Abstract: The prevalence of cardiometabolic risk factors has increased in Slovakian adolescents as a result of serious lifestyle changes. This cross-sectional study aimed to assess the prevalence of insulin resistance (IR) and the associations with cardiometabolic and selected lifestyle risk factors in a sample of Slovak adolescents. In total, 2,629 adolescents (45.8% males) aged between 14 and 18 years were examined in the study. Anthropometric parameters, blood pressure, and resting heart rate were measured, fasting venous blood samples were analysed, and HOMA-IR was calculated. The mean HOMA-IR was 2.45±1.91 without a significant intersexual difference. IR (cut-off point for HOMA-IR=3.16) was detected in 18.6% of adolescents (19.8% males, 17.6% females). IR was strongly associated with overweight/obesity (especially central) and with almost all monitored cardiometabolic factors, except for TC and systolic BP in females. The multivariate model selected variables such as low level of physical fitness, insufficient physical activity, breakfast skipping, a small number of daily meals, frequent consumption of sweetened beverages, and low educational level of fathers as the significant risk factors of IR in adolescents. Recognizing the main lifestyle risk factors and early IR identification is important in terms of the performance of preventive strategies. Weight reduction, regular physical activity, and healthy eating habits can improve insulin sensitivity and decrease the incidence of metabolic syndrome, type 2 diabetes, and CVD in adulthood.

Keywords: adolescents; cardiometabolic risk factors; insulin resistance; abdominal obesity; lifestyle; nutritional habits

1. Introduction

Cardiovascular diseases (CVDs) are one of the most serious problems related not only to health but also to the social and economic situation in all developed countries of the contemporary world [1], and this unfavorable epidemiological situation is significant in Slovakia as well. CVDs are still the most common chronic diseases and in the long run, they hold a leading position in the causes of death (nearly 50%) as well as in the causes of hospitalization in the Slovak population [2].

CVDs are often considered to be diseases of the elderly, but many epidemiological studies have shown early stages of the atherosclerotic process in childhood and adolescence [3]. At this age, individuals with atherosclerotic lesions cannot be identified by clinical signs only, so attention should be focused on biochemical markers (particularly the blood lipids levels), anthropometric examinations, and blood pressure level measurements, which help to reveal risk indicators of atherogenesis [4]. The youngest age groups should become the target groups of interventions aimed at reducing cardiovascular risk, because childhood and adolescence are extremely sensitive periods

of life in terms of the effects of cardiometabolic risk and the development of atherosclerosis, hypertension, and diabetes in adulthood [5].

Insulin resistance (IR) can be defined as a condition in which peripheral tissues do not respond sufficiently to insulin, which gradually leads to impaired glucose tolerance and later to the development of type 2 diabetes. Insulin resistance can be considered also as a separate risk factor for CVD and is associated with other metabolic diseases. Insulin resistance is a central risk factor for metabolic syndrome (MetS) and stimulates the development of other cardiometabolic risk factors such as dyslipidemia, arterial hypertension, hyperglycemia, and other pathological conditions of the organism. One of the first IR warning signals is the proliferation of adipose tissue as an important endocrine organ, especially in the waist area [6]. Thus, IR is closely linked to abdominal obesity. In addition to abdominal obesity, high levels of fasting insulin are present, by which the organism tries to overcome the biological effect of insulin reduction [7,8].

Metabolic syndrome is a phenomenon of modern society [9]. It is commonly defined as a grouping of chronic diseases that include obesity, type 2 diabetes, hypertension, dyslipoproteinemia, and CVD [10]. It develops in individuals with a genetic predisposition and with an inappropriate lifestyle, i.e., in the case of excessive energy intake, insufficient physical activity, etc. Various cardiovascular and metabolic risk factors for atherosclerosis, and its complications arise gradually.

Although MetS was originally described in adults and was not known in children before 1980, the clustering of cardiometabolic risk factors begins at a young age and, currently, the same metabolic diseases found in adults can be found in 13% of normal-weight children and 38% of obese children [5,10]. Early identification of risk factors is very important to allow preventive actions. However, the selection and definition of these risk factors with cut-off values are not without discussion and controversy, especially in the pediatric population, where cut-off values for homeostasis model assessment (HOMA-IR) are very variable and the definition of MetS is even more complicated [11]. These complications arise not only because children are in the early stages of cardiovascular and metabolic changes, but also because of physical development and adolescence. Therefore, age-corrected cut-off values should be considered [10].

The MetS prevalence in children is lower than in adults, estimated at 2—9.4%, but it is higher in obese children and adolescents (12.4-44.2%) [12]. There is not yet a sufficient consensus among children and adolescents on how to define MetS, or how to predict future cardiovascular risk using MetS or other risk factors or algorithms used in adulthood. Existing definitions of MetS for children have been derived from definitions for adulthood on the assumption that conditions are similar throughout life, although the predictive value of MetS in children has not yet been determined [13,14].

In 2007, the International Diabetes Federation (IDF) presented the definition of MetS in children and adolescents [15]. It provides a standard that simplifies the comparison of the results of individual studies because the use of different definitions of MetS in children and adolescents has in the past led to significant differences in the MetS prevalence in the international literature from 0 to 59% [16].

In the last decades, many interventional studies have gained a wealth of new knowledge about foods and nutrients that positively or adversely affect the cardiovascular system not only in the adults [17] but also in adolescents [18]. Healthy nutrition plays an important role in both primary and secondary CVD prevention and has a beneficial effect on blood lipid levels. Adverse associations of cardiovascular health with increased intake of sodium, saturated fats, meat, fast foods, and sweetened beverages have been reported in children and adolescents [19]. Children with a higher intake of sweetened beverages had a 55% higher risk of overweight/obesity compared to children with a lower intake. One to two servings of sweetened beverages per day were associated with an increased risk of type 2 diabetes development by 26% compared to occasional consumption (less than one serving per month) [20]. Even moderate sweetened beverages consumption (>1.3 cups per day) can be an important cardiometabolic risk predictor of young people, regardless of their weight [21].

Physical inactivity doubtless belongs to CVD risk factors. Insufficient physical activity is also significantly associated with the development of MetS and is probably a decisive factor in IR development [22]. Increasing physical activity in all age categories is an important factor in

preventive cardiology [23] and can effectively improve cardiovascular morbidity and mortality. Regular physical activity in childhood and adolescence is especially important because of the formation of lifelong habits. Low aerobic fitness in children and adolescents is associated with a higher prevalence of cardiometabolic risk factors (abdominal obesity, elevated blood pressure, increased levels of insulin, glucose and blood lipids, increased IR prevalence and enlarged left ventricle of the heart) [24-27].

Sleep has an essential role in growth, maturation, and good health during childhood and adolescence [28]. However, shortening and reduced sleep quality is a common problem in children and adolescents [29]. Examination of more than 4,000 adolescents has shown that, in healthy adolescents, sleep disorders are associated with abnormalities in CVD risk factors—elevated total cholesterol (TC) levels, higher body mass index (BMI), and hypertension [30,31]. The results of a study on almost 7,000 Lithuanian children aged 12–15 years showed that short sleep (<7 hours) was significantly associated with an increased risk of prehypertension and hypertension [29]. An analysis of 25 studies showed that all studies indicated significant associations between sleep duration and childhood overweight and obesity [32]. Intervention strategies aimed at optimizing sleep hygiene in childhood and adolescence may therefore play an important role in terms of CVD prevention in adulthood.

This cross-sectional study aimed at determining the prevalence of IR in adolescents and its relationship with obesity and other cardiometabolic and selected lifestyle risk factors, as well as selected factors of personal and family history in males and females. These indicators are of great importance for CVD prevention in adolescents and young adults.

2. Materials and Methods

2.1. Study design

The analyzed sample of adolescents was selected from the project "The Support of Cardiometabolic Health in the Secondary Schools in the Bratislava Self-governing Region" (Respect for Health), which was conducted at secondary schools within the Bratislava Self-governing Region (14 grammar schools and 48 secondary vocational schools). The project was approved by the Ethics Commission of the Bratislava Self-Governing Region on 19 April 2011. All procedures were according to the ethical standards as laid down in the 1964 Declaration of Helsinki and its later amendments. From all legal representatives of children, written informed consent was obtained before being enrolled in the study. Participation in the study was fully voluntary and anonymous, with no explicit incentives provided for participation. All participants were informed about the significance and the course of individual measurement and examination procedures.

From all of the students enrolled in high schools in the Bratislava Self-Governing Region (n=19,172; 9,821 males, 9,351 females), 4,382 adolescents (2,097 males, 2,285 females) aged 11–19 years participated in this project (22.9%). Students <14 and >18 years were excluded. Selection criteria were age (decimal age 14.00 - 18.99 years according to WHO criteria) and complete anthropometric, blood sample, and blood pressure (BP) examinations. An exclusion criterion was the presence of any illness (acute and/or chronic). The final selected and evaluated sample consisted of 2,629 adolescents aged 14-18 years with a mean age of 17.1 ± 1.04 years, 1,205 boys (45.8%), and 1,424 girls (54.2%). The basic characteristics of the adolescents and intersexual differences are in Table 1.

2.2. Anthropometric measurements

Basic anthropometric measurements focused on overweight/obesity and abdominal obesity (i.e., weight, height, waist circumference, body fat content) were performed by the trained staff directly at schools. Body fat content and weight were measured using a digital body composition scale (OMRON BF510) with an accuracy of 100 g. The subject stood in light clothing on metal electrodes with bare feet, their palms firmly gripped the handles with electrodes, and their hands were freely lowered (we subtracted 500 g for clothing from the measured value). The body fat percentage

measurement was based on the bioelectrical impedance method. The body height was measured using an altimeter (TANITA LEICESTER) on a horizontal floor surface with an accuracy of the whole millimeter (the measured person was barefoot, upright, the seat and shoulders touched the scale, with the head upright). Body mass index was calculated; overweight and obesity was evaluated according to the percentile curves from the 6th National Anthropometric Survey on physical development of children and youth in the Slovak Republic in the year 2001 [33]. Subjects below the 3rd percentile were classified as underweight, subjects above the 90th percentile as overweight, and above the 97th percentile as obese. Body fat content (category underweight, normal weight, overweight, obesity) was evaluated according to McCarty [34].

Waist circumference was measured using a flexible non-elastic tape in an expiration position directly on the skin in the horizontal plane at half the distance between the crista iliaca anterior superior and the lowest rib (with accuracy to the whole millimeter) and evaluated according to the IDF consensus for defining MetS in children and adolescents [15]. From the measured data, waist-to-height ratio (WHtR) was calculated; WHtR >0.5 was evaluated as central obesity.

2.3. Blood pressure and resting heart rate measurement

Blood pressure and resting heart rate (HR) were measured using an automated digital device OMRON M-6 COMFORT under standard conditions on the right arm (after a minimum of 10 minutes of sitting with back supported and legs on the floor). Before the examination, subjects did not eat or smoke for 2 hours. The average values of BP and HR from the 2nd and the 3rd measurements (with a 5-minute break between measurements) were calculated. BP values at the age of <18 years were classified using percentile values of systolic and diastolic BP according to age, height, and gender [35,36] and, in 18-year-olds, according to the adult population classification [37].

2.4. Biochemical blood analyses

A sampling of fasting venous blood for laboratory examination was performed by qualified nurses under the physician's guidance, standard biochemical analyses were performed by a central certified laboratory. Total cholesterol, triglycerides (TG), and high-density lipoprotein cholesterol (HDL-C) blood levels, glycemia, concentrations of high-sensitive C-reactive protein (hsCRP), and insulin level were examined using standard laboratory methods. Low-density lipoprotein cholesterol (LDL-C) level was calculated via Friedewald equation, atherogenic index of plasma AIP=log(TG/HDL-C) [38], and (HOMA-IR) [39,40] were calculated as well. Blood lipids levels were evaluated according to the recommendations for the diagnosis and treatment of dyslipidemias in children and adolescents in the Slovak Republic [3]. Non-HDL-C levels were classified according to cut off points of the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents [41]. AIP >0.21, glycaemia ≥5.6 mmol/L, hsCRP ≥3 mg/L, and insulin >20.0 mIU/L, were considered as high risk levels. Cut-off point ≥3.16 for HOMA-IR was considered to be risky for insulin resistance [39].

The MetS prevalence was evaluated according to the IDF consensus for the definition of MetS in children and adolescents, separately in the age group <16 years and 16+ years [15], as the presence of central obesity plus two or more other components (elevated BP, TG, glycemia, and/or reduced HDL-C level).

2.5. Physical fitness assessment

The overall physical fitness was assessed using the Ruffier test, which is used to assess cardiovascular fitness [42]. Fitness was evaluated as follows: Ruffier index (RI) =0 – excellent, 0.1-5 – good, 5.1-10 – average, 10.1-15 weak, and >15 insufficient.

2.6. Questionnaires

The objective examination was supplemented by the comprehensive student's questionnaire, where we focused mainly on selected lifestyle characteristics: smoking (current = any in the past

month / former), leisure-time physical activity (frequency and duration per week), sleeping duration and sedentary activities duration (work/game at the computer, watching TV, learning) on working days and weekends, psychosocial factors (stress situations experiencing at school and in privacy: frequently – occasionally – exceptionally – no), and nutrition and nutritional habits: number and regularity of daily meals (regularly/daily –irregularly/occasionally – never), frequency of food groups' consumption per week (daily, 3-6-times, 1-2-times, rarely/never). In this study, we recorded the consumption of only sweetened beverages. In the questionnaire designed for parents, we focused on the adolescent birth weight and the breastfeeding duration, the current weight of the parents, and their highest educational level. Multiple response options were dichotomized (desirable/acceptable vs. risky) for multivariate logistic regression.

2.7. Statistical analyses

For statistical data processing, the methods of descriptive statistics (frequencies, means ± standard deviations) were used. Relationships between continuous variables were assessed using a two-sample t-test, categorical data were compared using contingency tables and chi-square test. For multiple comparisons, ANOVA (one-way analysis of variance) was used. The relationship between IR and cardiometabolic factors, lifestyle factors, and selected data on personal and family history was tested using bivariate analysis, which resulted in crude odds ratios at the 95% confidence interval: Multivariate logistic regression models were used as well (separately for the cardiometabolic, lifestyle, and personal/family history variables), which resulted in adjusted odds ratios at the 95% confidence interval. P-values <0.05 were considered as statistically significant. In the case of multivariate logistic regression, collinear variables were excluded (LDL-cholesterol, diastolic BP, BMI, and waist circumference). All variables were entered into general logistic backward stepwise regression model, the elimination method was used to remove non-significant predictors from the model in 16 steps. The statistical packages Epi InfoTM software, version 7.1.5.0, Atlanta, GA, USA, and SPSS, version 24 (International Business Machines Corp.; New Orchard Road; Armonk, NY, USA) were applied.

3. Results

The basic sample characteristics, intersexual differences, and risk markers prevalence are shown in Table 1 (the average age of boys and girls was the same, i.e., 17 years). The table shows significant intersexual differences for almost all monitored parameters, except for the level of TG, blood insulin, and the HOMA-IR (no significant differences between genders). Males displayed significantly higher values of anthropometric measurements, except for the total body fat percentage, higher values of the atherogenic index, glycemia, and systolic/diastolic BP. Significantly higher body fat content, higher levels of TC, LDL-C, HDL-C, hsCRP, and HR in females were presented.

According to BMI, males had a significantly higher prevalence of overweight/obesity (30.7% vs. 22.9%; p<0.001), but according to body fat content females had a significantly higher prevalence of overweight (14.0% vs. 7.9%, p<0.001). The abdominal obesity according to the IDF criteria [15] was more frequent in females (not significant), but, according to WHtR, significantly more frequent in males (12.3% vs. 8.4%, p<0.001).

The Ruffier fitness test showed significant intersexual differences and overall poor fitness of adolescents, which was significantly worse in girls. The average RI for boys was 9.2±4.0 (in the range of average fitness) and for girls it was 10.5±4.1 (in the range of weak fitness), p<0.001.

Selected lifestyle and eating habits characteristics are given in Table 2. Females reported a significantly higher prevelance of smoking, shorter leisure-time physical activity duration per week, and, conversely, longer duration of sedentary activities (work/game at the computer, watching TV,

learning), more frequent stressful situations (at school, in privacy), a lower average number of meals per day and more frequent breakfast skipping.

Mon-Fri – working days; TV – television. Data are presented as mean ± standard deviation, or as count and (percentage). ¹smoker – any cigarette during the past month

The mean HOMA-IR in the whole cohort was 2.45 ± 1.91 (males 2.53 ± 2.25 and females 2.39 ± 1.58). Mean HOMA-IR values were higher in 14- to 17-year-old males and in 18-year-old females, and had a declining trend in both genders (Figure 1). Insulin resistance according to the HOMA-IR was observed in a total of 18.6% of adolescents (19.8% of boys and 17.6% of girls, p=0.147), the average value of HOMA-IR increases significantly regarding the overweight and obesity prevalence (Figure 2). The IR prevalence in adolescents with normal weight was 11.6%, overweight 26.3%, but in obese it was up to 56.3%.

In the whole sample (n = 2,629), 38 (1.4%) adolescents met the IDF criteria for the MetS diagnosis (32 boys, 2.7%, and 6 girls, 0.4%, p<0.001). All of them were in the range of overweight/obesity. In the

overweight/obesity group (n=696), the MetS prevalence was 5.5% (8.6% of boys and 1.8% of girls, p<0.001).

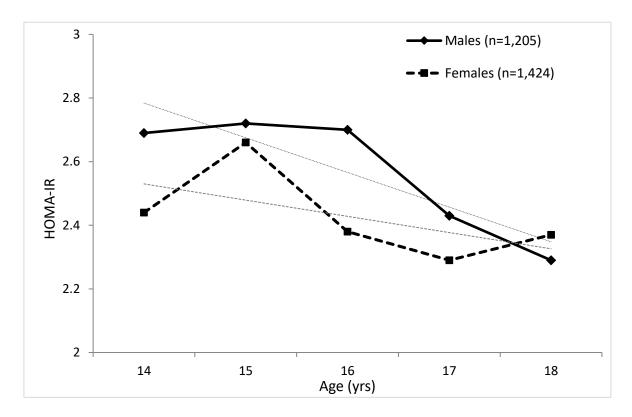

Figure 1. The mean HOMA-IR values in adolescents according to age categories (with linear trend lines).

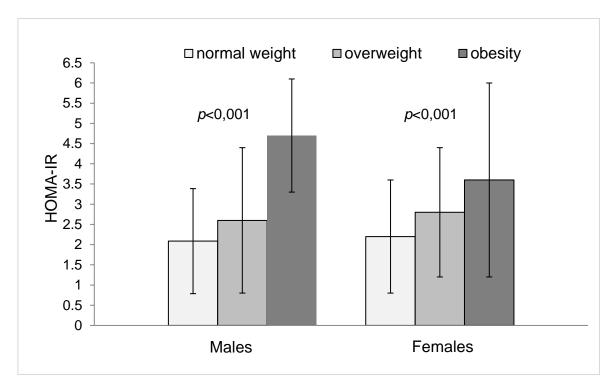

Figure 2. The mean HOMA-IR values in adolescents according to BMI categories.

Bivariate analysis showed highly significant associations of IR with all observed cardiometabolic factors in boys. This was similar in the case of girls, except for TC level and systolic BP. Among the metabolic parameters, in both genders the closest relationships of HOMA-IR with the TG level (OR=5.27; 95% CI 3.79-7.32; p<0.001 in males; OR=2.28; 95% CI 1.67-3.09; p<0.001 in females) and AIP (OR=5.51; 95% CI 3.64-8.34; p<0.001 in males; OR=3.65; 95% CI 2.20-6.06; p<0.001 in females) were observed, and with all anthropometric parameters, especially waist circumference (OR=13.48; 95% CI 8.76-20.76; p<0.001 in males; OR=3.70; 95% CI 2.64-5.19; p<0.001 in females) and WHtR (OR=9.88; 95% CI 6.80-14.37; p<0.001 in males; OR=3.98; 95% CI 2.68-5.90; p<0.001 in females).

Regarding lifestyle factors, multivariate analysis revealed significant associations of IR with insufficient physical fitness and inadequate physical activity in both genders (Table 4). In addition, skipping breakfast and insufficient sleep time during weekends in males, a low number of meals a day, and a frequent consumption of sweetened beverages in females showed significant associations with IR. Paradoxically, we found significant inverse associations of IR with smoking in boys and with frequent stressful situations at school in girls.

In terms of personal and family history factors, low birth weight showed significant association with IR only in bivariate analysis and only in males (OR=0.53; 95% CI=0.27-1.07; p<0.05). Multivariate logistic regression confirmed a significant association of IR with higher educational level of mothers and with the higher current weight of both parents in males, and with lower educational level of fathers in females (Table 5).

Table 5. Selected variables of adolescents' personal and family history associated with insulin resistance (defined according to HOMA-IR) in males (n=1,205) and females (n=1,424) – multivariate logistic regression analysis

Finally, a backward age, and gender-adjusted stepwise elimination logistic regression model, was performed; non-significant variables were removed stepwise from the model (Table 6). This model showed a significant association of IR with increased TG level, body fat content, and WHtR among cardiometabolic risk factors (association with lower HDL-C level revealed only borderline significance), with poor physical fitness, insufficient physical activity duration per week, non-smoking status, the infrequent occurrence of stressful situations at school, irregular/no breakfast consumption and frequent sweetened beverages consumption among lifestyle risk factors, and with lower educational level of the fathers and higher educational level of the mothers among family factors.

4. Discussion

The CVD prevalence in Slovakia is shifting to younger age groups. Risk factors accelerating the development of these diseases have been active since early childhood. Most of the main risk factors playing a key role in CVD development are significantly related mainly to lifestyle factors, such as

smoking, unhealthy nutrition, and physical inactivity [35]. The lifestyle of children and youth has changed significantly in recent years. Children are less physically active; staying outside and playing games has been replaced by endless sitting in front of a computer and TV, combined with the consumption of unhealthy foods (especially fast-food and various sweetened or salted delicacies) and sweetened soft drinks. As a result, childhood obesity, IR, elevated BP, metabolic syndrome, and prevalence of type 2 diabetes has increased in adolescents and young adults.

The most common causes of IR are overweight/obesity, lack of physical activity, poor diet, excessive fructose intake, and smoking [43]. Insulin resistance is a major pathogenetic mechanism associated with a predisposition to premature CVD. Several indices are used to assess IR, e.g., HOMA, or to assess insulin sensitivity, e.g., QUICKI (Quantitative Insulin Sensitivity Check Index). In our study, we used the HOMA-IR, given that this index is more reliable and credible in children and adolescents and has been used as a measure of IR in this population group [39]. This index was first introduced by Matthews et al. [44] in 1985 and its use is advantageous because it is a practical, fast, and inexpensive method. We considered a cut-off point of ≥3.16 [39] to be risky in terms of IR. In adults, HOMA-IR values ≥2.5 are considered in IR, but the exact cut-off value for children and adolescents has not been established [45]. In several papers, the cut-off values for adolescents range from about 2.2 to 5.3, but these studies vary considerably in design, sample size, age, nutritional status, and the stage of puberty of their participants [45]. In a 2015 survey [46], the lowest cut-off value for HOMA was found to be 1.65 for girls and 1.95 for boys [47] and the highest 3.82 for girls and 5.22 for boys [48]. Van der Aa et al. [49] even report limit values of 1.14-5.56, resulting in a wide range of IR prevalence, from 5.5% to 72.3%. This wide variation of cut-off values also makes it very difficult to compare the prevalence of IR in different countries and ethnic groups, and it is not entirely clear which cut-off value is best for defining IR in adolescents.

In our sample, almost one fifth of adolescents, 18.6% (19.8% of boys and 17.6% of girls), had a risk of IR without significant intersexual differences in average HOMA-IR values (2.53 boys, 2.39 girls, p=0.077). The same cut-off value was used by authors in Košice (Slovakia) in a group of 224 high school students with an average age of 18 years and found only a 13.9% prevalence of IR [50]. The IR prevalence in a relatively small sample of Brazilian children (n=162) aged 12-18 years was slightly higher, 23.5% at the same cut-off point of 3.16, but at overweight/obesity prevalence of 45.7% [51]. However, if we used the lowest recommended cut-off values [47], the prevalence of IR would increase to 53.7% (males) and 68.3% (females). This is questionable for the overweight/obesity prevalence in our cohort (30.7% males / 22.9% females). Slightly higher average values of HOMA-IR (2.77 in boys and 2.93 in girls) were found by the authors in a group of 691 healthy adolescents from urban areas in India [52], although it was a slightly younger age group (10- to 17-year-olds). The shape of the curve of HOMA-IR average values in different age groups was also different. In Indian adolescents, the lowest values were found at the age of 13 with a subsequent increase and maximum values at the age of 17. In our sample, the course was opposite: after the age of 15, the average HOMA-IR values decreased with the lowest values at the age of 17 years (in females) and 18 years (in males).

Adolescence is a critical period for the onset of obesity and other metabolic disorders associated with body fat accumulation. Overweight adolescents are at high risk of becoming obese in adulthood and more susceptible to the development of CVD. Early cardiovascular disease risk factors identification and IR diagnosis in adolescents is therefore of great value in the prevention of chronic diseases, as it plays a central role in the development of the metabolic disorder [1,46]. In our study, we confirmed a highly significant relationship between IR and overweight/obesity: the mean HOMA-IR value in normal-weight adolescents was only 2.14±1.34, in overweight adolescents 2.74±1.70, but in obese adolescents this value was up to 4.25±3.78. HOMA-IR shows high significant correlations with all anthropometric indicators of overweight/obesity in bivariate analysis—the closest relationship with waist circumference and WHtR was found in males as well as in females, but in reverse order. Ashwell et al. [53] consider WHtR as a better screening tool for cardiometabolic risk factor identification compared to waist-to-hip ratio or BMI. It can be used both in adults and children in different ethnic groups. Unlike waist circumference, which increases with age, WHtR almost does not change with age, so it can be considered the best central obesity indicator in adolescents of both

genders. Similar associations have been found by other authors who agree that the waist circumference and especially WHtR are good predictors of IR and MetS in adolescents and can be used for simple non-invasive identification of individuals at risk [11,52,54,55]. We can confirm these findings; among the variables of backward stepwise logistic regression analysis, age and genderadjusted, WHtR showed the closest association with IR in adolescents of all significant factors.

Hyperinsulinemia is an independent risk factor for CVD development because it accelerates the onset of dyslipidemia. Insulin resistance leads to increased fatty acid oxidation, which provides a substrate for the TG synthesis and increases the release of LDL-C into serum [56]. A study evaluating serum insulin levels over eight years in children and young adults showed that dyslipidemias were three times more common in patients with hyperinsulinemia [57]. The bivariate analysis confirmed highly significant associations of IR with dyslipidemia in our cohort, while the multivariate logistic regression confirmed a significant association of IR only with triglyceride levels in both genders and with non-HDL-C in females. Triglyceride levels remained the only high significant value among blood lipids even after backward stepwise logistic regression analysis. In a large sample of the Korean population, Kim et al. [58] showed significant positive associations of IR measured as HOMA-IR with waist circumference, BMI, TC, TG as well as TG/HDL-C ratio and negative association with HDL-C, whereas IR was significantly associated with TG/HDL-C ratio, regardless of the waist circumference.

Adolescence is characterized by increased vulnerability and exposure to stress and is considered one of the most difficult periods of life, as many changes take place at several levels (e.g., psychological, physical, environmental, and social). The HELENA study conducted in a large sample of adolescents aged 12.5–17.5 years from six European cities found that females experienced more stress than males [59], which is probably related to higher adipose tissue in adolescent girls compared to boys [60]. These findings support the hypothesis that stress may promote excessive fat storage in the body via the interrelationships of the stress system and the mechanisms of energy homeostasis and IR. In our cohort, a significantly higher stress load of females and a significantly higher prevalence of overweight/obesity according to body fat content in females were confirmed. However, paradoxically, a significant inverse association of IR with the experience of frequent stressful situations at school in females was found.

Sleep is an important factor for normal growth and development during childhood and adolescence [28] and is related to physical, cognitive, emotional, and social development. Sleep depression is considered an independent risk factor for IR development. Several data refer to an association of sleep duration reduction with decreased insulin sensitivity. It is thought that interventions to sleep prolongation could reduce diabetes and obesity risk in adolescents [61]. We found a significant association between shorter sleep duration and HOMA-IR during the weekends only in males; this relationship was not confirmed in females. In contrast, Dorenbos et al. [61], in a small group of 137 children (mean age of 14.4 years), confirmed that sleep duration and quality are important factors that affect insulin sensitivity.

Another lifestyle factor that can directly or indirectly affect insulin sensitivity is physical activity. Several studies have found that increased physical effort increases insulin sensitivity in overweight adolescents, even when there is no change in body weight or body fat content [61]. Sedentary behavior characterized by activities with low energy expenditure (sitting or lying down, watching TV, sitting in class, etc.) is a relatively new risk factor for CVD in later life and attracts considerable attention as a potential risk factor for obesity in young people [62]. We confirmed a highly significant association of IR with insufficient physical fitness and insufficient physical activity in both genders. In contrast, the sedentary activities duration (learning, watching TV, work/game on a PC) did not confirm any association with IR in either genders, neither separately nor as the sum of all sedentary activity durations. On the other hand, Altenburg et al. [63] found in a sample of young adults aged 18–28 years that cardiometabolic biomarkers significantly positively correlated with TV watching, but not with the time spent at the computer. They therefore recommend that these two variables should be assessed separately. This could be a common impact of TV watching and consumption of high-energy and often-advertised foods: adolescents who declared frequent TV watching declared also a higher consumption of fatty foods, fast foods, and sugary drinks, and less fruit and vegetables

[64,65]. Coombs and Stamatakis [62] came to similar conclusions. On the other hand, Fletcher et al. [66] found moderate to strong evidence of a relationship between watching TV, overall sedentary behavior, and obesity, independently of eating habits.

Smoking is an important risky behavior in adolescents worldwide with potential adverse health effects. It is assumed that early smoking onset age is an important public health issue but there are controversial outcomes regarding the health consequences of adolescents [67]. Kelishadi et al. [68] confirmed in 5,625 Iranian students aged 10–18 years increased risk of MetS and some other cardiometabolic risk factors in smokers (active as well as passive). However, our results are controversial: male smokers (current/former) had less odds of having IR than non-smokers. These inconsistent findings can be explained by relatively short smoking time, a low number of cigarettes smoked, and a definition of a current smoker (any cigarette in the past month). Despite these results, tobacco use prevention among adolescents has to be reinforced.

One of the main causes of obesity, IR, and MetS is generally considered to be food choices and eating habits. It is even assumed that there is some connection between sleep deprivation and food choice, i.e. that people with sleep deprivation more often tend to choose unhealthy foods high in energy and fat content [61]. Breakfast is commonly considered to be a key component of a healthy diet that contributes to the all-day diet adequacy and psychological wellbeing [69]. Adolescents who frequently skip breakfasts are thought to be more likely smokers and alcohol drinkers, with inadequate physical activity compared to regular breakfast consumers who have shown higher cardiorespiratory fitness. Several studies have also confirmed an association between skipping breakfast and overweight/obesity development in adolescents [70, 71]. We confirmed a significant inverse association between regular breakfast consumption and IR in males, as well as a significant inverse association between IR and the total number of meals per day and a significant positive association with frequent sweetened beverages consumption in females. A backward stepwise logistic regression analysis in the whole sample of adolescents confirmed the significance of skipping breakfast and frequent sweetened beverages consumption (daily/several times a week) in IR development. A significant relationship between the sweetened beverages' frequency consumption and HOMA-IR was also confirmed in the HELENA study [72]. It is well known that excess fructose (as a lipogenic sugar) intake has harmful effects on CVD risk factors and that there is a strong link between fructose and added sugar consumption with MetS [73]. We have not identified significant associations IR with any other food commodities, probably due to skewed food consumption data (overweight/obese adolescents underestimated consumption of obesogenic food groups), which is typical behavior in overweight/obese individuals [74].

Family history, ethnicity, prenatal and postnatal nutrition, obesity, pubescence, eating habits, and sedentary lifestyle may affect insulin sensitivity in the pediatric population [45]. It is argued that low birth weight may affect the risk of CVD and that breastfeeding may protect against the development of type 2 diabetes, CVD, and obesity [75]. Of these perinatal factors, we can confirm (but only in bivariate analysis) a significant association of HOMA-IR with the low birth weight of boys. We did not find any significant differences concerning the breastfeeding duration. Similarly, no effect of breastfeeding on IR was confirmed by Huybrechts et al. [60] in the HELENA study. We also monitored the associations of IR with the current weight and educational level of both parents from the family questionnaire. A study of more than 1,000 Canadian children and adolescents showed that families with a higher level of education had a lower incidence of one or more MetS risk factors compared to families with a lower educational level. This can be attributed to the impact of higher educational level on health awareness and habits such as eating habits and physical activity [76]. It is therefore recommended that low-educated parents raise awareness of early CVD risk in their children [77]. A significant relationship was observed between parental education and the weight of children in a group of more than 1,500 Sicilian children—the obesity prevalence was significantly higher regarding low education of the mother or father [78]. According to these authors, the results suggest that having a mother with a lower level of education can be considered a risk factor for childhood obesity. However, in a previous study in northern Tuscany, the authors found that the impact of a father's education is stronger than that of a mother [79]. We can confirm these results; in our study a significant inverse association between higher education of fathers and IR prevalence was found. This relationship was the opposite concerning the mother's education. A significant relationship between IR and the higher weight of both parents was found only in males.

5. Conclusions

In our study, a relatively high incidence of IR without significant intersexual differences was found in a large sample of adolescents in the Slovakian capital self-governing region. In both genders, the highly significant associations of IR with overweight/obesity, specifically with abdominal obesity expressed as WHtR, were confirmed. Regarding blood lipids, triglyceride levels had the closest association with IR. When it comes to lifestyle factors, a highly significant relationship of IR with insufficient physical activity and low physical fitness in both genders was found, but we were unable to confirm the impact of daily sedentary activities duration. Skipping breakfast, the low number of meals per day (only in females), and frequent consumption of sweetened beverages were proved to be significant predictors of IR regarding nutritional habits. Parents' weight and parental educational level (especially of fathers) can also play an important role in the development of IR in children.

For a fast, cheap, simple, and non-invasive screening method for at-risk adolescents, a waist circumference measurement and WHtR calculation can be recommended.

Early IR identification and recognition of risk factors for atherosclerosis are very important from a prognostic and preventive point of view. An early lifestyle change can prevent the development of IR, or even diabetes and complete MetS. Therefore, in the prevention of atherosclerosis, CVD, and diabetes type 2, the improvement of insulin sensitivity by weight reduction, increased physical activity and the choice of healthy foods (especially restricting dietary sugars and limiting fructose intake) has an irreplaceable place.

Author Contributions: J.J., K.H. conceived and designed the project, K.H., M.S., Z.S. collected and analyzed the data, K.H. A.F., I.K., J.B. performed literature search and drafted sections of the manuscript, J.J., L.A. wrote the manuscript, J.J., D.V., L.A. analyzed the data, J.J., L.A. provided critical revision of the manuscript. All authors have read and approved the submitted version.

Funding: This manuscript was partially supported by the Bratislava Self-governing Region.

Acknowledgments: We want to thank all the collaborators participating in the data collection within the study "Support of Cardiometabolic Health in the Secondary Schools in the Bratislava Self-Governing Region".

Conflicts of Interest: The authors declare no conflict of interest.
