Abstract: The non-symmetrical collapse of an empty cylindrical cavity is modelled using Smoothed Particle Hydrodynamics. The presence of a nearby surface produces an anisotropic pressure field generating a high velocity jet that hits the surface. The collapse follows a different dynamic based to the initial distance between the centre of the cavity and the surface. When the distance is greater than the cavity radius (detached cavity) the surface is hit by travelling shock waves. When the distance is less than the cavity radius (attached cavity) the surface is directly hit by the jet and later by other shock waves generated in the last stages of the collapse. The results show that the surface is hit by a stronger shock when distance between the centre of the cavity and the surface is zero while showing more complex double peaks behaviour for other distances.

1. Introduction

Cavitation is a phenomenon occurring in a liquid that undergoes rapidly changes in pressure. At first a bubble, or cavity, nucleates and grows over a nucleation site. After growing up to maximum value, the cavity collapses generating shock waves [1].

When the pressure field in the liquid is isotropic, the cavity preserves its symmetry and the collapse has spherical symmetry [2–4]. However, when an anisotropic pressure field drives the collapse, the cavity does not preserve its symmetry and folds in a specific direction generating a high velocity flow known as jet [1,5]. The anisotropic pressure field is generated by the so-called anisotropic driver, which also defines the jet folding direction [6]. The most common anisotropic drivers are: rigid or free surface, gravity, presence of neighbour bubbles or a combination of the above. Another mechanism that makes a cavity folds during the collapse is the interaction with a shock waves that folds the cavity in the shock direction. This situation is known as shock-induced collapse, while the pressure driven collapse is called Rayleigh collapse [7,8].

From an engineering point of view, the high-speed jet generated in the Rayleigh collapse by the presence of a nearby solid surface is the scenario most addressed in literature [8,53]. In fact, the high-speed flow can hit the surface causing erosion and eventually loss of material. This phenomenon, known as cavitation erosion, is undesirable in industrial, military and power station equipment such as pump impellers, high-speed propellers and turbine blades [9–11].

Thanks to its Lagrangian nature, Smoothed Particle Hydrodynamics (SPH) can handle problems with large deformations better than mesh-based technique [12] and, for this reason, it is particularly suited for studying cavitation. Joshi et al. [13] developed a Smoothed Particle Hydrodynamics axisymmetric solver to simulate a shock induced collapse of an empty cavity and the erosion process of the nearby surface. Pineda et al. [14] used a SPH-ALE method to study a gas filled cylindrical cavity Rayleigh collapse far and near a surface. Nair & Tomar [15] used SPH to simulate an oscillating gas filled cylindrical cavity under a variable isotropic pressure field. Albano & Alexiadis [16] developed a SPH model to study the Rayleigh collapse of a gas filled cylindrical cavity that takes in account the heat diffusion at the gas-liquid interface. Among these studies, only Joshi et al. and Pineda et al. take in account anisotropic collapses. Joshi et al. only for the shock induced collapse case, while Pineda et al. only for cavity detached from the surface. Despite its importance in practical applications, non-symmetrical Rayleigh collapse of surface attached cavities, to the best of our knowledge, has never been investigated with the SPH method. Moreover, cavities commonly nucleate on surfaces rather than away from it [17–19]. This work, therefore, develops a SPH model for a non-symmetrical Rayleigh collapse of a cylindrical cavity which is considered the greatest causes of erosion and material loss [8,53].

2. Model

2.1. Smoothed Particle Hydrodynamics

Smoothed Particle Hydrodynamics is a mesh-free particle method originally developed by Gingold Monaghan [20] and Lucy [21] and used in a wide range of applications: astrophysics [22], shock waves [23–26], explosion [27–29], thermo-fluid flows [30], thermo-capillary flows [31], multiphase flow [32,33], Biological flows [34], non newtonian fluid flows [35,36].

Thanks to its particle nature SPH is part of the Discrete Multi-Physics framework where, coupled with other particle methods [37–39], is used to address complex physics phenomena [40–44] to overcome the single weakness of each method.

The idea behind the SPH formulation lies in the integral representation of any continuum function $f(\mathbf{r})$ depending of the three-dimensional position vector $\mathbf{r}$

$$f(\mathbf{r}) \approx \iiint W(\mathbf{r} - \mathbf{r}', h)d\mathbf{r'},$$

where $W$ is the smoothing function or kernel and $h$ is the smoothing length. Dividing the domain in a finite number of computational particle with their own mass $m = \rho dr$, is possible approximate any continuum function $f(\mathbf{r})$ as

$$f(\mathbf{r}) \approx \sum \frac{m_i}{\rho_i} f(\mathbf{r}_i)W(\mathbf{r} - \mathbf{r}_i, h),$$

where $m_i$, $\rho_i$ and $\mathbf{r}_i$ are mass, density and position of the $i$-th particle. Eq 2 is known as particle approximation in SPH literature [12].

We used the SPH particle approximation to discretise continuity, momentum and energy conservation equation:
\[
\begin{aligned}
\frac{dp}{dt} &= -\rho \nabla \cdot \mathbf{v}, \\
\frac{d\mathbf{v}}{dt} &= -\frac{1}{\rho} \nabla \cdot P, \\
\frac{d\rho}{dt} &= -\frac{1}{\rho} (P(\nabla \cdot \mathbf{v}) + \mathbf{\tau} : \nabla \mathbf{v}),
\end{aligned}
\]

where \( \mathbf{v} \) is the velocity vector, \( e \) internal energy and \( \Pi_{ij} \) is the artificial viscosity introduced by Monaghan [23]. The Monaghan artificial viscosity depends on a constant parameter called dimensionless dissipation factor, \( a \), and from the speed of sound of particle \( i \) and \( j \), \( c_i \) and \( c_j \), with the following relationship.

\[
\Pi_{ij} = -ah \frac{c_i + c_j \cdot \mathbf{v}_{ij} \cdot \mathbf{r}_{ij}}{\rho_i + \rho_j r_{ij}^2 + eh^2}.
\]

To solve the set of Equations shown before, an Equation Of State (EOS) that links pressure \( P \) and density \( \rho \) is required.

2.2. Computational set up

In this work, we focus on the non-symmetrical collapse induced by an anisotropic pressure field. The anisotropy is generated by non-symmetric water domain shown in Fig 1. The domain is divided in three concentric regions, delimited by three different radii. In each region, different types of computational particles are used:

- Cavity \((r < R_0)\): inside the yellow region in Fig 1, particles are removed to generate an empty cavity with \( P_b = 0 \).
• Liquid ($R_0 < r < R_S$): inside the blue region in Fig 1, particles are modelled as water following a liquid EOS. The density is set as $\rho_L = 1000$ [kg m$^{-3}$] with initial pressure $P_\infty$.

• Shell ($r > R_S$): inside the red region of Fig 1, are modelled as in the liquid region. Moreover, they have fixed position and density to keep constant pressure as boundary condition. The extension of shell region has been discussed in previous work [16]. The lower part of this region also acts as a wall inducing anisotropy in the pressure field during the collapse.

The green region in Fig 1 does not refer to a different type of particle. We highlight it because, later on, the pressure generated during the collapse will be monitored in the green region. As explained in the next section, when a non-symmetric collapse is studied, it is necessary to quantify the anisotropy of the collapse. When the anisotropy is induced by the presence of a nearby solid surface, is common to use the stand-off, $\gamma$ [6] defined as

$$\gamma = \frac{d}{R_0},$$

where $d$ is the distance between the cavity centre and the wall (see Fig 1) and $R_0$ its initial radius. The dynamic of a cylindrical cavity in a Rayleigh collapse, where the driving force is the pressure difference between the pressure in the liquid, $P_\infty = P_L$, and the pressure in the cavity, $p_h$, is described by a 2D Rayleigh-Plesset (2DRP) equation [45]:

$$\frac{P_\infty - p_h}{\rho} = \left(\frac{dR}{dt}\right)^2 + R \frac{d^2R}{dt^2} \ln \left(\frac{R}{R_\infty}\right) + \frac{1}{2} \left(\frac{dR}{dt}\right)^2 \left(\frac{1}{R^2} - \frac{1}{R_0^2}\right).$$

However, the 2DRP equation only describe the dynamic of a symmetrical collapse. Form our knowledge an equation to validate the dynamic of a non-symmetrical collapse has still to be developed. For this reason, as commonly done in literature [14,16,45,46], the model presented as been validated for the case of symmetric collapse against Eq 6 [16].

In the simulations we use the Lucy Kernel [12] and the Tait EOS [12] with a smoothing length of $h = 1.3 \cdot dL$ where $dL$ is the initial particle spacing. The dimensionless dissipation factor, time step and speed of sound were set as $\alpha = 1$, $t_s = 1e-10$ [s] and $c_0 = 1484$ [m s$^{-1}$]. The sensitivity of the results to parameters like the kernel function, EOS or $h$, was investigated in a previous publication for the case of symmetric collapse [16]. In the next section, the particle resolution for the specific case of non-symmetric collapse is discussed.

2.3. Software for simulation, visualisation and post-process

The simulations were run with the open source code simulator LAMMPS [47,48]. The visualisation and data post-processing were generated with the Open Source code OVITO [49].

3. Results

As mentioned in the introduction, collapsing cavities formed during cavitation generate high-pressure shock wave [1]. When the collapse occurs near a solid surface, the symmetry of the cavity is not preserved and this produces a high velocity flow known as re-entrant jet [5,7,8]. The characteristics of the jet depend on $\gamma$ (see Eq 5). When $\gamma > 1$, the jet hits the opposite side of the cavity generating a high pressure shock wave that travels in the direction of the solid surface. When $\gamma \leq 1$, the jet hits directly the solid surface generating a water hammer pressure [50,51] that causes erosion.
3.1. Preliminary results

Four preliminary simulations with different particle resolutions have been carried out with \(R_0 = 100 \text{ [\(\mu\text{m}\)]}, P_o = 5 \text{ MPa} \) and \(\gamma = 1.2\). These values are chosen to match those commonly used in computational studies \([13,16,51]\). Fig 2 shows the total collapse time and the max jet speed for the different resolutions. Particle resolution is specified as the ratio between the initial particle spacing \(dL\) and the initial cavity radius \(R_0\).

![Graphs showing the results for collapse time (a) and max jet speed (b)](image)

Figure 2. Resolution convergences for collapse time (a) and max jet speed (b)

Both the collapsing time and max jet velocity converge for \(dL/R_0 \geq 40\). This resolution value was also independently found by Joshi et al. and Pineda et al.. At this resolution, the model correctly reproduces jet formation \([5,7]\). Fig 3 shows that, as the collapse proceeds, wall proximity produces a pressure difference between the top and the bottom of the cavity. This pushes down the upper-side of the cavity inducing the formation of a high-velocity/low-pressure jet.

In Section 3.3 we show simulations at higher resolution. In fact, at higher resolutions, we will be able to uncover more details of the velocity pattern occurring during the collapse.
Figure 3. Shape evolution with pressure and velocity field ($dL/R_0 = 80$, $\gamma = 1.2$ & $P_\infty = 5$ MPa)
3.2. Stand-off and pressure analysis

To study the effect of $\gamma$ on the collapse, eight different stand-offs, in the range $[0; 1.4]$, are simulated with $P_{\infty} = 5 \text{ & } 50 \text{ MPa}$. The upper limit $\gamma = 1.4$ was chosen since this study focuses on strongly deformed collapses, which are known to produce cavitation erosion $[1,8]$. In Fig 4, the dimensionless collapsing time and the maximal pressure at the wall are plotted for different $\gamma$. The dimensionless time is defined as the ratio between $t_\gamma$, the collapsing time obtained in the simulation for a given $\gamma$, and $t_\infty$, the collapsing time for $\gamma \to \infty [16]$. The dimensionless pressure is defined as the ratio between the maximal pressure at the wall and the characteristic pressure of a Rayleigh collapse $[51]$. The pressure at the wall is calculated at the green circle shown in Fig 1 positioned below the centre of the cavity with a diameter of 0.01 mm

![Figure 4](image-url)

Figure 4. Dimensionless collapse time (a) and dimensionless pressure (b) for different stand off and pressure ($dL/R_0 = 40$)

The collapsing time shows a maximum for $\gamma = 1$ and a minimum for $\gamma = 0$. When $\gamma = 1$, the lower part of the cavity touches the wall, while the upper part is free to move (Fig 5c). During the collapse, the cavity loses its symmetry generating a re-entrant jet, which travels for the whole diameter of the cavity before reaching the surface. When $\gamma = 0$ the cavity reduces to a semi sphere. Therefore, the collapse is symmetric again (Fig 5h) and, in fact, $t_\gamma/t_\infty \approx 1$ (Fig 4a) as for $\gamma \to \infty [16]$. The pressure is shown in Fig 4b. The normalized maximum wall pressure is thought to scale with $\gamma^{-1} [1,6]$. However, this was reported for values of $\gamma > 1.4$, which are outside the range investigated in this study. Other studies show results similar to ours in the range of investigation $[52,53]$. 
Figure 5. Cavity shapes for different stand off ($dL/R_0 = 40$ & $P_\infty = 5$ MPa). Each shape shows the cavity outline at a different time.
3.3. Pressure and speed developed in high-resolution collapse

For 3 different stand-offs (0.0, 0.6 and 1.0), pressure histories at the centre of the surface (i.e. green circle in Fig 1) are plotted in Fig 6.

![Figure 6. Pressure trend for different stand off (dL/R0=133 & \(P_\infty = 50\) MPa).](image)

For \(\gamma = 0\), the pressure shows a single maximum of roughly 1200 MPa. This pressure is generated by a water hammer impact of the collapsing cavity on the surface. Since the symmetry is preserved, see Section 3.2, the collapse ends when the cavity impacts on the surface generating a high-pressure shock wave (Fig 7a). After the impact, the pressure at wall decreases as the shock moves into the liquid (Fig 7b & 7c).
When \( \gamma = 0.6 \) & 1 the pressure shows a double peak. Similarly to \( \gamma = 0 \), the first peak is generated by the water hammer impact of the cavity with the surface (Fig 8a & 9a). After the impact the jet splits into two high-speed/low-pressure lateral jets (Fig 8b) that will later impact with the sides of the cavity generating collapsing circles and a pair of “side” pressure waves (Fig 8c & 9b).

The collapse ends when the fluid fills the circles. When this happens a third pair of pressure waves is generated (Fig 8d & 9c). The waves will later merge at the centre resulting in a second pressure peak (Fig 8e & 9d). Fig 10 shows a schematic representation of a wall-attached cavity collapse with the three pairs shock formation for \( \gamma = 0.6 \). It can be difficult to clearly identify these hydrodynamics patterns if the simulation is run at lower resolution (e.g. Joshi et al. 2019).

**Figure 7.** Pressure and velocity field in the liquid and the spacial pressure trend at the wall (\( dL/R_0=133, \gamma = 0 \& P_\infty = 50 \text{ MPa} \))
Figure 8. Pressure and velocity field in the liquid and the spacial pressure trend at the wall ($dL/R_0=133$, $\gamma = 0.6$ & $P_\infty = 50$ MPa).
As shown in Fig 6, when $\gamma = 1$ the first peak is higher compared to the first peak of $\gamma = 0.6$. Before hitting the surface, the jet travels a longer distance for $\gamma = 1$ rather than $\gamma = 0.6$. Therefore, it is accelerated by the pressure gradient for longer resulting in a higher water hammer pressure at the wall [8, 50, 54].
However, for the second peak, the behaviour is reversed and the peak is higher for $\gamma = 0.6$. The water between the collapsing rings and the wall acts as a shield mitigating the shock wave [25,55]. When $\gamma = 1$ the distance between the rings and the wall is higher than $\gamma = 0.6$ resulting in a greater mitigation effect and lower pressure peak.

![Diagram](image-url)

**Figure 10.** Schematic representation of a wall-attached cavity collapse ($\gamma = 0.6$): blue surface represents the cavity, black arrows represent the liquid flow, red circles represent the shock waves propagation at different collapse stages.

### 4. Conclusion

A SPH model is developed to study non-symmetrical Rayleigh collapse of an empty cylindrical cavity. When the cavity collapse near a solid surface the anisotropy of the pressure field induce the formation of the re-entrant jet. This anisotropy is quantified with the stand off, $\gamma$.

Different collapses in the range $0 \leq \gamma \leq 1.4$ are discussed showing that the model is able to correctly simulate the jet physics and the consequent pressure fields at the surface.

We study the collapse of attached cavities ($\gamma \leq 1$), where the the liquid exerts the maximum pressure over the surface. When $\gamma = 0$ the collapse is symmetric again and pressure shows a single max which corresponds to the end cavity collapse. When $0 < \gamma \leq 1$ the pressure shows multiple peaks which reflect a more complex behaviour with the circles formation and collapse.

This work shows the importance of studying the collapse of cavities attached to the surface. This case is less investigated than the detached collapse, but a better understanding of the final stages of the attached collapse is essential to improve predictions of cavitation erosion. For this reason,
the simulations are run at higher resolution than previous studies. Only in this way, in fact, certain hydrodynamic features of the collapse can clearly emerge from the simulations.
