Abstract

Background: While controlling the COVID-19 pandemic has been the primary objective worldwide, its effect on human behavior, altered lifestyles, and in turn, the impact on chronic non-communicable diseases cannot be ignored. Ten months into the pandemic, much-published literature has emerged on altered lifestyles following the lockdown measures imposed by governments all over the world to control the virus spread.

Objective: In this narrative review, we explore the impact of lockdown measures on the six lifestyle factors – namely, diet, physical activity, sleep, stress, social connectedness, and the use of tobacco, alcohol, or other harmful substances.

Methods: We searched PubMed and the World Health Organization's global literature database on COVID-19 and included 298 articles. Using a meta-ethnographic approach, we provide an interpretative synthesis of relevant articles.

Results: Among the six lifestyle factors, most of the retrieved articles focused on stress, emotional well-being, and physical activity. Fewer articles discussed alterations in dietary habits, sleep patterns, and the use of tobacco, alcohol, and other harmful substances. Most of the articles included in our review identified the negative effect of lockdown measures on each of the lifestyle factors in many parts of the world. Interestingly, encouraging lifestyle trends were also highlighted in a small number of articles included in our review. Such trends can positively influence the outcome of lifestyle-related chronic diseases, such as obesity and diabetes.

Conclusions: These unprecedented circumstances provide an opportunity to better understand the negative impact of strict lockdown measures on lifestyles, and at the same time, help identify and initiate positive behavioral changes, which if consolidated, may improve chronic disease outcomes in the long run. It would be up to governments, communities, and academia to learn - and benefit from lessons learned from the COVID-19 pandemic - with the ultimate objective of better educating and promoting healthy lifestyles among communities.

Keywords: COVID-19, Lifestyle, Diet, Physical activity, Stress, Smoking, Substance, Alcohol, Emotional well-being, Social connectedness

Background

The ongoing COVID-19 pandemic has caused thousands of deaths, overloaded health systems, and disrupted social and economic infrastructure worldwide. While the world remains focused on controlling the pandemic, its impact on lifestyles and in turn, on chronic non-communicable diseases (NCDs) which account for over 70% of the global mortality, cannot be ignored. COVID-19 controls, requiring people to stay at home and practice physical distancing to prevent transmission, call for greater attention to lifestyle factors and understanding their effect on NCDs.

Various degrees of lockdown measures, including restricting travel and movement, have helped reduce the virus spread. However, these measures also diminish the access and attraction of people to healthy food; widen inequities between communities; result in suboptimal physical activity levels; exacerbate anxiety and stress; impair the quality of optimum sleep; and, encourage substance abuse to allay anxiety and fear of the disease¹. A large body of published literature has emerged on altered lifestyles since the onset of the pandemic. To our knowledge, there is no synthesis of this emerging literature on altered lifestyle factors during the pandemic.

Given the wide scope of lifestyle-related factors, we conducted a narrative review to help understand these further in the realm of COVID-19. We aim to synthesize the alteration (positive or negative) in lifestyle factors among individuals and communities owing to the effects of lockdown measures implemented by various countries. This narrative review can be an instructive and valuable source for stakeholders interested in weighing the effect of lockdown measures on lifestyles. Additionally, it can inspire further research in the emerging field of lifestyle medicine and its potential effect before, during, and after pandemics such as COVID-19. For the purpose of our review, we recognize the American College of Lifestyle Medicine (ACLM) definition of a healthy lifestyle that includes eating a predominantly plant-based diet, being physically active, sleeping well, managing stress, remaining socially connected, and refraining from the use of tobacco, alcohol, and other harmful substances. When optimally practiced, these six lifestyle factors can prevent, treat, and in some cases even reverse chronic disease. Our narrative review will focus on these six lifestyle factors and how they may have been altered during the COVID-19 pandemic.

Methods

We conducted the narrative review utilizing a *best-evidence synthesis* approach put forward by Green et.al². A successful narrative review following this approach is expected do the following: “present information that is written using the required elements for a narrative review, be well structured, synthesize the available evidence pertaining to the topic, and convey a clear message”². Following the Scale for the Assessment of Narrative Review Articles (SANRA)³, we have reported our methodology with the checklist included as Appendix 1.

Search strategy

The search strategy included both keywords, as well as controlled vocabulary (such as MeSH terms). The keywords included the following: COVID-19 AND (lifestyle OR dietary habits OR physical activity OR sleep OR tobacco OR alcohol OR substance OR stress OR relationships) AND (lockdown OR quarantine OR isolation). We searched using these terms in PubMed and the World Health Organization (WHO) global literature database on coronavirus disease with no restrictions on language, geography, or publication date. The reference lists of the retrieved articles were scanned for additional articles relevant to our review.

Inclusion and exclusion criteria

We included all articles that discussed lifestyle in the context of the COVID-19 pandemic. The review focused on the six lifestyle factors included in the definition of a healthy lifestyle by the American College of Lifestyle Medicine.

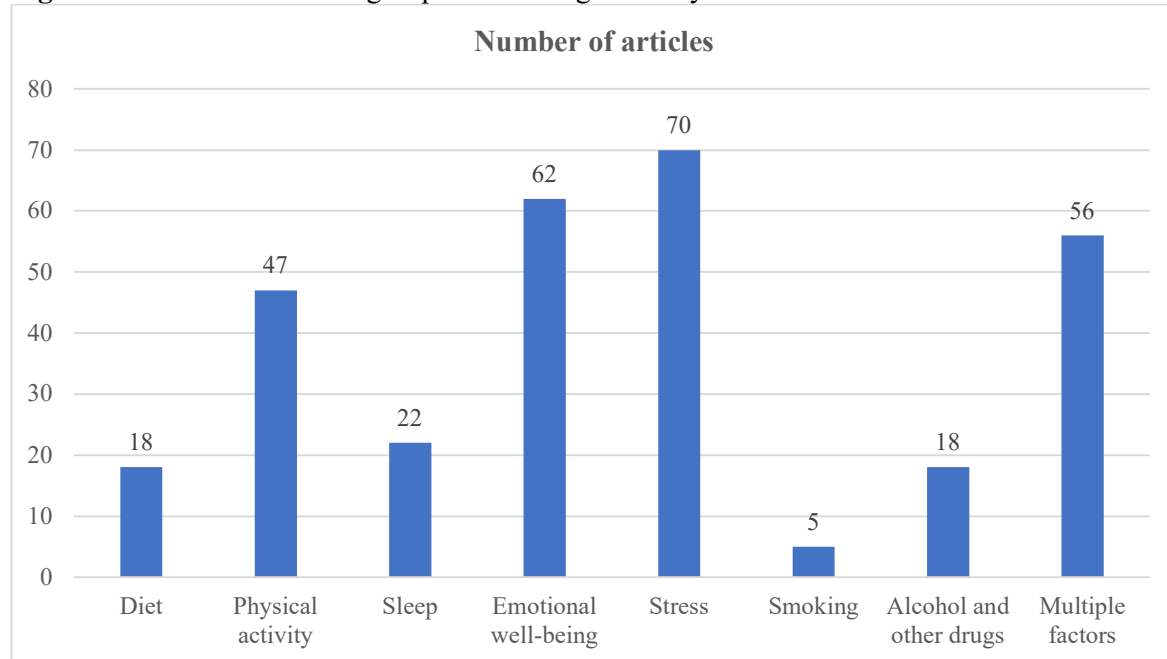

Articles were excluded if they did not focus specifically on any of the six lifestyle factors and did not discuss about lifestyle within the COVID-19 context. Additionally, we excluded published literature describing modelled effects of lockdown during COVID-19.

Information extraction

Identified articles meeting our inclusion criteria were imported into Endnote X9⁴. One reviewer screened the title and abstract of the identified articles. From the included articles, the authors extracted qualitative and quantitative information on the COVID-19 related lockdown and its effects on six lifestyle factors (diet, physical activity, stress, connectedness, sleep, and tobacco or other substance use). For primary studies with quantitative data, we paid specific attention to the study design, results, and the conclusion. For articles other than primary studies, we focused on the discussion and conclusion sections. For the qualitative studies, opinions/perspectives, and viewpoints, we have taken a meta-ethnographic approach to provide an interpretative synthesis. Though the ACLM definition combines smoking, alcohol, and substance use as one lifestyle factor, we looked at them separately to explore them in greater depth. When articles studied more than one lifestyle factor and discussed the impact of lockdown measures on patients with pre-existing NCDs, we grouped them under articles that discussed multiple factors. The information extracted from the included articles was classified according to the six lifestyle factors and summarized below:

Results

Our original search yielded a total of 1286 articles. After title, abstract and full-text screening, 298 articles were found to be relevant to the scope of our narrative review. Figure 1 shows the number of relevant articles discussing various lifestyle factors. Among the six lifestyle factors, the retrieved articles predominantly focused on stress, emotional well-being, and physical activity. A smaller number of studies were identified for change in dietary habits, sleep patterns, and the use of tobacco, alcohol, and other harmful substances. Articles with quantitative data are referred to as ‘studies’ in the manuscript. Such data was available in 160/298 (54%) of the included articles

Figure 1. Number of articles grouped according to lifestyle factors

Dietary habits

Most of the literature included in our narrative review with reference to dietary habits indicates an alteration in the eating behaviors of people in many parts of the world. Most survey-based studies report an increase in the intake of unhealthy foods by the majority of respondents, while a small number demonstrate a higher intake of healthy foods. A Polish study including 2,381 participants found that 34% of respondents reported eating more during the lockdown⁵, while another study from the same country involving 1,097 participants found 30% of the participants reported weight gain during the lockdown⁶. Whereas, among 3,533 respondents from Italy, 46.1% reported consuming more food and 19.5% had gained weight⁷. Staying home has limited access to fresh vegetables and fruits, particularly in the most vulnerable and poorest sections of the society due to limited availability, accessibility, and affordability^{5,8}. In richer households, staying home encouraged excessive use of unhealthy foods, such as processed and fast foods in many parts of the world^{6,9,10}. An Italian study reported an increased uptake of ‘comfort foods’ including chocolates and ice-creams used by participants to allay anxiety caused by the lockdown⁷. Additionally, to overcome boredom, some people turned towards snacking which led to excessive weight gain relatively quickly^{6,7,11}.

Interestingly, in some situations staying home encouraged many individuals to eat fresh home-made food, as evidenced by the reduction in the purchase of ready-made meals and by the dominance of in-person grocery shopping as the major source of food and food purchases^{7,12}. A large study of 7,514 participants from Spain found residents reporting a higher intake of fruits, vegetables, or legumes. The study participants were predominantly young university educated females¹³. Gender (females faring better), family members staying at home, (less) TV watching while eating, geography, and (higher) maternal education have been determined to be factors influencing healthy food intake¹⁴. In our review, we found that individuals who were overweight/obese pre-pandemic gained more weight, while the undernourished lost more weight⁶. Studies also report that individuals with eating disorders diagnosed prior to the

lockdown fared worse during the lockdown period due to low self-directedness and less adaptive coping^{9, 15}.

Physical activity

The lockdown period saw a general reduction in physical activity levels as evidenced from the studies included in our review. A study from China of 339 participants revealed a significant reduction in the average exercise intensity for both males and females during the lockdown period (average steps per day: before vs during 7038 ± 1923 vs 3741 ± 1042 step, $P < 0.001$ and 8321 ± 3000 vs 3728 ± 1726 step, $P < 0.001$ for female and male, respectively)¹⁶. A similar observation was also made in Italy where 68% of participants in a study with a sample size of 490 adults reported a decrease in their exercise levels¹⁷. 43% of respondents in a Polish study sample of 2381 also reported a reduction in their physical activity during the lockdown period. An international, multi-country online survey of 1,047 participants found that the number of days per week of all physical activity declined by 24% during the lockdown period. The number of minutes per day spent on physical activity decreased by 33.5% while the sitting time had increased 5-8 hours among the respondents⁹. The working from home environment has predisposed individuals to spend more time sitting, leaning, reclining or lying down on the bed⁹. There is no predictable pattern as to who were less active during the lockdown period. While some studies found previously physically active individuals became less active during the lockdown period^{18, 19}, other studies found no change¹⁸, or further reduction in physical activity among previously inactive individuals²⁰. A cross-sectional study across 64 cities in China with 369 participants, concluded that previously physically active individuals were in greater distress as a consequence of the lockdown²¹. It was also observed that older people, those who were used to exercising in groups, and others who were not accustomed to online apps (which support exercise routine), suffered more with the reduction in physical activity levels¹⁹.

Lockdown has also provided an opportunity to be creative in finding ways to stay physically active. In South Korea, for example, it was observed that the public bicycle sharing system recorded an increase in the commuters and weekend users²². It is, however, to be noted that such initiatives require commitment from the citizens and authorities in ensuring adherence to physical distancing, hand hygiene, use of facemasks, and cleaning of public facility/site surfaces. Staying physically active in home environments is possible and its feasibility has also been shown during the lockdown period in countries like Japan²³. Studies done during the COVID-19 pandemic have reconfirmed that individuals who remained physically active during the lockdown period had lower odds of suffering from stress, anxiety, and depression²⁴.

Sleep

Stay-at-home restrictions made many people experience insomnia as evidenced from the studies included in our review. In a large cross-sectional study across France, two weeks after the lockdown, 74% of the 1,005 nationally representative participants reported trouble sleeping when compared to 49% in the last survey pre-lockdown²⁵. A study including 400 university students and administrative staff in Italy found 40% of the respondents suffering from insomnia while 15% specifically had trouble in sleep initiation²⁶. Factors found to be associated with disturbed sleep were increased blue light exposure from extended screen time scanning for COVID-19 updates, browsing the internet to keep busy, and working remotely from home^{25, 27}. Respondents in some studies reported sleeping more during the lockdown period. Even among those who slept more, the reported sleep quality was poor^{28, 29}. Those who slept more also reported experiencing sleepiness during the day and increased daytime sleep duration in a

study on 203 corporate professionals and 325 university students in India³⁰. In the same study, it was also observed that females, younger people, and those experiencing loneliness and COVID-19 related worries had greater difficulty with sleep³⁰. One study reported an increased frequency in the uptake of sleeping pills²⁵. Increased stress due to COVID-19, information overload, inconsistent bedtime, and low mood are all contributors to insomnia and its harmful effects on health³¹.

Individuals with previously erratic sleep patterns and social jetlag, on the other hand, were provided with an opportunity to normalize their sleep patterns and improve sleep hygiene for optimum functioning as indicated by a few studies³²⁻³⁴. One study from the United States of America found that the reduced rigid workload and school schedules actually led to improvement in the overall sleep quality for some individuals³⁵.

Substance use

Tobacco

While studies on smoking behavior during the COVID-19 lockdown period were few, we found a mixed pattern in the available studies. A cross-sectional study involving 345 American participants found half of the respondents retaining their pre-lockdown level of smoking, a quarter of them reducing their smoking levels, and the rest actually increasing the amount³⁶. The same study also found that while 20% of respondents showed an increased motivation to quit, 15% showed a reduction in motivation³⁶. In a multi-country study involving 6,800 combustible and e-cigarette users from Italy, India, South Africa, the United Kingdom (UK), and the United States of America (USA), indoor smoking had increased in India and Italy, thereby increasing the risk of secondhand smoke exposure among family members³⁷. There was a wide variation in people's beliefs from the countries in this study pertaining to the association of smoking with COVID-19. In India, a substantial proportion of the respondents believed that smoking increased the risk of COVID-19, while in Italy, the majority of those surveyed believed that there was no relation between COVID-19 risk and smoking. Results from other countries were inconclusive. Anxiety, boredom, and stress as experienced by many people during COVID-19 contributed to increased smoking in some individuals^{6, 38}.

Despite many deterrents, motivated individuals saw the lockdown period as an opportunity to become healthy and quit smoking³⁹. The motivation to quit was more discernible among those who smoked tobacco cigarettes than electronic cigarettes³⁶. Smokers who had a family member or someone close to them suffer from COVID-19 displayed a greater motivation to quit³⁶. Many parents ideally want to appear on their best behavior in front of their children and it is postulated as one of the reasons for them to cut down on their cigarette intake while spending more time at home⁴⁰.

Other harmful substances

Among other substances that cause dependence, alcohol stands out as one of the most commonly used psychoactive substance during the lockdown period⁴¹, in spite of alcohol supply not being assured in many countries. A study from India documented that alcohol shop closures led to alcohol-dependent individuals experiencing withdrawal symptoms and suicides⁴². Where alcohol was available, people resorted to increased alcohol intake to overcome adverse psychological outcomes of the lockdown including stress and insomnia⁴³. Data from the Office for National Statistics in the UK demonstrates that alcohol sales rose by over 30% in month on month volume. In a survey of 6,416 people from China, 32% of regular alcohol drinkers reported increasing their consumption during the lockdown period⁴⁴. Interestingly, in a survey of 1,555 people in the UK, one-third reported that they had stopped or reduced

drinking during the lockdown while one-fifth drank more frequently during the same period ⁴⁵. A large study from Australia found that people who prior to the pandemic were heavy drinkers, middle-aged, and had higher incomes, increased their drinking during the pandemic ⁴⁶. This study also found that individuals who had experienced recent job loss, those who were stressed/depressed and had altered eating and sleep habits consumed larger amounts of alcohol. It was identified that those who consume alcohol found it more difficult to cope with the mental health impact of the pandemic and the associated lockdown ⁴¹.

In addition, the European Monitoring Centre for Drugs and Drug Addiction determined that people using drugs may face additional risks during the crisis, particularly because of the ageing cohort of opioid users and the associated comorbidities ⁴⁷. Though the data is sparse at the present time, most experts agree that movement restrictions reduced the availability of illicit drugs ⁴⁸, thereby increasing the demand for de-addiction services. Limited availability of these services added to the despair of the addicted population. There was one study from France, however, which found an increase in cannabis use among 31.2% (195 of 620) of regular cannabis users making up 5.44% (620 of 11,391) of total participants, increased usage. ⁴⁹

Stress

Watching, reading, or listening to the constant stream of COVID-19 related news led to increased anxiety among individuals and families ⁵⁰. A study from China reported the psychological impact of COVID-19 expressed as mild-to-severe anxiety among 25% of 7,143 college students ⁵¹. 65% of 432 respondents in another study from Hong Kong reported clinical levels of depression, anxiety, and/or stress. Older adults, especially those in isolation and with cognitive decline, were identified to be more prone to anxiety, stress, and depression ⁵⁰. Articles also suggest that quarantined healthy adults suffer from symptoms of ill mental health like post-traumatic stress, anger, and confusion ⁵². We found few studies that were able to make a clear distinction between the stress levels experienced by the general population as part of the community quarantine vs. those who were quarantined as part of contact tracing or after testing as COVID-19 positive. Few studies also seem to suggest greater stress experienced by both those under isolation ⁵³ and others under home quarantine as part of contact tracing ⁵⁴. One study from China, however, found that home self-quarantine was associated with an increased happiness as compared to those who were in community quarantine ⁵⁵.

Stress levels have been higher in some groups, such as ,women (particularly pregnant women), older people (particularly with pre-existing mental health conditions), the economically deprived, and those with chronic medical conditions ^{50, 56-58}. Extreme stress driven by the fear of COVID-19 infection, financial crisis, loneliness, pressure to quarantine and isolate when positive, and the unavailability of alcohol have been identified as drivers of suicidal ideation and suicides during the pandemic and the associated lockdown ^{59,60}. A healthy diet and refraining from reading updates about COVID-19, were very often shown to be the best predictors of lower levels of anxiety and depressive symptoms ⁶¹.

Emotional wellbeing and social connectedness

Restriction of movement during the pandemic has led to significant reduction in social activity among family, friends/neighbors, and for entertainment ^{62, 63}. This reduction contributed to diminished life satisfaction in over 30% of participants in a large, multi-continent study involving 1,047 participants ⁶³. Prolonged social media use has had a deleterious effect on the overall social well-being of individuals as reported by a study in Saudi Arabia ⁶². Studies have found that the lack of social interaction has a more profound effect on people with higher income and education ⁶². Lack of social interaction also has a negative impact as more time

passes for older people, as evidenced by a large cross-sectional study in the UK ⁶⁴. Children have reported being more restless, irritable, and inattentive during the lockdown with increased screen time being the likely contributor ⁶⁵. Girls and women confined to homes and quarantine facilities face increased family tensions, an overload of domestic work, and remain vulnerable to physical and emotional abuse ⁶⁶. Intimate partner violence, characterized by physical, sexual, or emotional violence between partners, is also of concern in these challenging times of staying home and physical distancing ⁶⁷.

Lifestyle of patients with chronic diseases

Studies show that patients with pre-existing, non-communicable diseases have found it difficult to maintain a healthy lifestyle ⁶⁸. Patients with coronary heart disease, diabetes, and cancer have had to compromise on their physical activity routine and dietary pattern in particular ^{69, 70}. In a study from France, 45% of 195 patients with chronic heart disease had >25% reduction in physical activity and 24% of patients had gained >2 kgs of weight ⁷¹. Patients fearful of acquiring COVID-19 infection have also been found to postpone medical care for their chronic problems, leading to greater physical and psychological distress while adding to the suffering of several chronically ill patients ^{56, 68, 72}.

Discussion

Our narrative review highlights altered lifestyles of people worldwide during the lockdown period of the pandemic. Both positive and negative changes in the six lifestyle factors (diet, physical activity, stress, connectedness, sleep, and tobacco or other substance use) have occurred, and their impact has varied in different instances and they are summarized in Table 1. These findings could be instructive to health practitioners and health departments in their strategies to prevent chronic diseases.

For dietary habits, at the start of the pandemic, the United Nations Systems Standing Committee on Nutrition warned that the COVID-19 pandemic would disrupt food systems globally. The committee predicted a deterioration in the nutritional status of individuals due to altered dietary practices ⁷³. Particular concern was expressed over ‘food environments’, with both external (availability and quality) and internal dimensions (accessibility, affordability, acceptability, and desirability) of the food systems ⁷³. Recent observations, nine months after the onset of the pandemic, now appear to confirm earlier fears of malnutrition and disrupted food environments, particularly in disadvantaged communities ⁷⁴. In general, the availability of healthy, plant-based food is ample in well-to-do communities. However, access to such food during the pandemic could be limited, at least in some settings and for specific populations.

Table 1. COVID-19 related lockdown and lifestyle influence

Lifestyle factor	Positive factors	Negative factors
<i>Healthy diet</i>	Home-food	Non-availability of vegetables and fruits; reliance on processed foods
<i>Physical activity</i>	Exploring new opportunities for remaining physically active in a home-environment	Closure of gymnasiums and parks; limited time for physical activity
<i>Sleep</i>	Opportunity to regularize sleep cycle	Excess screen-time and stress
<i>Tobacco, alcohol and substance use</i>	Reduced availability and motivation to quit	Stress, anxiety and boredom increasing use
<i>Emotional well-being</i>	Increased family time	Domestic violence; family tensions; and women abuse
<i>Social connectedness</i>	Opportunity for acts of kindness	Loneliness; social isolation

Lack of access may present health risks--such as lower immunity and adverse chronic disease outcomes--to individuals in those settings.

Alternatively, staying at home has encouraged individuals to eat fresh, homemade food among some populations⁷⁵, likely due to additional time available to cook. Home-cooking not only helps cut down the intake of unhealthy processed and fast foods, but also has proven emotional and health benefits⁷⁶. Further research is needed to understand the motivational factors behind healthy dietary practices during the pandemic and whether pre-pandemic awareness and practices likely led to a positive influence.

It is well known that any amount of physical activity, no matter how little, is beneficial. Sedentary behavior associated with excessive television watching, increased internet browsing time, playing screen games, and using mobile devices are shown to negatively impact chronic disease outcomes⁷⁷. With parks and gymnasiums closed and public movement in the open discouraged, the ability of people to remain physically active has proven to be challenging during the lockdown period. Though the majority of studies have shown a reduction in physical activity levels and increased sedentariness during the lockdown, it is heartening to note that some individuals in select settings have seen an opportunity to be creative in finding ways of staying even minimally active (e.g., gardening, exploring online free exercise routines, and walking up and down the stairs/steps) in a home environment^{19, 78}.

Adequate sleep improves concentration and diligent decision-making. Disrupted and suboptimal sleep on the other hand has been correlated with an elevated body mass index, obesity, metabolic syndrome, and type 2 diabetes⁷⁹. Exposure to blue light also increases night-time heart rate, blood pressure, and core body temperature, and suppresses melatonin and sleepiness. The high prevalence of insomnia and an increase in screen time during the lockdown periods are concerning and a reversal of some of these newfound habits will be

important in order to promote sleep hygiene in communities and reap the benefits of sleep in improving mood, immunity, and overall health and well-being of individuals and communities. Reports of people hoarding cigarettes and alcohol along with food and toilet paper during the early phases of the pandemic are suggestive of the fact that smoking cessation and quitting alcohol may not have been a priority during the lockdown period; our review confirms this. Some smokers wanting to quit may have found accessing smoking cessation clinics a challenge due to suspension of non-essential health services, as have those dependent on alcohol and other psychoactive substances. Getting substance cessation and control programs back on track at local, national, and international levels will require a doubling of efforts as countries start relaxing lockdown measures.

Most of the studies in our review have unequivocally pointed towards high stress levels among populations worldwide. Stress is causally associated with risky behaviors, such as smoking, physical inactivity, and heavy alcohol use, all of which are independent risk factors for chronic diseases—leading to additional concern. However, on the positive side, staying at home provides an opportunity for families to bond and engage in activities at their convenience, which can elicit relaxation and calming responses. Examples of such activities include prayers, meditation, and breathing exercises, all having positive health benefits⁸⁰. Nevertheless, we did not find any studies where communities claimed to be using such positive coping measures to alleviate stress. This may indicate a lack of awareness in communities regarding the importance of healthy lifestyle measures for stress management, as well as, public health professionals/healthcare practitioners not emphasizing the importance of addressing lifestyle-related factors adequately.

More importantly, one cannot deny that of all the altered lifestyle factors, the crucial one has been the loss of connectedness and social networking. This is unfortunate since positive resonance and micro-moments of connectivity encountered in situations of togetherness are associated with health and longevity. Virtual connectivity, though inadequately studied, and small acts of kindness where possible during this period, remain the best measures of improving relationships and connectedness. The lockdown has no doubt led to an increase in family time, at least for nuclear families in most instances. This may have been an opportune time for families to bond and strengthen relationships. One concern of staying home, however, has been reports of increased domestic violence. Future research is likely to provide more answers to the questions surrounding the nature of relationships and domestic activities, and their overall impact—positive or negative—on mental and physical health.

During this period, patients with pre-existing NCDs have suffered both from their inability to maintain a healthy lifestyle and neglect from national health authorities and hospitals with guidance issued to delay routine care and non-urgent procedures. Since an advisory by the US Medicare and Medicaid Centers in mid-March to delay non-urgent procedures, adult patient visits for primary care and gastroenterology services declined by 49% and 61% respectively⁸¹. This could, inevitably, compromise patients receiving timely care. Tapper and Asrani⁸² discuss care in the context of managing patients with liver cirrhosis (a common complication of obesity and diabetes) and suggest three challenging phases in treating patients with chronic disease: 1) the current ‘intense period’ with a delay in routine care 2) a ‘return to the norm’ when physical distancing ends and health systems respond to a backlog of cases, and 3) a ‘protracted period’ of poor outcomes due to unabated disease progression. The world is headed towards a catch-up period with respect to NCDs due to altered lifestyles and concomitant treatment backlog.

The American College of Lifestyle Medicine proposes healthy lifestyle measures to reduce chronic disease risk and improve immunity during this period¹ (Table 2). Though the measures may appear relatively easy and simple enough to implement, many people may not adhere to these recommendations for a variety of reasons, including poverty, lack of education,

unaffordability of technological resources, cramped living spaces, and poor city planning. Governments, health care practitioners and communities should do everything possible to break those barriers and ensure universal access to health lifestyle measures for all.

Table 2. Healthy lifestyle measures to reduce chronic disease risk and improve immunity [1]

- Stress management by practicing techniques like meditation and yoga.
 - Healthy eating focused on a plant-based diet and whole grains.
 - Remaining physically active.
 - Quitting smoking and harmful substances.
 - Optimizing good sleep hygiene.
 - Maintaining social connections virtually like video or phone calls with friends and families.

Strengths and Limitations

This narrative review is a comprehensive analysis of the existing literature on the impact of COVID-19 related lockdown on the lifestyles of people globally. As the review is narrative, we included all the relevant and available published literature on the subject to ensure comprehensiveness. We have not done a quality assessment of each of the publications and instead used data as reported in the articles. Most of the studies included in our review are observational, which is an inherent limitation of the review study design. Despite this general limitation--as is the case with narrative reviews--we do not consider this a major impediment to our research pursuit, as our analysis relies largely on trends and qualitative aspects of data. We also acknowledge that home quarantine, institutional quarantine, community quarantine, and isolation can have different levels of impact on lifestyles, but we did not find adequate number of studies in each category to analyze them separate

Conclusion

COVID-19 has disrupted our lifestyle balance. Based on its rapid assessment of service delivery for NCDs in 163 countries, the World Health Organization has identified that the COVID-19 pandemic could throw the global health progress on NCDs off track ⁸³. This requires that we act as one world and make every effort to promote healthy lifestyles in communities worldwide. COVID-19 will likely redefine conventional public health by placing additional emphasis on healthy lifestyles, disease prevention, and self-care. Given the strong evidence for lifestyle medicine, incorporating lifestyle medicine in day-to-day medical practice is likely to receive worldwide attention. Serious consideration should be given to augment professional health curricula by including topics such as evidence-based public health practices, lifestyle medicine, and building health systems that can address the holistic needs of local populations before, during, and after crisis situations. Also, integrating basic health, infectious disease and lifestyle education in school and undergraduate college education would be a step in the right direction. It would be up to the governments, communities, and healthcare delivery systems to learn and benefit from the lifestyle medicine lessons during and consequent to the COVID-19 pandemic--with the ultimate objective of promoting healthy lifestyles in communities.
