zero-field offset	300	nT
offset drift with temperature	27	nT/°C
dynamic range	500	μT
linear response	200	μT
nonlinearity/FS	$< 10^{-3}$	-
range (FS)	200 or 500	μT
hysteresis/FS	$< 10^{-3}$	-
supply voltage	3.3	V
size	$3 \times 3 \times 1$	mm <sup>3</sup>
adc resolution	14	bit
max output data rate	200	Sa/s
max I <sup>2</sup> C clock	400	kHz

### 3. Scalability

The system developed aims to measure simultaneously the environmental field and the field generated by a small, closely located magnetic source (dipolar magnet). The finite dynamic range of the sensors makes necessary to deal with fields contributions of comparable intensities. This condition should be fulfilled at least on a sensor subset providing a number of independent data sufficient to localize the magnet, i.e. not smaller than the number of freedom degrees of the system.

Good operating conditions can be identified as those in which the dipole generates on the sensors fields ranging from 1/10 to 10 times the ambient one. So, keeping in mind the environmental field normal value of some tens of μT, the  $1/r^3$  dependence of the dipolar field, and the typical magnetization values of permanent magnets (about  $1T/\mu_0$  for the used Nd devices), one finds that the best condition is fulfilled when the sensor-magnet distance is about 50 times larger than the linear size of the magnet. E.g., a one cm<sup>3</sup> magnet produces a field comparable to the Earth one at about a half-meter distance. The chip size being sub-millimetric, this thumb rule applies when scaling down the system size as long as the sensor-magnet distance still remains much larger than the sensor size (e.g., magnets as small as 1 mm size can be used at a distance of about 5 cm from the sensors).

Of course, accordingly to the required tracking accuracy, the sensor positions must be known with an adequate precision. In our case, the latter is determined by the PCB mount and is submillimetric. However, the determination of the sensor positions can be improved on the basis of magnetometric data analysis [22], and in some of our preliminary prototypes such kind of procedure resulted to be crucial to guarantee the reliability of the tracking algorithms.

### 4. Sensor calibration

MR sensors have a relatively accurate response in terms of linearity, but suffer from important offset and variable gain. Moreover both gain and offset may vary with temperature and change in time. In addition, unpredictable values are found after powering up the device.

An important improvement has been introduced on the basis of a pulsed field cycling technique. This technique of reset field pulses has been also studied to improve the ultra-low frequency performance of MR devices [23]. Modern magnetoresistance ICs contain apposite inputs to apply reset pulses (strong current pulses flow in a conductor built in the proximity of the magnetoresistive element, in order to re-magnetize its components in an appropriate and reproducible way).

In more integrated devices the current pulses are produced internally and the reset field cycle is automatically applied at the restart. The reset operation brings the sensor to work properly (reasonably low offsets and reasonably ideal gains along all the axes); nonetheless whenever good accuracy is required, some calibration procedure [24] is advisable or necessary. In fact, the final offset value is substantially non-zero, and the gain may differ by several percents among the sensors contained in a

single IC. An accurate evaluation of the offsets and gains makes it possible to convert the raw data into field measurements, so to overcome these non idealities.

Our setup includes in the hardware, in the firmware, and in the software apposite parts devoted to facilitate the calibration procedure. Similarly to what described in Ref.[24], the calibration procedure is accomplished by recording many data (simultaneously for all the 3D sensors of the array), while rotating the system freely and randomly in a (nominally) homogeneous field. In this measurement, each sensor feels the magnetic induction vector  $\vec{B}$  as it moves on a spherical surface centered in the zero-field point of a Cartesian co-ordinate system: whenever the measured quantities  $\vec{V}$  does not span a spherical surface, this can be due to non-zero offsets, to unequal gains, and to non-linear terms in the sensors' response. In the hypothesis of a linear response, the measured quantities describe an off-center ellipsoid rather than a centered spherical surface: the displacement of the center is then caused by the offsets, while the eccentricity is due to the gain anisotropy.

It is worth noting that similar calibration procedures based on static measurements have been proposed, as well. It is indeed possible to build up a tri-axial field generator, finely calibrate it with the help of a scalar magnetometer and then use it to produce a rotating field of an assigned intensity. The latter can be, in turn, applied to calibrate vectorial sensors such as triaxial magnetoresistive devices [25].

An optimization procedure is used to determine offsets and gains for all the sensors, and to save those values for successive data conversion. As described below (see Sec.5), this kind of calibration measurement is more favourably performed with no cable connection. The optimization is usually done over data sets containing several hundreds measurement (a maximum of  $N=2000$  measurements is set by the eeprom memory size), and the minimized quantity being

$$f = \sum_{i,j,k,n} \left[ B_0^2 - \left( T_{ij}^{(k)} (V_{j,n}^{(k)} - O_j^{(k)}) \right)^2 \right]^2, \quad (1)$$

where  $k$  is the sensor index running from 0 to  $K-1$ ,  $O_j^{(k)}$  are the offset vectors to be determined,  $T_{ij}^{(k)}$  are elements of triangular matrices (to be determined),  $n$  denotes the measurement index (running from 1 to  $N$ ), and  $B_0$  is the field modulus. The latter can be assigned arbitrarily, or from an independent measurement performed by scalar sensor (e.g. an atomic magnetometer) if quantitative field and dipole-moment estimations are required.

The elements  $T_{ij}^{(k)}$  are ideally equal for  $i=j$  (the inverse gains), while the off-diagonal elements are ideally zero for  $i > j$ . In contrast, the diagonal element can be different from each other if the gain is not isotropic, and the off-diagonal element could be non-zero, in the case of possible small misalignments (imperfect orthogonality) of the three axes.

Let the optimal offsets and conversion matrices be given by  $O_j^{(k-opt)}$  and  $T_{ij}^{(k-opt)}$ , respectively, and let's define

$$B_{i,n}^{(k)} = \sum_j T_{ij}^{(k-opt)} (V_{j,n}^{(k)} - O_j^{(k-opt)}) \quad (2)$$

that is the  $i^{th}$  component of the field in the position  $\mathbf{r}_k$  of the  $k^{th}$  sensor, as obtained from the sensors output  $V_j$  in the  $n^{th}$  measurement.

Once the offsets are removed and the response has been made isotropic, further calibration is necessary to refer all the sensors to one co-ordinate system. To this aim, the data recorded in the mentioned calibration measurement are compared to each other. One sensor (let it be the  $0^{th}$  one) is selected as a reference one, and a rotation matrix is determined for each sensor with  $k = 1 \dots K-1$ , by minimizing the vector differences between the field measured by that sensor and the reference one. In our implementation the rotation matrices are defined in terms of Euler angles, and the minimized quantities are:

$$g = \sum_{i,j,n} \left( B_{i,n}^{(0)} - R_{i,j}^{(k)} B_{j,n}^{(k)} \right)^2, \quad (3)$$

where  $R_{i,j}^{(k)} = R_{i,j}(\theta^{(k)}, \phi^{(k)}, \psi^{(k)})$  are rotation matrices defined by the three angles  $\theta^{(k)}, \phi^{(k)}, \psi^{(k)}$  to be determined for each  $k = 1 \dots K - 1$ .

In conclusion, each of the  $K$  sensors requires the determination of nine parameters (three offsets, three gains, three orthogonality-imperfection-compensation terms) for the conversion of the recorded values  $\vec{V}^{(k)}$  into magnetic induction vectors  $\vec{B}^{(k)}$  and each sensor (apart from the reference one) requires the determination of three rotation angles. The whole set of  $m = 9K + 3(K - 1)$  calibration parameters ( $m = 93$  in the considered case of  $K = 8$  sensors) is saved at the end of a calibration procedure and made available to perform the  $\vec{V} \rightarrow \vec{B}$  conversions in the subsequent measurements.

Once the calibration parameters have been determined, a field estimation referenced to a unique Cartesian frame is available. This enables an additional procedure to check the validity persistence of the calibration parameters. This validation is performed by comparing the field components measured by the  $K$  sensors in homogeneous field with their median value. In particular, the software evaluates, for each sensor, the quantity

$$E_k = \frac{1}{N-1} \sum_{n=1}^N \sum_{i=1}^3 (B_{k,n,i} - \tilde{B}_{n,i})^2, \quad (4)$$

where  $B_{k,n,i}$  denotes the  $i^{th}$  component of the field as measured by the  $k^{th}$  sensor at the  $n^{th}$  measurement in a set of  $N$ , and  $\tilde{B}_{n,i}$  denotes the median value of the  $i^{th}$  component of the field measured by the  $K$  sensors at the  $n^{th}$  measurement. The presence of anomalously large  $E_k$  values produces an alert, and the user can disregard the data from the corresponding sensor(s) in the subsequent tracking, or decide to execute a new calibration.

## 5. Power supply

The circuit is normally supplied through the USB port, however it is possible to start it in a battery-supply mode, in order to acquire and store the calibration data with no cable constraints. To this aim, there is a button connecting the battery, and a button starting the calibration measurement. When the calibration measurement starts, a circuit maintains the battery connection. During this self-supplied operation, a flashing LED denotes the acquisition. At the end of the acquisition, the self-supplied mode is maintained for a 30 s, during which the operator can connect the cable. In this manner, the circuit remains supplied, and no reset pulses are applied. This feature is designed to guarantee that the acquired data accurately describe the sensor response, since the latter could be modified in the case of a ICs reboot, due to the automatically applied reset pulses.

## 6. Parallel I<sup>2</sup>C buses

Apart from the problem arose from the fixed I<sup>2</sup>C address (a feature that characterize many MR IC types) it is advantageous to parallelize the communication with sets of ICs, both to accelerate the global data acquisition rate and to enable simultaneous (i.e. mutually time-consistent) measurements. We have studied and developed a simple, but effective circuit enabling both parallel data reading from the sensors and fast composite data transmission to PC. The developed electronics may communicate (for hardware configuration and for data transfer) with eight ( $K = 8$ ) chips at once, providing thus up to  $K \times 3$  magnetometric data per reading. The data transfer rate is limited either by the sensor throughput rate over the I<sup>2</sup>C bus or by the composite data transmission rate over the USB port: in the present implementation a rate as large as 100 Sa/s (2400 data/second) has been demonstrated, while a 200 Sa/s (4800 data/second) is the limit set by the IC specifications. Concerning the USB communication, it is a potential bottle neck. It is machine dependent and may vary unpredictably e.g. with the number of processes running in the computer, and particularly with the presence of other connected interfaces.

## 7. Firmware

An overview of the firmware principle of operation is represented in Fig.3. When the system starts up, the peripherals of the microcontroller are configured and the variables used (MCU Init) are initialized. In particular, among the configured peripherals, it is worth mentioning the ADC converter which measures the supply voltage and the timer for the real time operating system (RTOS) described below. In addition, a map of the sensors that are actually connected is built. The latter is then used when the data are transferred from the parallel I<sup>2</sup>C buses to the on-board memory or to the USB interface, as described in Sec.6.

Subsequently a test is performed to verify if the system has been started by connecting the USB cable or by pressing the power button: in the second case a switch (mosfet transistor) is closed, to maintain the battery power supply when the power button is released by the user.

At the same time it is evaluated whether the system calibration button (P0) was also pressed during the power-up phase; in this case a flag variable called *cal\_Flag* is set to True. This flag is used during the operation of the RTOS. The next operation (Sensor Init) is the initialization of the sensors that have been detected and included in the sensor map.

Now the RTOS can start. A scheduler rules the execution sequence and times of the various programs (tasks) within an iterated cycle. During this cycle it is evaluated –for each task– whether it is time to run it on the basis of the time elapsed after the last execution: individual time intervals are defined for each task.

The tasks to be performed are:

- Reading the state of the buttons (Read buttons) (every 5 ms)
- Granting communication between the module and the PC via an USB interface (USB) (every 10 ms). If the buffer contains a character, this is added at the end of a string variable. If this character is a line termination character, the string variable is analyzed by a subroutine (Parser) and, if it is recognized as a valid command, such command is executed.
- Performing other operations (every 1 s). These operations consist in testing whether the USB cable has been connected then disconnecting the battery from the system to prevent unnecessary discharge; if, during a calibration procedure, the P0 button is pressed, the system is switched off; the same thing happens after a preselected period of time following the end of the system calibration.
- Reading the MR sensors: the period is determined by the *Conv\_rate* or *Cal\_rate* variable
- Reading the temperature sensor (every 100ms)

The flowcharts of two significative tasks are represented as an example in Fig.4

## 8. Data transfer

The data transfer can be performed both in ASCII format (useful for debugging) and in binary format. The measurement can be executed both one by one (on demand) and continuously. In the second case, a "start-conversion" command is sent, and a continuous data flux is transferred (the DAQ rate has been previously set and can be as large as 200 Sa/s) until a "stop-conversion" command is sent. In these conditions the binary transmission is compulsory to prevent data overflow. A peculiar transmission protocol has been designed to detect transmission errors. As seen in Sec.2, the data are signed two-byte integers. However, the 14 bit resolution makes impossible that some values are generated. We use this feature to implement a one-byte transmission check. The values are transmitted after having been added to  $2^{14}$  (so to make all of them positive) and after having doubled the result (so to make all the data values even). Under this condition, neither the most significant byte nor the least one can be "FF", and such *reserved* "FF" value is used as a end-of-line marker in the USB communication. The received data are then truncated at the "FF" byte, and the whole data set is disregarded whenever "FF" does not occur after  $K \times 3 \times 2$  significant bytes. This features improves the system reliability, making it robust with respect to data-transfer misalignments.

## 9. Data elaboration

The computer program that controls the device is written in LabView. It contains several units designed to

- Initialize the communications
- Select the sensor settings (dynamical range, filters, acquisition rate)
- Check the temperature
- Download the raw calibration data from the eeprom
- Analyze the calibration data and infer the conversion parameter set
- Start the measurement
- Convert the raw data into magnetic values
- Analyze the magnetic data to track the magnetic source
- Show and save the tracking output

The first operations are made at the start or on demand, while the last two tasks are performed online and require accurate programming to prevent data overflow with consequent lost data or delayed system response. Particular care must be devoted to the data analysis program that infers the magnet position and orientation from the magnetometric measurement. Details about this problem will be extensively provided elsewhere, while here we shortly summarize the methodologies applied to this aim.

The software implemented to extract tracking data from magnetometric data is based on a standard best-fit procedure using a Levenberg Marquardt algorithm [11,26–28]. The input data are the magnetometric values and a set of sensor co-ordinates, and the best-fit procedure uses a model with the field of an arbitrarily located and oriented dipole field superimposed to a homogeneous field. The fit output consists of 9 values representing three spatial co-ordinate of the dipole, three dipole moment components, and three background field components (we are neglecting the redundancy mentioned in the Sec.). The need of determining 9 co-ordinates makes evident that the thumb-rule discussed in Sec.3 should apply for at least three 3D sensors, with obvious advantages in terms of accuracy and reliability when a larger number of sensors are close enough, as to detect the inhomogeneous field generated by the dipole. Assuming that the magnet moves slowly with respect to the acquisition rate, every fit output is profitably used as a guess for the next evaluation [14]. As known, a reliable guess helps greatly accelerating the convergence of non-linear functions as those used in the present case.

To date, a last-step-output guess has proved to work efficiently in tests with sources moving at a speed of a few cm/s and rotating at a few rad/s. More advanced guessing, based on the analysis of a longer tracking history, could be developed for faster magnetic sources and will be assessed in future work.

We verified that an ordinary personal computer with a single last-track guess, is capable to run the best-fit procedure in a time shorter than the 10ms acquisition time, so to provide an estimation of the dipole position and orientation before that a new data set is acquired, thus getting substantially a real-time functionality.

## 10. Results

In this section, we report few examples of tracking results obtained with the described system and a preliminary characterization of its performance. All these data are obtained with a Nd magnet 0.5 mm in thickness and 2 mm in diameter as a dipolar source, using the prototype shown in Fig.2. In this case (as visible in Fig.2) the array contains 3+5 sensors on two parallel PCBs displaced by 16 mm from each other, along the  $z$  direction. Hereafter the  $z$  positions are referred to the 3-sensors PCB, i.e. the  $xy$  plane is defined as that containing that PCB, while the 5-sensors PCB lays on the  $z = 16$  mm plane. The magnet can be slowly driven by means of a gearmotor to follow a circular trajectory 10 mm in radius around the  $z$  direction.

The Fig.5 shows a reconstructed trajectory as it is obtained with the sensor array in static condition and the dipole (which is oriented radially) that rotates on the  $z = 26$  mm plane.

The Fig.6, upper plot, shows a reconstructed trajectory obtained with the magnet performing a similar circular trajectory on the  $z = 29$  mm plane. This time, the sensor array, which are rigidly assembled with the magnet driver, is held in hands and moved freely to test the robustness of the measurement with respect to the reorientation in the environmental magnetic field.

The motion applied to the assembly is approximately a rotation (about one turn back and forward) around the  $x$  axis. In this case, the system measures the environmental field with significantly changing components, whose values are represented in the middle plot of Fig.6, as evaluated along the tracking procedure. Finally, the bottom plot shows the corresponding time evolution of the position co-ordinates. The figure proves that the reconstructed trajectory is negligibly disturbed by the array motion. The experiment is performed in a "normal" room containing furniture with ferromagnetic frames, computers, and other sources of potential magnetic interference.

Preliminary quantitative estimates of the position uncertainty are based on the variance of the detected 3D position: in static condition, we measure a RMS  $\sigma_r = (\sigma_x^2 + \sigma_y^2 + \sigma_z^2)^{1/2}$  of 131  $\mu\text{m}$  when the magnet is held still on the  $z$  axis, at  $z = 27$  mm. In these conditions, the relative RMS of the measured environmental field and of the dipole modulus are respectively is  $\sigma_B/B = 0.25\%$  and  $\sigma_m/m = 0.77\%$ .

The same kind of estimation, performed when the assembly is hand-held and freely rotated, gives  $\sigma_r = 270 \mu\text{m}$  and  $\sigma_m/m = 1.7\%$ . In synthesis, the position tracking is robust and submillimetric both when the array is kept static and when it is randomly reoriented with respect to the environmental field. The small variance of the dipole modulus estimations indicates that the system has a good robustness with respect to ambient field variations. In addition, the environmental field inhomogeneities typical of normal working rooms do not constitute a problem. On the contrary, the tracking system fails when magnetized devices approach too closely the sensor array.

We notice an unexpectedly large variance in the dipole modulus estimation when the magnet moves with respect to the sensor array. For instance, in the cases of the trackings of Figs. 5 and 6, we got  $\sigma_m/m$  values of about 7.6% and 9.8%, respectively. These large values could be ascribed to small uncertainties in the positions of sensors as well as to non-linearities in their responses. Despite this large variance in the dipole estimation, the quality of spatial tracking in Fig.6 is comparable with that of Fig.5: noticeably the worse uncertainty in the dipole vector determination is not associate with a relevant degradation of the position tracking.

As expected, the tracking performance with a given magnet drops dramatically when it is displaced too far from the sensor array, as to make the dipole field comparable with the system noise, or too uniform over the array size. This behaviour is well confirmed the data plotted in Fig.7. This figure shows the absolute position error (RMS of the reconstructed position) and the relative RMS of the dipole modulus, as a function of the  $z$  co-ordinate of the magnet, i.e. at increasing distances from the array.

Concerning the speed, we proved that the system may acquire and track continuously at the maximum sampling rate (currently set by the firmware at 100 Sa/s) on a standard personal computer (e.g. on an i5-7400 CPU, 3 GHz, 64 bit).

## 11. Conclusion

We have built and tested a cheap and reliable hardware based on commercial magnetoresistive sensors that, after appropriate calibration procedures, provides a set of 24 magnetometric measurement data with a rate as large as 100 Sa/s. The hardware contains a microprocessor enabling immediate data transfer to a personal computer, which in turns executes data elaboration to extract multidimensional (from 7D to 9D) spatial and angular co-ordinates of the magnetic source with respect to the sensor array and of the latter with respect to ambient field. The tracker is scalable in size and can be of interest for several kinds of applications ranging from medical diagnostics to virtual and augmented reality.

## 12. Patents

The subject of this work, in virtue of its interesting potentialities and of its demonstrated performance in terms of precision and achieved speed, belongs to the contents of a recently applied patent [29].

**Author Contributions:** Authors contributed differently to the development of the described work. A synthesis of the played roles is drawn here below: Conceptualization, Valerio Biancalana, Piero Chessa and Giuseppe Bevilacqua; Data curation, Valerio Biancalana, Piero Chessa and Antonio Vigilante; Formal analysis, Piero Chessa, Giuseppe Bevilacqua and Antonio Vigilante; Funding acquisition, Valerio Biancalana; Investigation, Valerio Biancalana, Roberto Cecchi and Yordanka Dancheva; Methodology, Valerio Biancalana and Piero Chessa; Project administration, Valerio Biancalana; Resources, Valerio Biancalana and Roberto Cecchi; Hardware and firmware Roberto Cecchi; Software, Valerio Biancalana, Piero Chessa and Antonio Vigilante; Supervision, Valerio Biancalana; Validation, Valerio Biancalana, Piero Chessa and Antonio Vigilante; Visualization, Valerio Biancalana, Piero Chessa and Antonio Vigilante; Writing – original draft, Valerio Biancalana; Writing – review & editing, Valerio Biancalana, Roberto Cecchi, Piero Chessa, Yordanka Dancheva and Antonio Vigilante.

**Funding:** This research received no external funding.

**Acknowledgments:** The authors acknowledge the valuable technical support of Leonardo Staccini (DSFTA).

**Conflicts of Interest:** The authors declare no conflict of interest.

**Figure 1.** Indicative and approximate representation of typical field and frequency ranges for different kinds of magnetometry technologies and of their possible applications. Magnetoresistors match requirements for navigation and tracking, while higher sensitivity is needed for biomagnetic detection (as in magnetocardiography MCG and magnetoencephalography MEG), where SQUIDS and AOM are the eligible choices. AOM in their radio-frequency (RF) implementations offer excellent performance at high frequencies. Flux gate sensors are produced in different grades of performance, and partially overlap with the MR applicability. Hall sensors are relegated to evaluating stronger fields, with quite small precision.

**Figure 2.** The prototype of the electronics equipped with a sensor array designed to perform eye tracking. The eight three-axial sensors appear in the two parallel PCBs on the left, while the acquisition, recording and data-transfer electronics is implemented in the PCB on the right, where batteries and USB connector are visible. The flat connection allows to interface the PCBs with 3+5 or 4+4 sensor arrays.

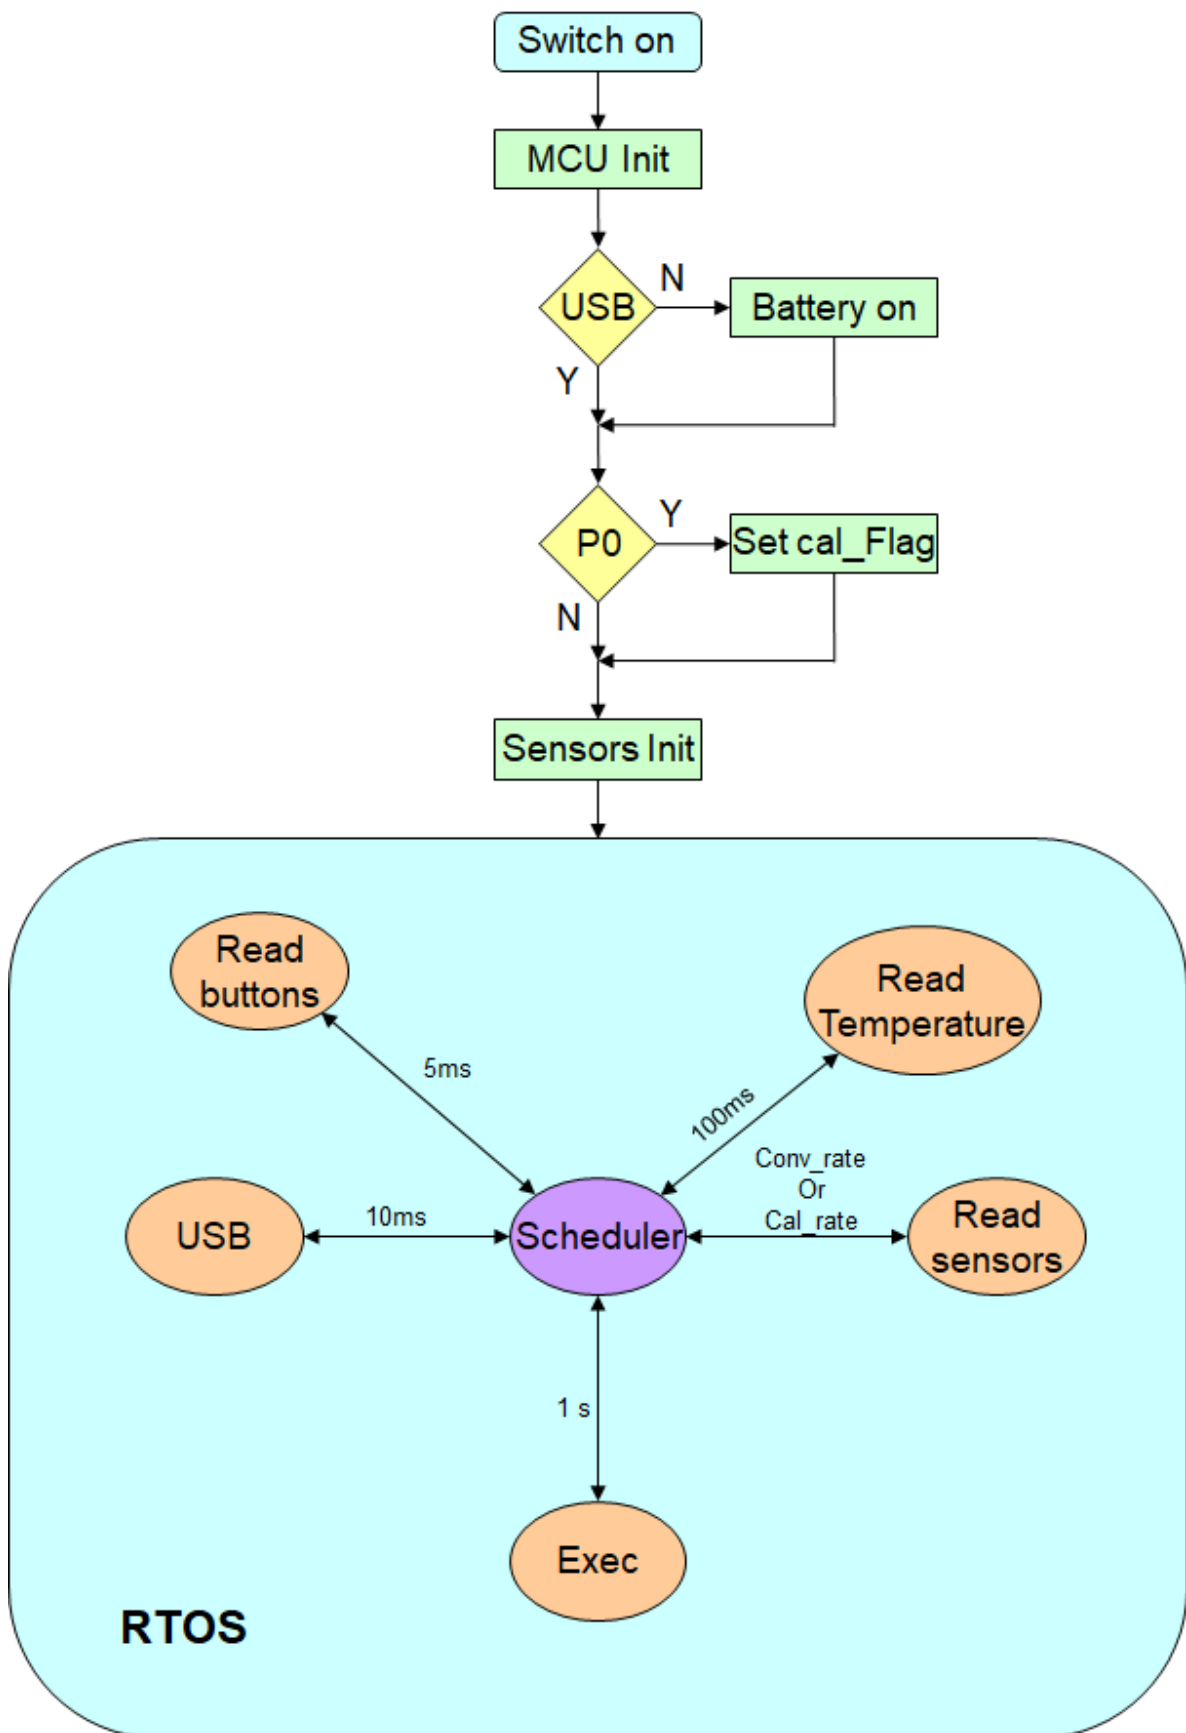

Figure 3. General flowchart of the firmware.

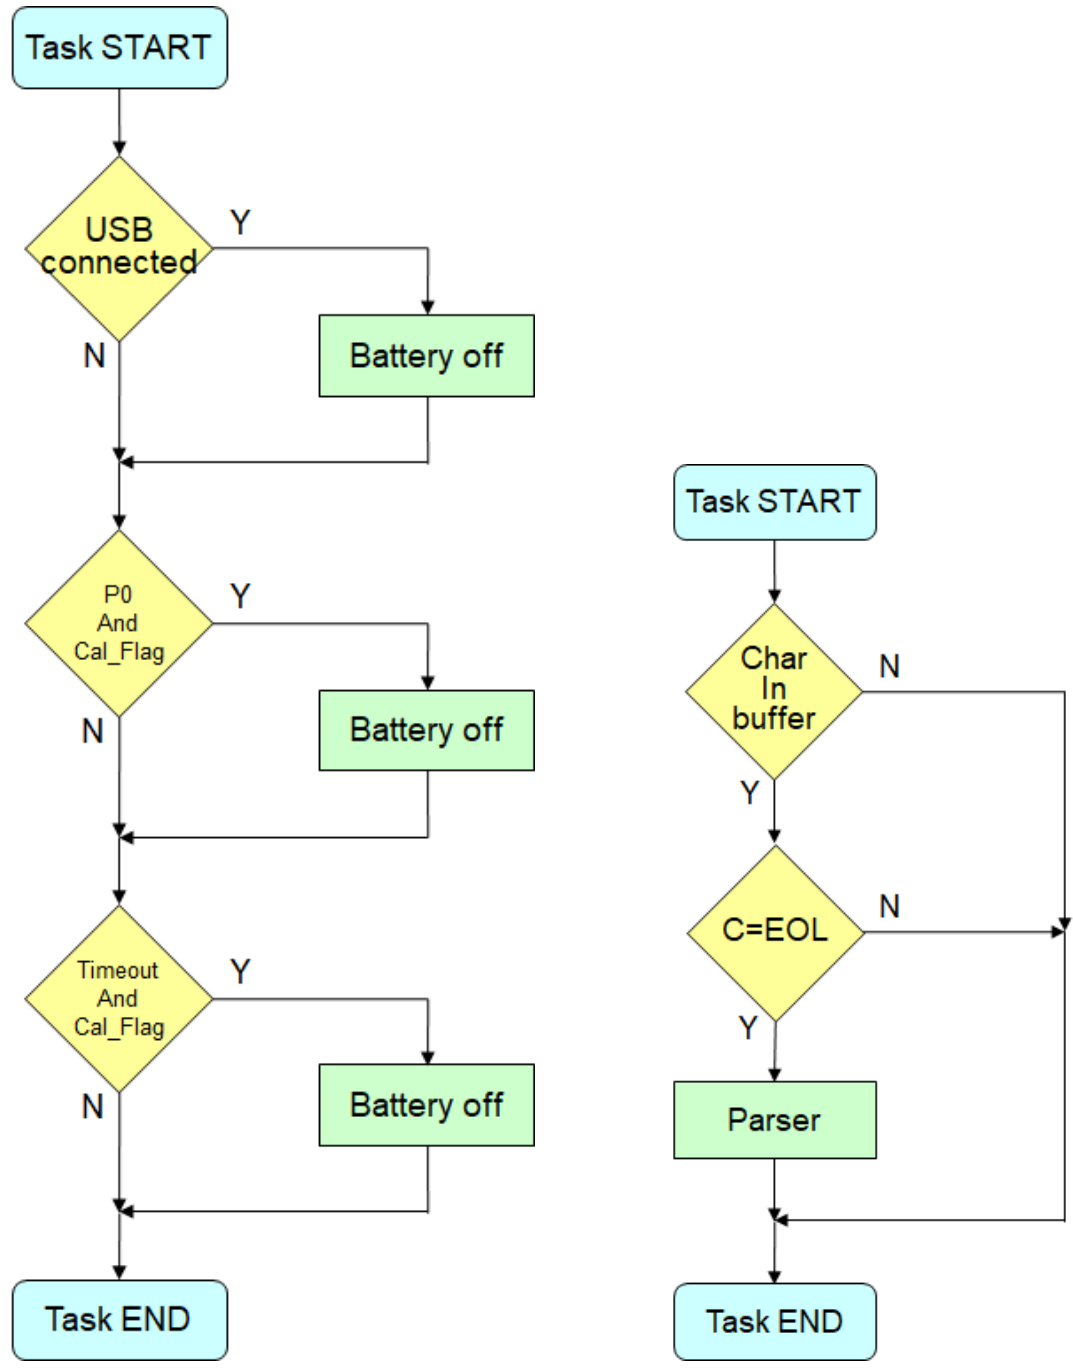

Figure 4. Flowcharts describing the EXEC and USB-communication tasks implemented in the firmware

**Figure 5.** Position track of a rotating magnet measured with the sensor array in static conditions. The acquisition rate is here set to 1/30 s.

**Figure 6.** The upper plot shows the position tracking of a rotating dipole as for Fig.5. Here the sensor array, which is rigidly assembled with the magnet-driver, it is held in hands and freely rotated, while the magnet-driver moves the dipole with respect to the sensor array. The middle plot shows the components of the estimated environmental field, with two of them heavily affected by the assembly motion. The lowest plot shows the evolution of the spatial co-ordinates, with two of them following the sine/cosine law dictated by the dipole rotation, and negligibly affected by the varying array orientation with respect to the environmental field.

**Figure 7.** Error (RMS) evaluated from repeated estimations of dipole position (left axis) and dipole moment modulus (right axis) as a function of the distance  $z$  from the PCB's, as obtained by moving the magnet along an axis passing by the array center.
