Abstract: Study of spatiotemporal dynamics of temperature is vital to assess changes in climate, especially in the Himalayan region where livelihoods of billions of people living downstream depends on water coming from the melting of snow and glacier ice. To this end, temperature trend analysis is carried out in Narayani river basin, a major river basin of Nepal characterized by three climatic regions: tropical, subtropical and alpine. Temperature data from six stations located within the basin were analyzed. The elevation of these stations ranges from 460 to 3800 m a.s.l. and the time period of available temperature data ranges from 1960–2015. Multiple regression and empirical mode decomposition (EMD) methods were applied to fill in missing data and to detect trends. Annual as well as seasonal trends were analyzed and a Mann-Kendall test was employed to test the statistical significance of detected trends. Results indicate significant cooling trends before 1970s, and warming trends after 1970s in the majority of the stations. The warming trends range from $0.028\text{ }^{\circ}\text{C year}^{-1}$ to $0.035\text{ }^{\circ}\text{C year}^{-1}$ with a mean increasing trend of $0.03\text{ }^{\circ}\text{C year}^{-1}$ after 1971. Seasonal trends show highest warming trends in the monsoon season followed by winter, pre-monsoon, and the post-monsoon season. However, difference in warming rates between different seasons was not significant. An average temperature lapse rate of $-0.006\text{ }^{\circ}\text{C m}^{-1}$ with the steepest value ($-0.0064\text{ }^{\circ}\text{C m}^{-1}$) in pre-monsoon season and least negative ($-0.0052\text{ }^{\circ}\text{C m}^{-1}$) in winter season was observed for this basin. A comparative analysis of the gap-filled data with freely available global climate datasets show reasonable correlation thus confirming the suitability of the gap filling methods.

Keywords: climate change; temperature trend; Himalaya; river basin; Nepal

1. Introduction

Global warming and climate Change are widely recognized as the most significant dilemma the world is experiencing today [1]. Studies based on direct measurements and remote sensing have suggested that higher greenhouse gases in the atmosphere are causing global climate change [2]. Global temperatures have been rising significantly over the last decade, despite year-to-year fluctuations associated with the El Niño-La Niña cycle of tropical ocean temperature [3]. Linear warming trends from 1951 to 2012 show an increase of global temperature by $0.12\text{ }^{\circ}\text{C decade}^{-1}$ [2]. However, the rate of temperature increase is different for different regions. The widespread retreat of glaciers and snow cover due to increasing temperatures have contributed to eustatic sea level rise [2]. This warming will also have significant impacts on the hydrological cycle of mountain river basins affecting livelihoods of population living downstream.

The Hindu-Kush Himalayan (HKH) region is characterized by mountainous environments [4]. Weather and climatic conditions over the Himalayan regions are of great interest to the scientific community [5]. HKH has the highest elevation range in the world and contains largest freshwater reserve in the form of snow and glacier ice outside the Polar Regions. Several studies have reported warming in the Himalayan region [4,6–10] which has caused shrinkage of glaciers [11–13], expansions of glacier-fed lakes [14–17], degradation of permafrost [18] and changes in the hydrological cycle of many mountain rivers [19,20]. For example, Lama et al. [13] reported a loss of about 22% of the glacier area in Mustang, within Narayani basin from 1980s–2010. The temperature is increasing faster than the global average in the Tibetan Plateau and Northern Hemisphere [10], Himalayan region and the influence of rising temperatures is greater in the Eastern Himalayas compared to that in the greater Himalayas [21]. Shrestha et al. [7] analyzed the maximum temperature since 1977 and found a warming trend of temperature by $0.06\text{ }^{\circ}\text{C}$ to $0.12\text{ }^{\circ}\text{C year}^{-1}$ in Middle Mountain and Himalayan region and of $0.03\text{ }^{\circ}\text{C}$ in Siwalik and southern plains. Kattel and Yao [9] reported an increase in temperature of $0.038\text{ }^{\circ}\text{C year}^{-1}$ in mountain stations of Nepal Himalaya. Khatriwada et al. [8] found that increases in maximum temperature ($0.05\text{ }^{\circ}\text{C year}^{-1}$) were larger than those of the minimum temperature increase ($0.01\text{ }^{\circ}\text{C}$) from 1981–2012) with the largest change observed during the pre-monsoon season in Karnali River basin. Similarly, Nepal [22] studied the impact of climate change on the hydrological regime of the Koshi river basin and found an increase in average maximum temperature of $0.058\text{ }^{\circ}\text{C year}^{-1}$ and $0.014\text{ }^{\circ}\text{C year}^{-1}$ for minimum temperature over the past 40 years. Model result of Nepal [22] also shows that the annual discharge of the Koshi River basin will increase by 13% by mid-century and snowfall will decrease substantially due to increasing temperature. A more recent study by Shrestha et al. [23] also showed increasing trend of seasonal maximum and minimum temperature from 1975–2010 in the Koshi trans-boundary basin. Similar study by Yang et al. [5] shows that air temperature has increased by $0.62\text{ }^{\circ}\text{C decade}^{-1}$ over the last 49 years (1959–2007) at Dingri station, northern slope of Mt. Everest. Liu et al. [24] also observed a cooling trend about $-0.06\text{ }^{\circ}\text{C decade}^{-1}$ in three stations out of 88 stations studied in Tibetan Plateau. Seasonally, some contrasting results are reported by previous studies. Duan and Xiao [10] reported highest warming trend in the monsoon season in Tibet. Liu et al. [24] and Yang et al. [5] found higher increasing trends in winter that ranges from $0.36\text{ }^{\circ}\text{C}$ to $0.86\text{ }^{\circ}\text{C decade}^{-1}$ in the same region. Similarly, Shrestha et al. [7] also reported highest increasing rate during the winter season and lowest in pre-monsoon season in whole Nepal. Few past studies also showed a relation between temperature and elevation to estimate the temperature-elevation gradient and found $0.72 \pm 0.01\text{ }^{\circ}\text{C } 100\text{ m}^{-1}$ [5] in Tibet and $0.50\text{ }^{\circ}\text{C } 100\text{ m}^{-1}$ in Langtang Valley, Nepal [25].

HKH regions have experienced an overall rapid warming, which has further influenced the climatic extremes and hydrological cycles in the region [26]. Several studies related to temperature trends have been carried out in this region using observed, reanalysis and satellite datasets. However, river basin scale studies of temperature trends are fairly limited in Nepal Himalayas. This study chooses a Narayani River basin to study the mean annual and seasonal temperature trend.

2. Study Area

Narayani River basin (Figure 1) also known as Gandaki River basin lies in the central part of Nepal between 25.49° N - 29.28° N and 85.02° E - 85.83° E . Narayani River basin is a transboundary river basin that originates from the southern edge of the Tibet (China), flows through Nepal to India, and contributing to the Ganges River. It encompasses a total area of $46,300\text{ km}^2$ [11], $32,104\text{ km}^2$ [27,28] of which is in Nepal. Narayani River has seven tributaries i.e., Marsyandi, Daraudi, Seti, Madi, Kali Gandaki, Budhi Gandaki, and Trishuli and it includes Terai, Hill, Mountain and High Himalayas including trans-Himalaya from south to north of the basin. About 40% of the basin is covered by agricultural land [27]. The upper part of this basin is covered with snow and ice which is the main source of water. The mean elevation of Narayani River basin is 4065 m a.s.l. and ranges from 180 m in the south to higher than 8000 m [29] in the north where the basin contains the Dhaulagiri (8167 m a.s.l.), Manaslu ($>8000\text{ m a.s.l.}$) and Annapurna (8091 m a.s.l.) peaks, which have very contrasting

climates. Langtang, Machhapuchhre, Manaslu, Dhawalagiri and Annapurna mountains in the basin have created the large variation in climate over the basin.

The Narayani River basin is dominated by monsoon with annual average precipitation ranges from 152 mm to 5493 mm. About 78% of annual precipitation occurs in the monsoon (June–September) [28,30]. Lowest precipitation is observed for driest regions including Mustang and Manang located at the leeward-side north of the Annapurna and Lumle receive the highest precipitation [31].

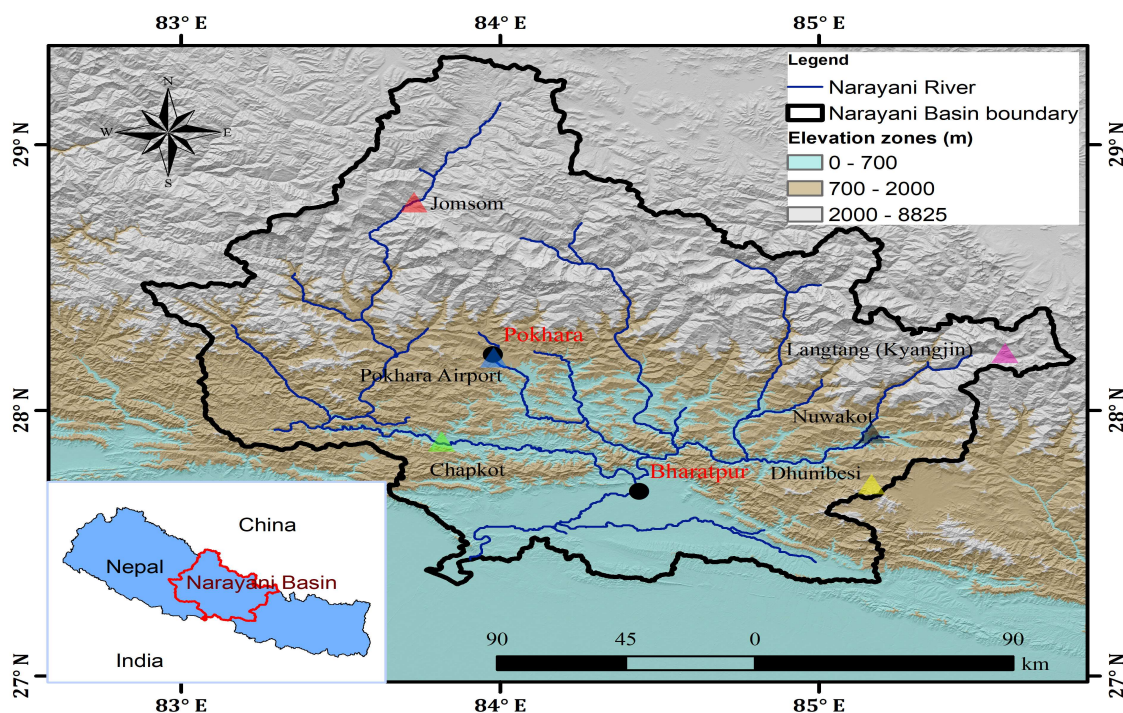

Figure 1. Narayani River basin with the location of the meteorological stations used in this study. The background of the basin shows different elevation zones based on Shuttle Radar Topography Mission Digital Elevation Model.

3. Methods

3.1. Data

Daily two metre temperature data of Narayani basin were obtained from the Department of Hydrology and Meteorology (DHM), Government of Nepal. Six stations were selected (Table 1) each representing different physiographic zones and elevation ranges from 460 m a.s.l. (Chapkot) to 3800 m a.s.l. (Langtang). Data ranges from 1 January 1956 to 31 December 2016. None of the stations has data for the entire period (Figure 2) and some of them have data gaps longer than 5 years. Langtang station has the shortest temperature record (1988–2008) and Nuwakot has the longest record (1956–2016) with significant gaps in between. Data available for selected stations were of different observation periods and missing observation dates. Missing data in each station were interpolated by linear and multiple regression methods (described in Section 3.3).

3.2. Basic Statistics

Langtang (Station ID 1000) is the highest elevation station among six stations (Figure 3) where daily mean temperature of 3.19 °C (Table 2) was observed. Nuwakot (Station ID: 1004) has the longest period (about 60 years) of observation from 1956 to 2015 with a daily mean temperature of 21.53 °C. Table 2 also shows the 95th and 99th percentile of recorded temperature and makes clear that data in all stations skewed towards the right and were not normally distributed. Similar magnitude of

skewness coefficient indicates similar seasonality in all stations. Auto-correlation for each station data were calculated and found more then 0.8 for one day time lag.

Table 1. Geographic coordinates of the six weather observatories and periods of observations.

Station ID	Station Name	Lat.	Lon.	Altitude (m)
810	Chapkot	27.883	83.817	460
804	Pokhara Airport	28.217	84.000	827
1004	Nuwakot	27.917	85.017	1003
1038	Dhunibesi	27.171	85.183	1085
601	Jomsom	27.783	83.717	2744
1000	Langtang	28.200	85.533	3800

Figure 2. Data coverage for the studied stations. Gaps in the lines indicate no available data for the period.

Figure 3. Time series of observed mean annual temperature (°C) without filling the gap.

3.3. Quality Control and Data Fill

All available data-sets for six stations from 1960–2015 were visually inspected using several time series plots and outliers +/- three standard deviation [32] were removed. Simple and multiple linear regression methods with ordinary least squares (OLS) assumptions were applied to fill the data gaps.

Each station was treated separately in order to fill the missing values. Independent variables for the model were selected based on the highest significant correlation coefficient with surrounding stations in the model development process to fill the gap. To improve the predictive power of the model, step-wise regression methods were used to select multiple independent variables. Only overlapping dates were used while developing the models and used for filling data gaps in studied stations.

Table 2. Distribution of temperature data over six observation station.

Station ID	95th Percentile	99th Percentile	CV	Mean	Median	Skew	Mean after Interpolation
810	28.85	31.68	26.36	23.27	24.77	−0.59	23.20
804	26.38	26.85	21.66	20.96	22.38	−0.46	21.06
1004	26.51	27.88	20.69	21.53	22.86	−0.59	21.45
1038	26.73	27.70	23.71	21.20	22.59	−0.50	21.19
601	18.85	20.77	29.53	11.77	11.68	−0.08	11.44
1000	8.20	9.13	11.29	3.19	3.36	−0.20	3.16

Step-wise regression is a semi-automated process of building a model by successively adding or removing variables based solely on the t-statistics of their estimated coefficients [53]. The step-wise regression options puts more power and information than does the ordinary multiple regression option and is especially useful for shifting through large numbers of potential independent variables and/or fine-tuning a model by poking variables in or out. When improperly used, it may converge on a poor model while giving a false sense of security. The step-wise option lets us either begin with no variables in the model and proceed forward (adding one variable at a time) or start with all potential variables in the model and proceed backward (removing one variable at a time). At each step, it computes different statistics and selects the best independent variables based on F-test. Although the selected stations are in different climatic zones when developing the regression models to fill gaps, independent variables selection was solely based on statistically significant ($p < 0.05$) correlations with independent variables so the impact of physiography and elevation were assumed to be minimal.

High R-squared values (>0.80) were observed with less scatter of observed and predicted mean annual temperature around best fit (Figure 4) when datasets from Jomsom, Dhunibesi, and Chapkot stations were used as dependent variables and Pokhara as the independent variable. While comparatively smaller value ($R^2 = 0.66$) was obtained when data from Langtang station used as dependent variable and data from Pokhara and Jomsom stations as dependent variables. The mean annual temperature after filling the gaps (Figure 5) were slightly lower than (about $0.10\text{ }^{\circ}\text{C}$) the mean annual temperature (Table 2) before filling the gaps.

3.4. Trend Break Detection Methods

Empirical mode decomposition (EMD) method [33,34] which is an adaptive method that is entirely empirical and captures the characteristics, was used for detecting the trend in different periods. Mhamdi et al. [34] have suggested that the EMD can be considered as an attractive and easy method for time series analysis and especially for time series trend extraction and therefore this method was adopted in this study. The key idea of EMD is to locally decompose data into oscillatory components so-called intrinsic mode functions (IMFs). In this study, we have used the EMD method for trend break detection in all six stations, however, the only result of the longest time-series (Pokhara station) is presented for brevity.

3.5. Seasonal and Annual trend Analysis

The Mann-Kendall Test is a widely used method by several researchers for long-term climatic variable trend analysis e.g., Karki et al. [31], Khatriwada et al. [8], Panthi et al. [28], Razvai et al. [35], Shrestha et al. [7] and Xu et al. [36]. Trend analysis was performed using Mann-Kendall non-parametric

statistical test on the annual long-term trend for the historical period (1960–2015) of temperature time series. Seasonal trends were studied using historical data from 1970–2015 as trend break was observed in the 1970s for most of the stations. The Mann-Kendall (MK) test [37,38] statistically assesses if there is a monotonic upward or downward are statistically significant or not. A monotonic trend means that the variable consistently increases (or decreases) through time, but the trend may or may not be linear. Basically Mann-Kendall test can be used in place of a parametric linear regression analysis, which can be used to test if the slope of the estimated linear regression line is different from zero. The regression analysis requires that the residuals from the fitted regression line should be normally distributed; an assumption not required by the MK test, that is, the MK test is a non-parametric (distribution-free) test [37]. However, there were some key assumptions associated with this test such as the requirement for observations obtained over time needs to be independent and identically distributed meaning a very long record and non-stationarity of the time series [38,39]. Hirsch et al. [40] suggested that the MK test can be best viewed as an exploratory analysis and is most appropriate to identify stations where changes were significant or of large magnitude and to quantify these findings.

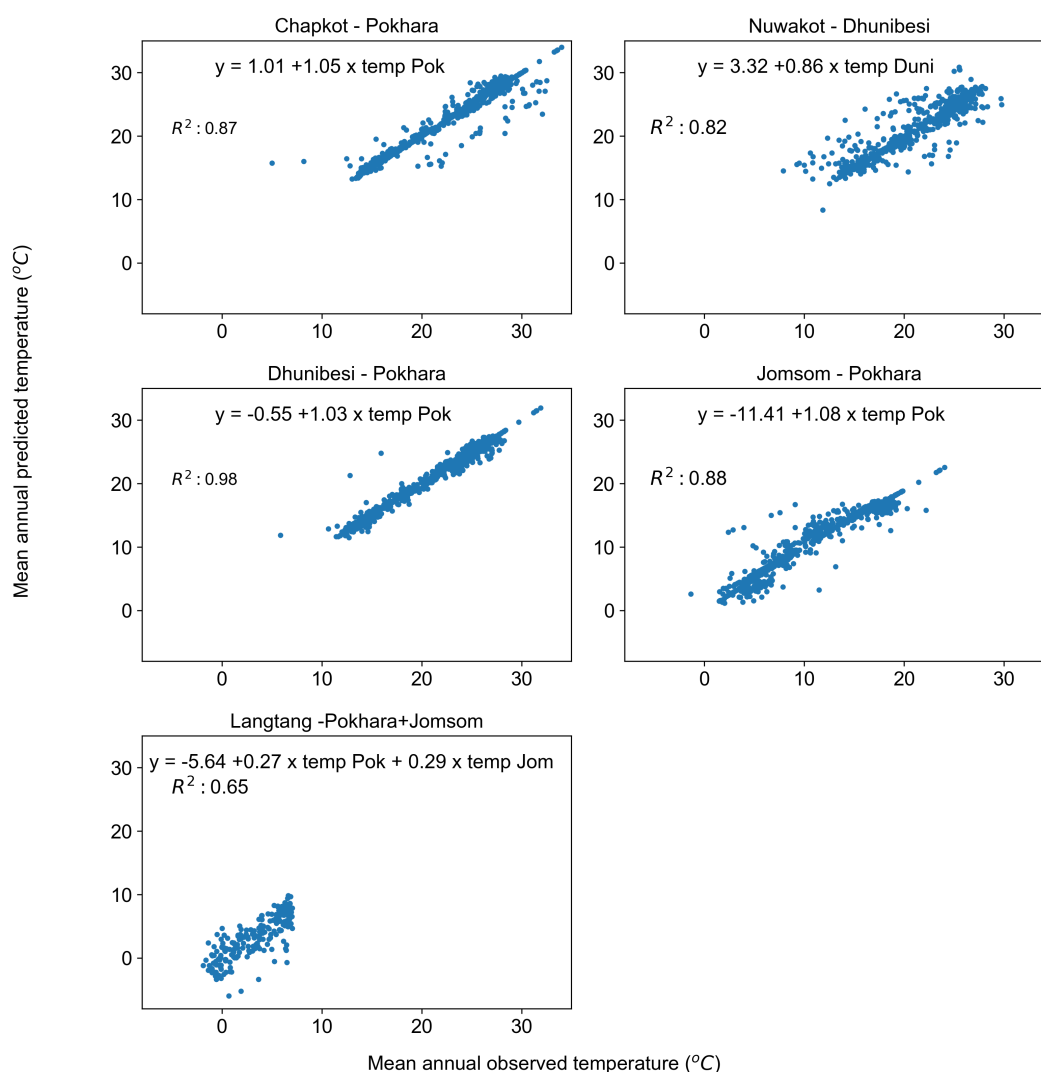

Figure 4. Scatter plot of temperature observation with the prediction from the model for the different stations.

3.6. Comparison of Station Data With Freely Available Global Climate Datasets

The gap filled daily mean temperature data from six stations were compared with global climate datasets from freely available sources. For this purpose, WorldClim Version 2.0, CHELSA (Climatologies at high resolution for the earth's land surface areas) Version 1.2, GLDAS (Global Land Data Assimilation System) Version 2.0 and MODIS (Moderate Resolution Imaging Spectroradiometer) satellite datasets were used.

Figure 5. Time series plot for annual mean temperature after filling the missing data.

WorldClim Version 2.0 is a spatially interpolated and gridded climate data for global land areas at a very high spatial resolution (approximately 1 km²) which is based on interpolation methods applied to meteorological station data [41]. The average monthly temperature data for 1970–2000 and ‘Annual Mean Temperature or BIO1 grid’ from WorldClim Version 2.0 were used in this study. CHELSA Version 1.2 is a high resolution (30 arc sec) climate data set for the earth land surface areas based on a quasi-mechanistical statistical downscaling of the ERA interim global circulation model [42]. The average monthly temperature data for 1979–2013 and ‘Annual Mean Temperature’ grid from CHELSA Version 1.2 were used in this study. GLDAS Version 2.0 uses satellite data products, ground-based observational data products, land surface modeling and data assimilation methods to generate global climate surfaces [43,44]. The parameter ‘near surface air temperature’ in Kelvin from GLDAS Noah Land Surface Model L4 monthly 0.25 × 0.25 degree Version 2.0 datasets were used in this study.

MOD11A2 Version 6.0 product, one of the several MODIS satellite products, was used in this study [45,46]. MOD11A2 Version 6.0 provides an average, 8-day, per-pixel land surface temperature (LST) in a 1200 × 1200 kilometer grid where each pixel value has a spatial resolution of 1 kilometer and the pixel value is a simple average of all the corresponding MOD11A1 LST pixels collected within that 8 day period. LST daytime and LST nighttime were extracted from the MOD11A2 grid for all six stations and separately averaged to obtain monthly average LST daytime and monthly average LST nighttime. Monthly averages of LST daytime and LST nighttime were further averaged to obtain monthly average LST for all months at all six stations. Since a single grid represents the 8-day average, a grid which is averaged using 8 days from two adjacent months was placed in the month with larger number of days used to create the 8-day average grid. Further, when a grid was averaged using equal or 4 days in two adjacent months, the grid was placed in both months to create the monthly average.

As data from these sources are freely available in the form of grids, these grids were uploaded as raster data in ArcMap 10.5. The grids and station coordinates were projected into the same geographic projection using the WGS-84 datum and the function ‘Extract Multi Values to Points’ in ArcMap was used to extract the pixel values at station coordinates. Raster Calculator function in ArcMap 10.5 was used to convert digital number values of MOD11A2 grid into degree Celsius and also to convert temperatures in Kelvin in GLDAS 2.0 data set to degree Celsius.

For comparison with WorldClim 2.0 monthly averages and annual mean temperature, station data from 1970 to 2000 were used to generate monthly averages and mean annual air temperature (MAAT hereafter). Similarly, for comparison with CHELSA Version 1.2 monthly averages and annual mean temperature, station data from 1979 to 2013 were used to generate monthly averages and MAAT. For comparison with GLDAS Version 2.0 monthly averages, GLDAS Version 2.0 monthly temperature data set ranging from 2001–2010 and station data from 2001 to 2010 were used to generate monthly averages and MAAT. For comparison of MOD11A2 Version 6.0 product with station data, MOD11A2 Version 6.0 for the year 2014 and 2015 was compared with station data for the year 2014 and 2015, respectively. Further, GLDAS Version 2.0 monthly temperature data set for the year 2014 and 2015 was also used for comparison.

Scatter plots were created and linear trend lines were fitted to observe the strength of linear correlation between station datasets and the freely available climate datasets at all stations.

4. Results and Discussion

4.1. Trend Break Observation

EMD methods were used to detect temperature trends in six stations within the Narayani River basin. Intrinsic mode functions (IMFs) 1 exhibit high frequency and can represent very short-term fluctuation (Figure 6), IMFs 2–3 captures a small percentage of variance, IMFs 4–5 capture mid-term effects described by periodic cyclic variation [47]. Finally, IMF 6, the residue component in EMD could represent the major trend [48] of annual average temperature in the long term that may be related with the increase or decrease of observed temperature in Pokhara station. From Figure 6, high fluctuation during the periods between 1960 and 1970 is observed in IMF1. Higher fluctuation represents higher temperature variability during the period 1960 and 1970. Higher variability during that periods impacts mid periodic cycle, shown by IMF4 as similar results are also discussed by [47] and [48] in their research. The annual average temperature is in a decreasing trend till 1972 and it breaks there and again the trend is in increasing order and represents the major trend of temperature (Figure 6). It may be related to rapid global warming after the 1970s with industrial evolution and increase of greenhouse gases (GHGs) and radiative forcings [2]. The small difference in the number of year of trend break might be attributed to the influence of local and regional climate.

4.2. Historical Observed Trend

The observed historical mean annual temperature anomalies after filling the gaps for the period of 1960–2015 were shown in Figure 5. This data-set represents the basis for calculation of the annual and seasonal trend for each station. Few extreme events of temperature anomalies ($\pm 2^\circ\text{C}$) relative to the long-term mean were observed in the data and also show the spatial variability in temperature as stations are located in different physiographic zones. The average annual temperature of the basin is 16.92°C , however, temperature varies largely with altitude.

Trends of mean annual temperature for six stations is shown in Figure 7. Analyses of mean temperature data from six stations within Narayani basin for the period 1960–2015 reveal warming trend usually after 1970s and cooling trend before this period. Trend break was observed in the 1970s for all stations i.e. in 1970 for Jomsom and Pokhara, in 1972 for Chapkot and Dhunibesi, in 1979 for Nuwakot, which is cross-validated with EMD results. However, the cooling trend for Langtang was detected in 1993, in which original dataset was ranging from 1988–2008 and data was extended for 1960–2015 by gap-filling techniques. The earlier period was dominated by the cooling trend in most of the stations and it might have influenced the data filling method and cooling trend for Langtang was extended up to 1993 from where continuous data was available. Overall, all six stations show the warming trends (Table 3) and we observed negative trends in the earlier periods. Studies related with temperature trends in the Narayani River basin are not well documented. Here, we have used the datasets from much earlier than the previous study, which were conducted either in

regional scale or different river basins. Our results of warming rates from Narayani basin are similar to Shrestha et al. [7], which was done for the whole of Nepal. Majority of stations (4 out of 6) in a later period and three stations out of six stations for the entire period show increasing trends of mean annual temperature at a statistically significant rate. The warming trends range from $0.008\text{ }^{\circ}\text{C}$ to $0.015\text{ }^{\circ}\text{C}$ with a mean warming trend of $0.011\text{ }^{\circ}\text{C year}^{-1}$ which is statistically significant at the 95% significance level (Table 3) for the entire period (1960–2015). However, analyses from later period that starts in 1971 reveal higher warming trends, which ranges from $0.028\text{ }^{\circ}\text{C}$ to $0.035\text{ }^{\circ}\text{C year}^{-1}$ with mean warming trend of $0.03\text{ }^{\circ}\text{C year}^{-1}$, which is similar to findings of previous studies e.g., Kattel and Yao [9]; Khatiwada et al. [8]; Shrestha et al. [7] focused on Central Himalayan region. The highest rate of increase in temperature was observed at Pokhara station ($0.035\text{ }^{\circ}\text{C year}^{-1}$) and Jomsom station ($0.029\text{ }^{\circ}\text{C year}^{-1}$) from 1971–2015. While, in case of the entire period, the highest rate of increasing mean annual temperature was observed at Nuwakot station ($0.015\text{ }^{\circ}\text{C year}^{-1}$).

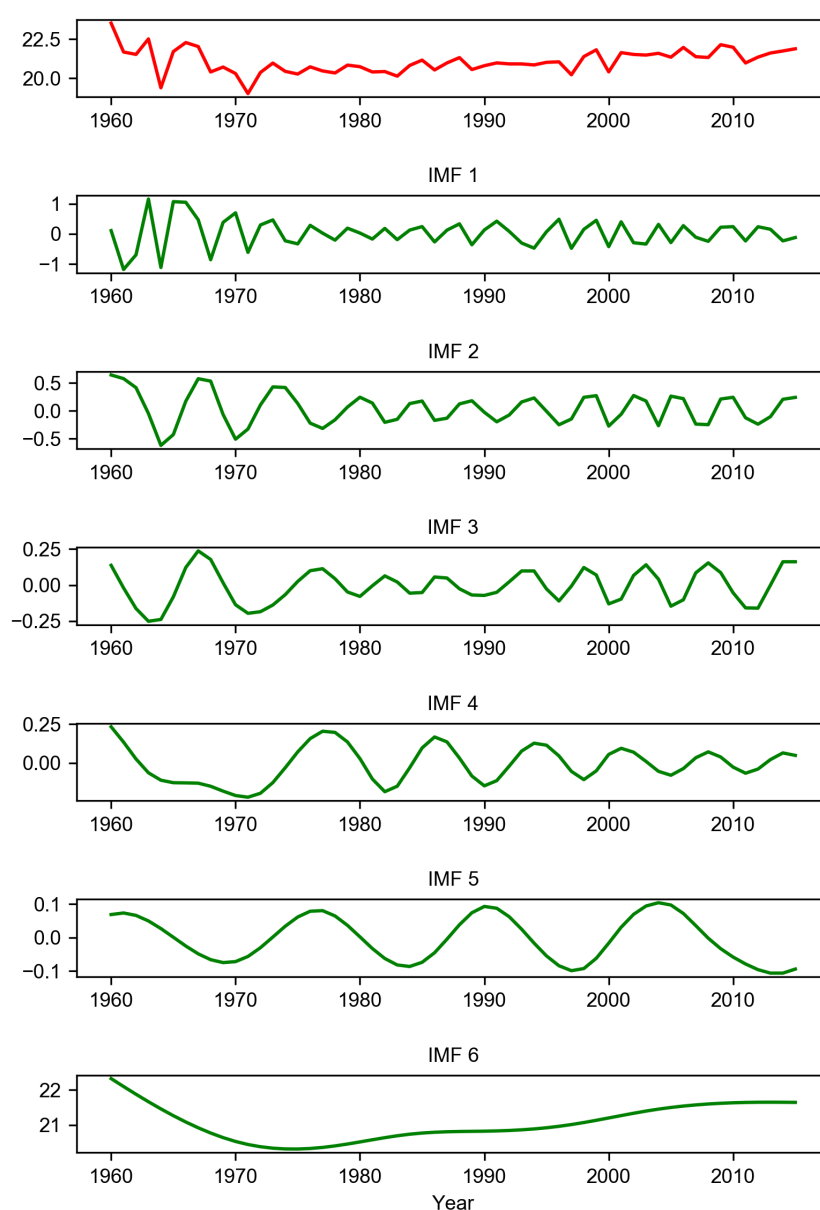

Figure 6. EMD decomposition of the annual average temperature (1960-2015) in Pokhara station, with IMFs components (IMF1-IMF6) and the final residue or preliminarily identified trend.

Mann-Kendall test was also used for the period 1970–2015 and 1980–2015 for each station and a statistically significant (95%) warming trend of $0.031\text{ }^{\circ}\text{C}$ and $0.032\text{ }^{\circ}\text{C year}^{-1}$ was observed respectively. The number of stations with statistically significant rates was increased to five except Chapkot station for the period 1970–2015. We investigated temperature trends at different elevations for the different time periods. This analysis did not show a clear relationship for all time periods and stations analyzed. However, comparison of the highest (Langtang) and lowest (Chapkot) elevation stations for the period 1980–2015 revealed higher warming rate at Langtang ($0.044\text{ }^{\circ}\text{C year}^{-1}$) compared to Chapkot ($0.013\text{ }^{\circ}\text{C year}^{-1}$). Additionally, highest warming rate ($0.04\text{ }^{\circ}\text{C year}^{-1}$) at Langtang station was observed from 1993 to 2015 in compared to other low altitude stations, however, this rate is not statistically significant. Similar values were also reported by Salerno et al. [49]. The insignificant statistical test can be attributed to high variability, significant gap and instrumental error involved with high altitude observations. Nevertheless, this is a sign of a high warming rate in the high mountain region and a less warming rate in low land areas. However, the test results for 1970–2015, 1990–2015 and 2000–2015 do not show a clear relationship between elevation and higher warming rates. Similar results are also shown by Kattel and Yao [9] and You et al. [4], and it might be possibly due to the small number of stations at different elevation zones. It needs to be verified using several stations in the region.

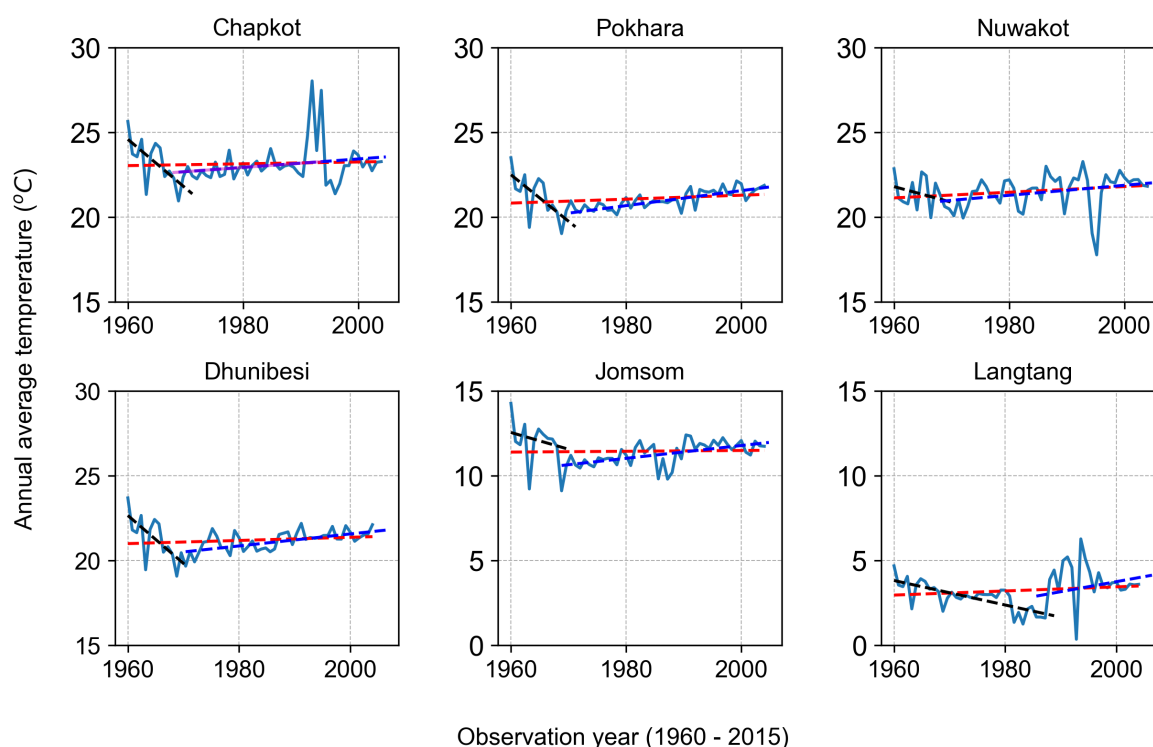

Figure 7. Historical mean annual temperature trend in Narayani river basin for six stations. The trend line for the earlier period for each station is denoted by black lines and later period is denoted by blue lines, while the overall trend is denoted by red lines.

Results obtained from the Mann-Kendall test for Pokhara and Dhunibesi stations revealed a significant cooling trend during the period ranging from 1960 to 1970–1972, which is similar to previous findings e.g., Liu et al. [24], Shrestha et al. [7] and others. Similarly, a statistically significant cooling trend was also observed at Langtang station for the period from 1960–1992. The mean cooling trend for Pokhara, Chapkot, Dhunibesi, and Langtang station was $-0.18\text{ }^{\circ}\text{C year}^{-1}$, however, cooling trend is not very significant for Jomsom and Nuwakot station in the studied period.

4.3. Seasonal Trends

The mean monthly temperature for the study period at each station (Figure 8) is lowest in January and highest during June–August. Lowest mean monthly temperature was found lowest at Langtang station (-0.88°C) followed by Jomsom station (3.71°C) in January. Highest mean monthly temperature was found at Chapkot station (28.31°C) in August followed by Dhunibesi station (26.20°C) in June. To get a better overview of the data spread from the mean, monthly average temperature variance (square of the standard deviation) for each station was calculated (Figure 9). Higher variance of monthly average temperature was observed in the months of April and December compared to other months. April indicates the transition between winter and summer month. Higher monthly mean variance in April is the indicator for changing the number of days in winter and summer. Hanjra and Qureshi [50], KC and Ghimire [51] also observed more frequent warmer days and less frequent cooler nights throughout Nepal. Annual maximum temperature is in an increasing trend with hot summer days while minimum temperature is in decreasing trend with cool winter days [52] which is reflected by the higher variance in the month of April and December.

Table 3. Mean annual temperature trend ($^{\circ}\text{C year}^{-1}$) in Narayani River basin at six different stations. ‘*’ represents statistically significant at 95% significant level.

Figure 8. Monthly averaged temperature for six station in Narayani basin.

For the seasonal study, a calendar year was divided into four different seasons [53]; winter (December–February), pre-monsoon (March–June), monsoon (July–August), and post-monsoon (September–November) to assess the seasonal temperature trends. The temperature at each station is in symmetry with the highest temperature during monsoon and lowest during the winter season.

The Mann-Kendall test results for seasonal trends show that the rate of increase of mean temperatures were higher in the monsoon than the other seasons (Figure 10), also reported by [10] for the Tibetan Plateau between 1988–2013, and lowest in the pre-monsoon season also reported by Shrestha et al. [7] in Nepal. The mean increasing rate in monsoon, winter, pre-monsoon and post-monsoon were 0.040°C , 0.036°C , 0.034°C and $0.032^{\circ}\text{C year}^{-1}$, respectively, and those values were statistically significant at 95% significance level. Warming rates in all seasons were consistent with observations made by Shrestha et al. [7], Khatiwada et al. [8], Liu et al. [24] at the basin scale and regional scale. Significant warming trends were observed at five out of six stations in the monsoon, winter and post-monsoon seasons and at four of six stations in pre-monsoon season (Table 4). Significant warming trend in winter is because of decreasing number of winter days which is also mention by Devkota [54] in his study. Warming trends during pre-monsoon, monsoon and post-monsoon were could be because of changes in monsoon onset time. Study presented by Sirvastava et al. [55] also indicates changes in monsoon time and its impacts on temperature trend.

Figure 9. Monthly average temperature variance at a different station.

Table 4. Mean seasonal temperature trend ($^{\circ}\text{C year}^{-1}$) in Narayani River basin at six different stations from 1970–2015. ‘*’ represents statistically significant at 95% significant level.

4.4. Temperature Gradients

Temperature gradients were calculated using temperature data from different elevations within the basin. A gradual decrease of mean annual temperature from south to north was observed from six stations at different elevations. The mean annual temperature was highest at Chapkot station (460 m a.s.l.) and lowest at Langtang station (3800 m a.s.l.). The lapse rates were calculated from linear regression between mean temperature and elevation and were found to be $-0.0060^{\circ}\text{C m}^{-1}$ with high value of coefficient of determination (Figure 11), which is similar to values reported by Baral et al. [25],

Immerzeel et al. [19], Takahashi [56] in the Langtang Valley of the same basin. Steepest temperature gradient ($-0.0064\text{ }^{\circ}\text{C m}^{-1}$) was observed during the pre-monsoon season is also consistent with observations from Baral et al. [25], Immerzeel et al. [57] in Langtang Valley, a mountainous part of Narayani basin. The largest ($-0.0052\text{ }^{\circ}\text{C m}^{-1}$) and least negative temperature gradient was observed during the winter season, whereas post-monsoon and monsoon season had the same value of lapse rates ($-0.0062\text{ }^{\circ}\text{C m}^{-1}$). However, very high lapse rates of $-0.0013\text{ }^{\circ}\text{C m}^{-1}$ and $-0.0009\text{ }^{\circ}\text{C m}^{-1}$ for the monsoon and winter season, respectively were reported by Chand et al. [58] between Langtang station and Lirung debris-covered glacier located at about 4100 m a.s.l. The discrepancies between different seasons were due to differences in relative humidity [57] and incoming solar radiation [25]. It may be further influenced by the wind circulation direction in different seasons, which may vary according to land use type [59]. The more gradual gradients of temperature between the debris-covered glacier and low land areas were due to the strong influence of surface heating during daytime to near-surface air temperature [58]. It indicates a strong relationship between temperature and elevation and is useful for prediction of temperature for high mountain areas, where there is lack of observation.

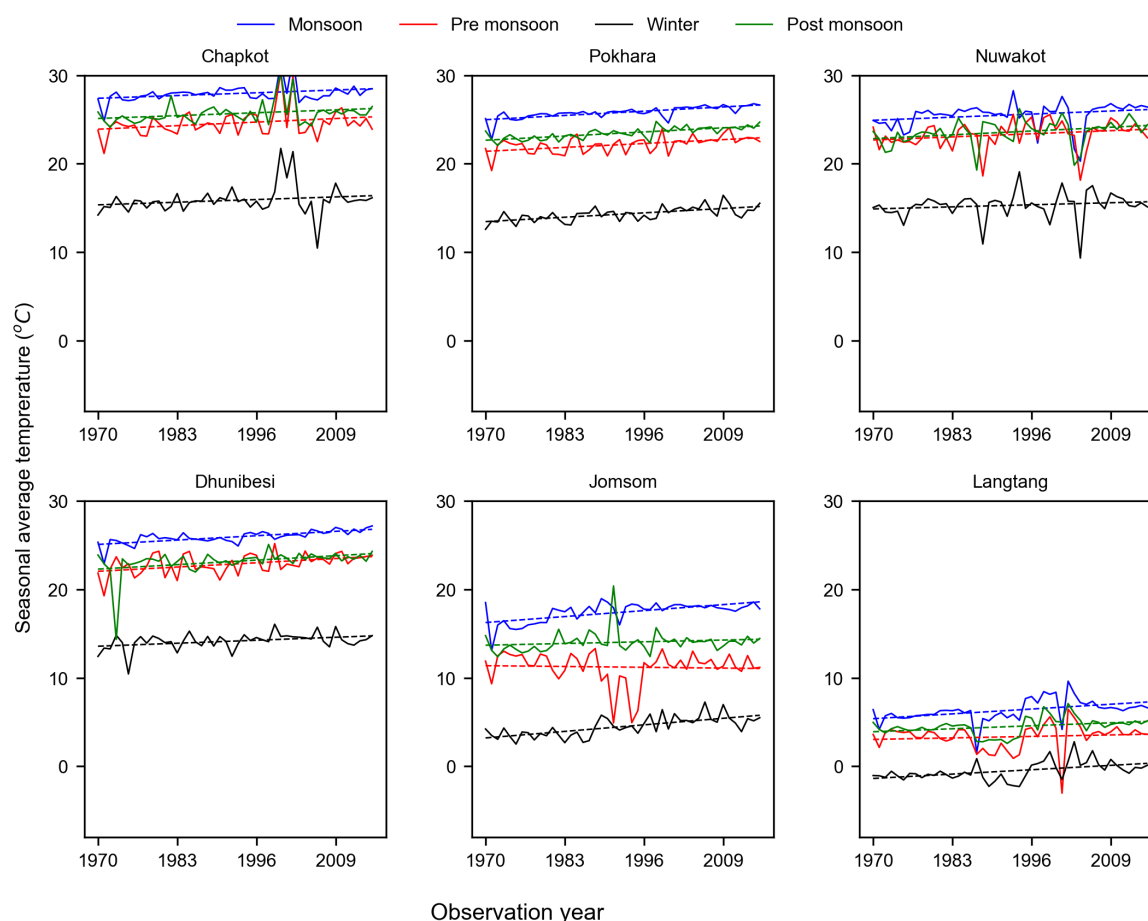

Figure 10. Historical mean seasonal temperature trend in Narayani river basin for six stations.

4.5. Comparison of Station Data With Freely Available Global Climate Datasets

Comparison of the mean monthly temperature from different modeled datasets (GLDAS 2.0, CHELSA 1.2) shows little difference in mean monthly temperature at Pokhara and Chapkot (Figure 12). Mean monthly temperatures were found to be lowest from GLDAS 2.0 for Jomsom and from CHELSA 1.2 for Pokhara and Nuwakot. There is no significant difference between mean monthly temperature values from WorldClim 2.0 (1970–2000) and station data (1979–2013). Data from WorldClim is closest

in agreement with station data which is quite obvious as WorldClim 2.0 is principally based on station data.

MAAT values were estimated using monthly temperature values for all six locations using Worldclim 2.0, CHELSA, station data set (1970-2000), station data set (1979-2013), station data set (2001-2010) and GLDAS 2.0 data set (2001-2010) (Figure 13). It can be observed that MAAT value obtained from station data set (1970-2000), station data set (1979-2013) and station data set (2001-2010) are similar for all locations. Compared to GLDAS 2.0 and Chelsa, MAAT obtained using WorldClim 2.0 is closer to the values obtained from station data set for Dhunibesi, Jomsom, Chapkot and Langtang. Large variations in MAAT values from different data set is observed for Jomsom, Nuwakot, and Dhunibesi.

Figure 11. The mean temperature at six stations plotted against elevation for the entire period (1960–2015), winter, post-monsoon, pre-monsoon and monsoon period.

Monthly temperature curves obtained from MODIS land surface temperature dataset for 2014 and 2015 show that there exists a significant difference between mean monthly LST daytime and LST nighttime temperatures at all stations suggesting noteworthy diurnal variations of temperature at these locations (Figure 14 and 15). Mean monthly LST nighttime temperature were missing for the monsoon month of July in Nuwakot and August in Pokhara and Dhunibesi. Similarly, mean monthly LST nighttime temperature was missing for the monsoon month of July 2014 in Chapkot and Pokhara as well. These missing values are possible due to presence of cloud cover affecting observations from MODIS satellites. Mean monthly LST nighttime temperatures were often the lowest among all datasets at all stations except Jomsom and Dhunibesi for 2014 as well as 2015. Mean monthly temperatures from LST (average) and station data were quite similar for Jomsom and Pokhara for 2014–2015. Mean monthly temperatures from LST (average) and GLDAS 2.0 were quite similar for Chapkot for 2015–2015.

Linearly fitted trend lines in scatterplots between mean monthly averages and MAAT values from WorldClim 2.0 and station data (1970–2000) show very strong correlation ($R^2 > 0.95$) between the two datasets for all stations (Figure 16).

Linearly fitted trend lines in scatterplots between mean monthly averages and MAAT values from CHELSA 1.2 and station data (1979–2013) also show very strong correlation ($R^2 > 0.94$) between the two datasets for all stations (Figure 17).

Linearly fitted trend lines in scatterplots between mean monthly averages from GLDAS 2.0 (2001–2010) and station data (2001–2010) show very strong correlation ($R^2 > 0.94$) between the two datasets for Jomsom, Dhunibesi and Pokhara while a reasonably strong correlation between the two datasets for Nuwakot ($R^2 = 0.78$) and Chapkot ($R^2 = 0.73$) (Figure 18).

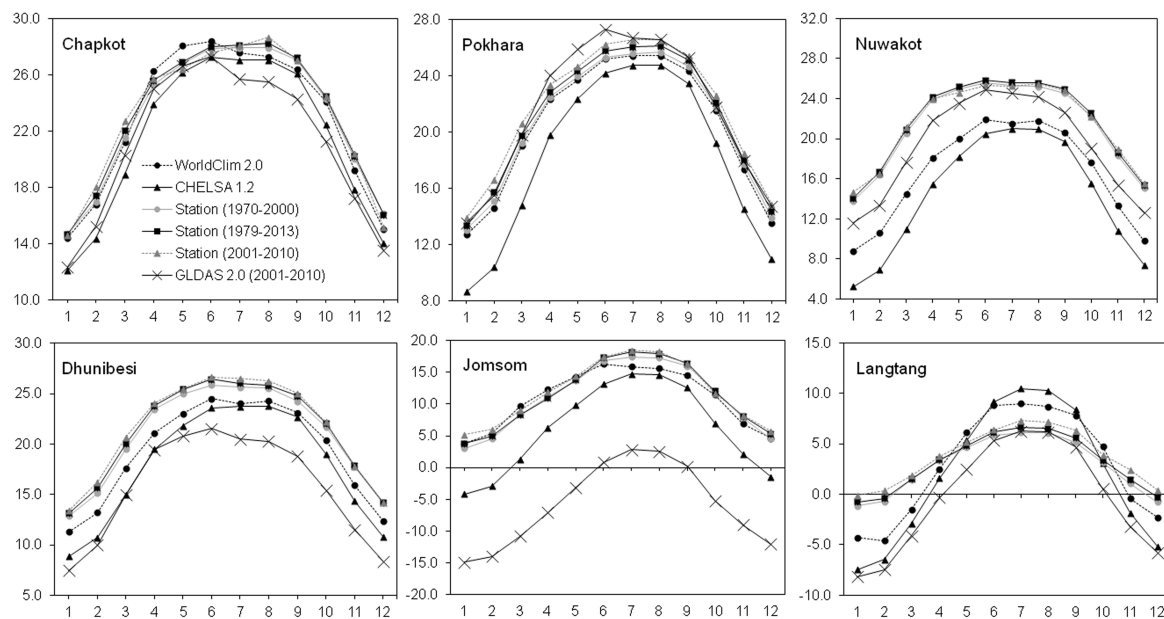

Figure 12. Comparison of mean monthly temperature from WorldClim 2.0, CHELSA Version 1.2, station data (1970-2000), station data (1979-2013), station data (2001-2010) and GLDAS 2.0 datasets. The numbers 1-12 in X-axis represent months in a year where 1 means January and 12 means December. Values in Y-axis represent temperature in degree Celsius.

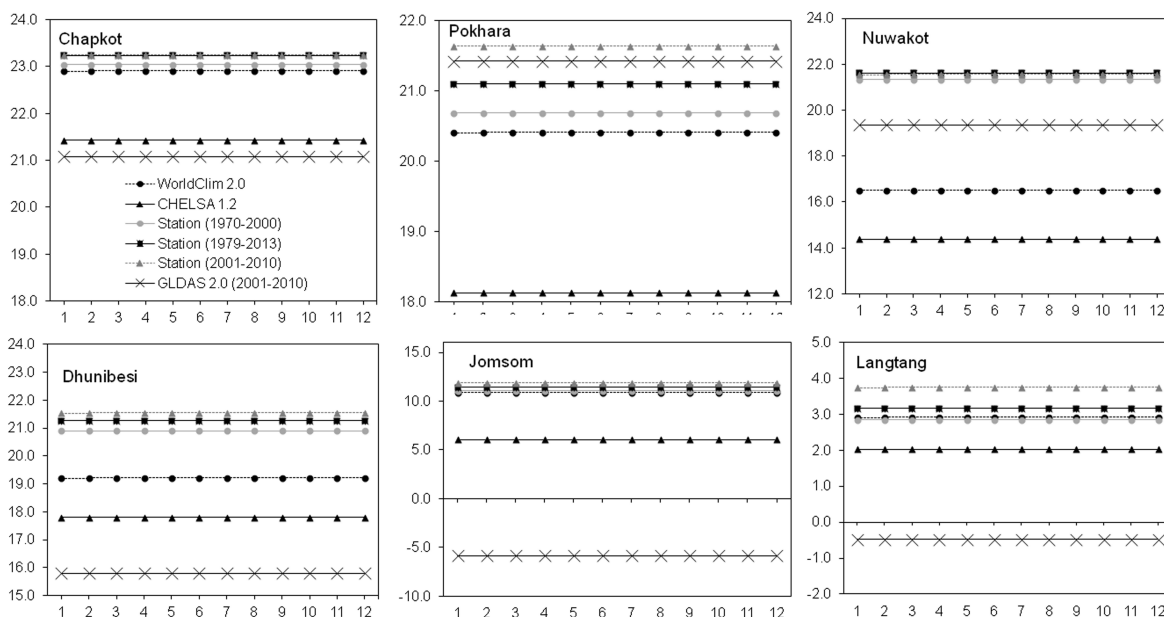

Figure 13. Comparison of MAAT from WorldClim 2.0, CHELSA Version 1.2, station data (1970-2000), station data (1979-2013), station data (2001-2010) and GLDAS 2.0 datasets. The numbers 1-12 in X-axis represent months in a year where 1 means January and 12 means December. Values in Y-axis represent temperature in degree Celsius.

Linearly fitted trend lines in scatterplots between mean monthly averages from MOD11A2 LST average of daytime and nighttime values (2015) and station data (2015) show a very strong correlation ($R^2 > 0.94$) between the two datasets for Nuwakot, Chapkot and Dhunibesi, a very strong correlation ($R^2 > 0.89$) between the two datasets for Jomsom ($R^2 = 0.89$), while reasonably strong correlation between the two datasets for Pokhara ($R^2 = 0.79$) and Langtang ($R^2 = 0.76$) (Figure 19). Similarly, mean monthly averages from MOD11A2 LST of daytime and nighttime values (2014) and station

data (2014) also showed a very strong correlation ($R^2 = 0.90$) for Pokhara ($R^2 = 0.93$), Nuwakot ($R^2 = 0.90$), Dhunibesi ($R^2 = 0.95$), Chapkot ($R^2 = 0.88$) and Langtang ($R^2 = 0.85$), while reasonably strong correlation for Jomsom ($R^2 = 0.78$).

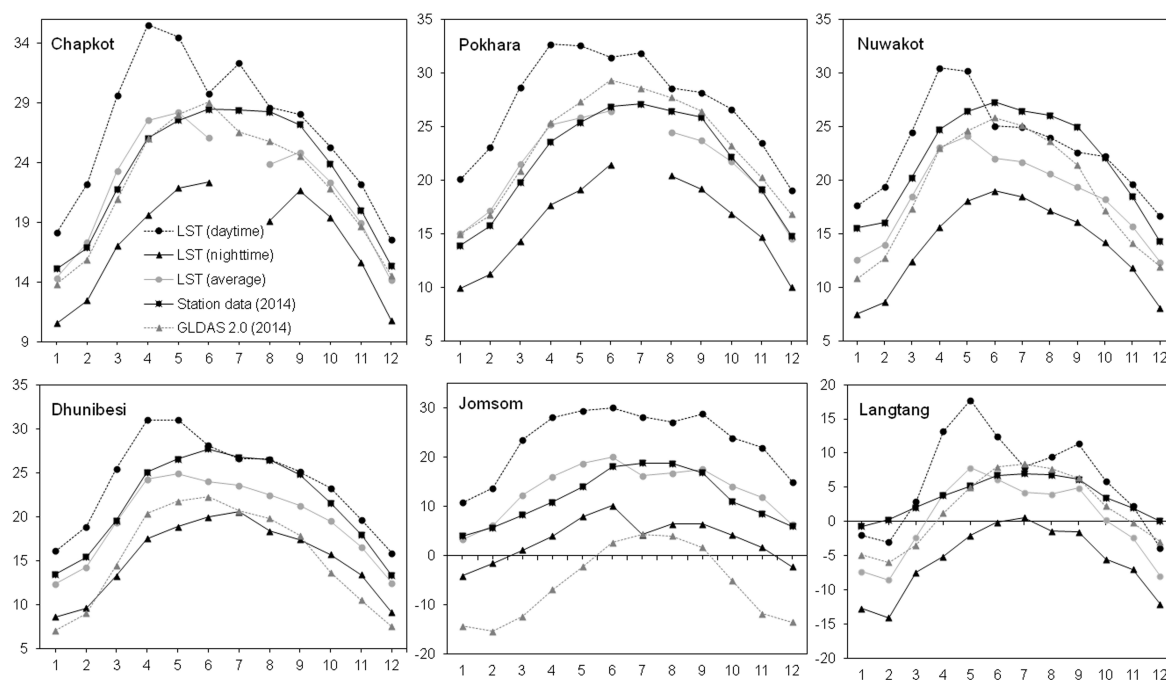

Figure 14. Comparison of LST (daytime), LST (nighttime), LST (average), station data (2014) and GLDAS 2.0 data (2014) for all six stations. The numbers 1-12 in X-axis represent months in a year where 1 means January and 12 means December. Values in Y-axis represent temperature in degree Celsius.

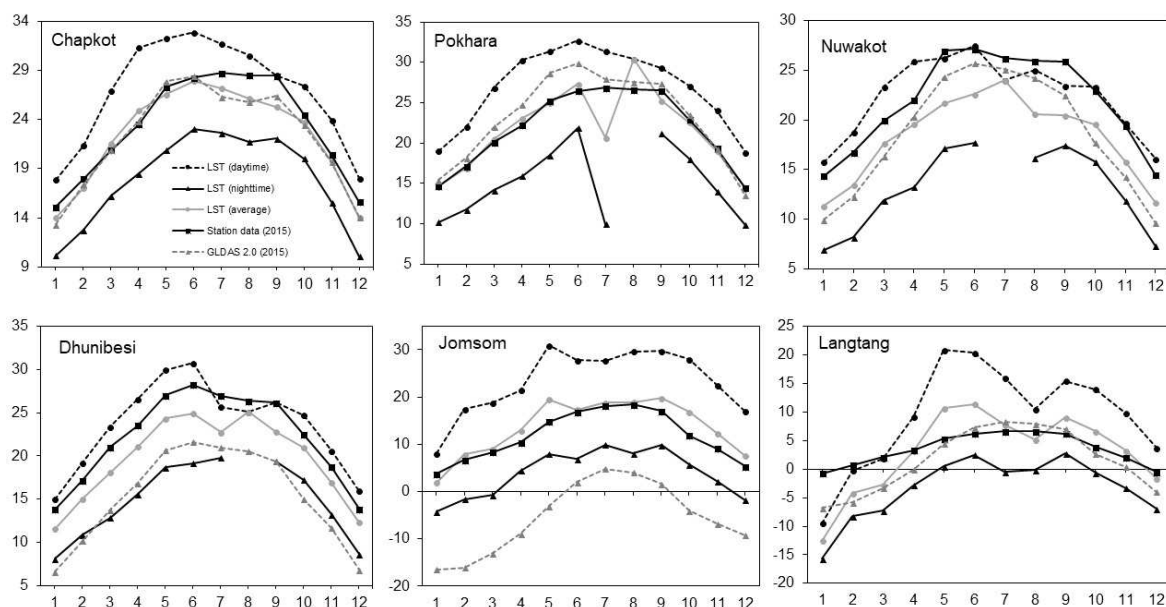

Figure 15. Comparison of LST (daytime), LST (nighttime), LST (average), station data (2015) and GLDAS 2.0 data (2015) for all six stations. The numbers 1-12 in X-axis represent months in a year where 1 means January and 12 means December. Values in Y-axis represent temperature in degree Celsius.

Overall, the gap-filled data after interpolation is in good agreement with climate datasets from different freely available sources. The consistency between gap filled data set and freely available climate data set justifies the procedure for gap filling which is usually necessary for the mountain regions where malfunctioning of weather stations is usually frequent. This also shows that freely available climate data sets are very good alternatives for remote areas which are otherwise lacking data set from well monitored weather stations.

Figure 16. Scatterplots between WorldClim 2.0 and station dataset (1970–2000) for all six stations with fitted linear trend lines. Values in X-axis and Y-axis represent temperature in degree Celsius. The equation of linear regression and R-squared values for all six stations were shown in the figure.

Figure 17. Scatterplot between CHELSA 1.2 and station dataset (1979–2013) for all six stations with fitted linear trend lines. Values in X-axis and Y-axis represent temperature in degree Celsius. The equation of linear regression and R-squared values for all six stations are shown in the figure.

Figure 18. Scatterplot between GLDAS 2.0 and station dataset (2001–2010) for all six stations with fitted linear trend lines. Values in X-axis and Y-axis represent temperature in degree Celsius. The equation of linear regression and R-squared values for all six stations are shown in the figure.

Figure 19. Scatterplots between MOD11A2 LST (average) and station dataset (2015) for all six stations with fitted linear trend lines. Values in X-axis and Y-axis represent temperature in degree Celsius. The equation of linear regression and R-squared values for all six stations are shown in the figure.

5. Conclusions

This study contributes to the understanding of annual and seasonal temperature trends for the last fifty years (1960–2015) and several intermediate periods in the Narayani river basin of Nepal. It also demonstrates that the application of simple and multiple linear regression methods with ordinary least squares assumption is efficient to fill gaps in temperature datasets. Gap-filled daily mean temperature

dataset is prepared for the duration 1960–2015. Further, this study applied EMD to identify the trend break and Mann-Kendall test to assess the mean temperature trend. Strong to very strong correlation between the gap-filled data after interpolation with temperature datasets from different freely available sources enhances the reliability upon the gap-filling procedure. Simultaneously, it also suggests that freely available temperature data sources can be equally useful for studies in mountain river basins where station-based data sources are scarce.

Based on analysis of long-term temperature datasets from six different stations located within the Narayani River basin, this study observed the following:

1. The mean annual temperature trend shows a trend break in 1970s for most of the stations. After 1970s, the mean temperature increased at a statistically significant rate in the majority of stations.
2. The rate of increase of mean annual temperature ranges from 0.028 °C to 0.035 °C year⁻¹ with mean warming trend of 0.03 °C year⁻¹.
3. The highest increase in annual temperature is recorded in monsoon season followed by winter season, post-monsoon season and pre-monsoon season, respectively.
4. The temperature lapse rate with altitude is 0.006 °C m⁻¹ in the Narayani River basin with the steepest value in pre-monsoon season.
5. The lapse rates calculated here are useful for temperature prediction in the higher Himalayan region where observations are scarce.

In general, an increasing trend of temperature which is higher than the global average makes glaciers and snow-covered areas in this region vulnerable to widespread melt which has significant impacts on the hydrological cycle. In this study, six stations were assumed as representative stations for the whole basin as they are located at different elevations and physiographic zones, however, inclusion of other available observed, reanalysis, and satellite datasets for this basin can be very useful to represent each micro-climatic zone within this basin.

Author Contributions: M.B.C. and B.C.B. designed the analysis. M.B.C. and B.C.B. performed the experiments, and analyzed the data. M.B.C. and B.C.B. wrote the manuscript with input from Prashant Baral and Niraj Shankar Pradhananga.

Acknowledgments: We are thankful to the Department of Hydrology and Meteorology, Government of Nepal (DHM, GoN) for providing a massive data.

Conflicts of Interest: The authors declare that they have no conflict of interest.
