Anomalous diffusion with an apparently negative diffusion coefficient in a one-dimensional quantum molecular chain model

Sho Nakade 1,‡, Kazuki Kanki 1,‡, Satoshi Tanaka 1,‡ and Tomio Petrosky 2,3,‡*

Abstract: An interesting anomaly of the diffusion process with an apparently negative diffusion coefficient defined through the mean-square displacement in a one-dimensional quantum molecular chain model is shown. Nevertheless, the system satisfies the H-theorem, so that the second law of thermodynamics is satisfied. The reason why the “diffusion constant” becomes negative is due to the effect of the phase mixing process, which is a characteristic result of the one-dimensionality of the system. We illustrate the situation where this negative “diffusion constant” appears.

Keywords: anomalous diffusion; one dimensional quantum system; irreversibility vs. reversibility

1. Introduction

Due to mathematical simplicity and some unique anomalies, the irreversible transport property in one-dimensional (1D) systems has attracted many physicists [1–6,6–9]. In the previous paper, we have analyzed an anomalous diffusion of an exciton as a quantum Brownian particle in a one-dimensional molecular chain [10]. We have shown that the momentum space separates into infinite sets of disjoint irreducible subspaces dynamically independent of one another due to the one-dimensionality. Then, we have analyzed the hydrodynamic mode of an exciton through a kinetic equation, and obtained a sound velocity, and a diffusion coefficient, defined in each subspace. Because of the separation into these subspace, we have shown these transport coefficients have a momentum dependence. As a result, the phase mixing due to the sound velocity affects the broadening of the spatial distribution of the exciton in addition to the diffusion process. Then, we have shown the increase rate of the mean-square displacement of the exciton increases linearly with time and diverges in the long-time limit. This leads to a divergence of the phenomenological diffusion coefficient $D(x)(t)$ defined by the following relation [11]

$$D(x)(t) \equiv \frac{1}{2} \frac{d}{dt} \langle (X - \langle X \rangle_t)^2 \rangle_t,$$

(1)

where $\langle \cdots \rangle_t$ means the average over the distribution function at time $t$.

Nevertheless, based on the microscopic dynamics starting from the Liouville-von Neumann equation for the density matrix, we have obtained the following convection-diffusion equation for the Wigner distribution function of an exciton $f^W(X, P, t)$ with the well-defined microscopic momentum dependent diffusion coefficient $D(P)$ and the
momentum dependent velocity of sound propagation $\sigma(P)$ after the local equilibrium is achieved [10]:

$$\frac{\partial}{\partial t} f^{W}(X, P, t) = -\sigma(P) \frac{\partial}{\partial X} f^{W}(X, P, t) + D(P) \frac{\partial^2}{\partial X^2} f^{W}(X, P, t).$$

(2)

In this paper, we will report an interesting anomaly of this one-dimensional system. As we will show that the anomaly will come from the competition between the time-symmetric behavior due to the phase-mixing process and the time-asymmetric behavior due to the diffusion process. Because of the linear divergence in time due to the phase mixing in the phenomenological diffusion coefficient $D^{(x)}(t)$ in Eq. (1), it seems that subtraction of the linear time-dependent term from $D^{(x)}(t)$ may give an appropriate phenomenological diffusion coefficient. However, we found that this new definition of the phenomenological diffusion coefficient has a situation that its value is negative. Indeed, we have obtained for a general initial condition of the distribution function of the exciton that [12]

$$D^{(x)}_{\text{const}} \equiv D^{(x)}(t) - t \langle (\sigma(P) - \bar{\sigma})^2 \rangle_{\text{eq}},$$

(3)

with

$$D^{(x)}_{\text{const}} = \bar{D} + \langle (X - \langle X \rangle_{t=0})(\sigma(P) - \bar{\sigma}) \rangle_{t=0},$$

(4)

where the second term of the right-hand side in Eq. (3) comes from the phase mixing in the sound propagation. As we will show that the second term of the right-hand side in Eq. (4) may have a negative value. Then, this new definition of the phenomenological diffusion coefficient has a situation that its value is negative. This implies that starting with a given mean-square displacement of the exciton, there is a situation in time where the mean-square displacement of the exciton decreases. Is this means the second law of thermodynamics is violated? In this paper, we will show that even in this unexpected situation, our kinetic equation satisfies the H-theorem. Hence, the second law of thermodynamics is not violated. We will also discuss a physical meaning of the situation where the mean-square displacement of the exciton decreases.

2. Model and Quantum transport equation

In this section, we introduce one-dimensional quantum molecular chain model. Moreover, we summarize the characteristics of an exciton propagation in this one-dimensional system, which we have reported in the previous paper [10].

We consider relaxation dynamics of an exciton which weakly interacts with phonons of an underlying lattice on a one-dimensional quantum molecular chain. The Hamiltonian of this system is given by [10,13]

$$H = H_0 + gV,$$

(5)

$$H_0 = \sum_p \varepsilon_p |p\rangle\langle p| + \sum_q \hbar \omega_q a_q^\dagger a_q,$$

(6)

$$gV = \sqrt{\frac{2\pi}{L}} \sum_{p,q} g V_q |p + \hbar q\rangle \langle p| (a_q + a_{-q}^\dagger),$$

(7)

where the exciton interacts with the phonons with a dimensionless coupling constant $g$ which indicates the order of the interaction, and the momentum of the exciton is designated by $p$ and its state by $|p\rangle$. The state $|p\rangle$ is normalized by the Kronecker delta. The notations $a_q^\dagger$ and $a_q$ denote creation and annihilation operators of the phonons with wave vector $q$, and $L$ denotes the length of the chain. We assume the free particle dispersion for the exciton and the linear dispersion for acoustic phonons as

$$\varepsilon_p = \frac{p^2}{2m}, \quad \omega_q = c|q|,$$

(8)
we have investigated the time evolution of the reduced distribution function \( f \) where the round bracket is defined by

\[
\langle \rho | f \rangle = \text{Tr}_{\rho} f,
\]
where \( \text{Tr}_{\rho} \) means that the trace is taken over all the phonon modes. The phonons are assumed to be in thermal equilibrium with a temperature \( T \) defined by

\[
\rho_{\text{eq}} = \exp \left[ -\frac{\hbar \omega_q a_q^\dagger a_q}{k_B T} \right].
\]

We can express the reduced density operator in terms of the Wigner representation [2,15] in the momentum space of the exciton as

\[
f_k(P,t) \equiv \langle P + \hbar k/2 | f(t) | P - \hbar k/2 \rangle,
\]
where the round bracket is defined by \( \langle p | \rangle \equiv \sqrt{L/2\pi\hbar} |p\rangle \) and normalized by the delta function in the limit \( L \to \infty \) as

\[
\langle p | p' \rangle = \delta(p - p').
\]

The Fourier transform of \( f_k(P,t) \) gives the Wigner distribution function in “phase space”:

\[
f^W(X,P,t) \equiv \frac{1}{2\pi} \int_{-\infty}^{\infty} dk e^{ikX} f_k(P,t).
\]

Note that the \( k = 0 \) component \( f_0(P,t) \) is a momentum distribution of the exciton, while the \( k \neq 0 \) components represent inhomogeneity in space.

The equation of motion of the reduced distribution function \( f_k(P,t) \) is obtained from the complex spectral representation of the Liouvillian [15]. In our previous papers, we have investigated the time evolution of the reduced distribution function \( f_k(P,t) \) by solving the complex eigenvalue problem of the Liouvillian in a situation where the
exciton weakly couples to the phonons. Here, we summarize the results for convenience of the readers. For details, see Refs. [10,13,16].

We found that the resonance condition between the exciton and phonons in the 1D system leads to the separation of the momentum space for the exciton into infinite sets of disjoint irreducible subspaces. In other words, due to the one-dimensionality, momentum states of exciton can change only within a subset of discrete momentum states:

$$P_v = (-1)^v (P_0 - 2vmc), \quad (v = 0, \pm 1, \pm 2, \cdots)$$

where a different choice of $P_0$ in the range

$$-mc \leq P_0 \leq mc$$

(19)
gives a different and disjoint set of momenta. Hence, momentum relaxation occurs independently within each momentum subspace toward the Maxwell distribution.

In the relaxation process of the momentum distribution $f_0(P_v, t)$ within a momentum subspace, there exist a stationary mode and decaying modes. Only the stationary mode remains after a finite relaxation time $\tau_{rel}$ determined from the eigenvalue problem for the time evolution of the momentum distribution [See Eq. (A26) in Ref. [10]].

Since the relaxation time $\tau_{rel}$ for the momentum distribution is finite, there exists a hydrodynamic regime where the wavenumber $k$ is small enough that the characteristic time for the relaxation of spatial inhomogeneity is much longer than the relaxation time $\tau_{rel}$ [17]. In this hydrodynamic regime, the momentum relaxation occurs in a very early stage. As a result, a local equilibrium is established before any appreciable change in spatial distribution occurs.

We have obtained the time evolution of the reduced distribution function $f_k(P_v, t)$ in the hydrodynamic regime at the local equilibrium with transport coefficients [10], a hydrodynamic sound velocity $\sigma(P_0)$ and a diffusion coefficient $D(P_0)$, as follows:

$$f_k(P_v, t) = e^{-\{ik\sigma(P_0)+k^2D(P_0)\}t} \varphi^{eq}_{P_0}(P_v) \sum_{\mu=-\infty}^{\infty} f_k^{init}(P_\mu),$$

(20)

where the origin of time $t$ is shifted to $\tau_{rel}$, and $f_k^{init}(P_\mu)$ is initial distribution of the exciton. The momentum distribution at local equilibrium follows the Maxwell distribution in each momentum subspace as

$$\varphi^{eq}_{P_0}(P_v) \equiv \frac{\exp[-\epsilon_{P_v}/k_BT]}{\sum_{\mu=-\infty}^{\infty} \exp[-\epsilon_{P_\mu}/k_BT]}.$$

(21)

The transport coefficients $\sigma(P_0)$ and $D(P_0)$ are obtained, respectively, as the real part and the imaginary part of the eigenvalues of the Liouvillian [10]. Since the eigenvalue equation consists only of components with discrete momenta (18) related to a $P_0$, the transport coefficients are defined at each $P_0$. Besides, the momenta in a subset (18) share the values of the hydrodynamic sound velocity and the diffusion coefficient as

$$\sigma(P_v) = \sigma(P_0), \quad D(P_v) = D(P_0), \quad (v = 0, \pm 1, \pm 2, \cdots).$$

(22)

Since the transport coefficients exist in each momentum subspace, they have momentum dependence in this 1D system [For the explicit forms of the sound velocity $\sigma(P_0)$ and diffusion coefficient $D(P_0)$, see Eqs. (63) and (64) in Ref. [10]].
The discussion later in this paper does not depend on the detailed forms of $\sigma(P_0)$ and $D(P_0)$. What are important are that they have momentum dependence, and that the sound velocity can take either positive or negative values depending on $P_0$ as

$$\begin{align*}
\sigma(P_0) &\leq 0 \quad \text{for} \quad -mc \leq P_0 \leq 0; \\
\sigma(P_0) &\geq 0 \quad \text{for} \quad 0 \leq P_0 \leq mc,
\end{align*}$$

and that the diffusion coefficient is always positive.

$$D(P_0) > 0, \quad \text{for any} \quad P_0. \quad (24)$$

The reduced distribution function (20) is a function of the discrete momenta $P_\nu$. However, since $P_\nu$ and $P_\mu$ take any real number when $P_0$ varies continuously in the range (19), the function $f_k(P, t)$ is defined to be a continuous function of $P$. Fourier transform of Eq. (20) gives a Wigner distribution function (17) for the exciton at local equilibrium. One can easily show that the Wigner distribution function follows the convection-diffusion equation (2).

### 3. H-theorem for the quantum transport equation

In this section, we prove that the H-theorem holds with the condition (24) when the Wigner distribution function follows the convection-diffusion equation (2). In the proof, we assume that the Wigner distribution function is normalized as follows:

$$\int_{-\infty}^{\infty} dX \int_{-\infty}^{\infty} dP f^W(X, P, t) = 1, \quad (25)$$

and satisfies the boundary conditions:

$$\lim_{X \to \pm \infty} f^W(X, P, t) = 0, \quad (26)$$

$$\lim_{x \to \pm \infty} \frac{\partial}{\partial X} f^W(X, P, t)|_{X = x} = 0. \quad (27)$$

As is well known, the Wigner distribution function is a quasi-probability distribution, and unlike distribution functions in classical systems, it can take negative values [18]. Therefore, if we define a functional in the form of $\rho \log \rho$, which is often used conventionally as the H-function, then this functional has an imaginary part when the Wigner distribution function has the negative values.

We then introduce a new function which is non-negative at any $X$ and $P$ with a sufficiently large constant $C \geq 0$ as follows:

$$f^W(X, P, t) \equiv \tilde{f}^W(X, P, t) + C \geq 0, \quad (28)$$

for the case $f^W(X, P, t)$ is bounded from below. (See the example shown in the next section.) It is clear that this function also obeys the convection-diffusion equation (2).

Let us introduce a functional with the new function (28) and the Wigner distribution function as

$$H_{[\tilde{f}^W]}(t) \equiv \int_{-\infty}^{\infty} dX \int_{-\infty}^{\infty} dP f^W(X, P, t) \log \tilde{f}^W(X, P, t). \quad (29)$$

Note that we use $f^W(X, P, t)$ only for the argument of the natural logarithm. This is because if we replace $f^W(X, P, t)$ in Eq. (29) with $\tilde{f}^W(X, P, t)$, then the functional diverges because of the factor $C$. 

We have

\[
\frac{d}{dt} H_{f^W}(t) = \frac{d}{dt} \int_{-\infty}^{\infty} dX \int_{-\infty}^{\infty} dP \left\{ f^W(X, P, t) - C \right\} \log \frac{f^W(X, P, t)}{C} = \int_{-\infty}^{\infty} dX \int_{-\infty}^{\infty} dP \left\{ \frac{\partial}{\partial t} f^W(X, P, t) \right\} \log \frac{f^W(X, P, t)}{C} - C \int_{-\infty}^{\infty} dX \int_{-\infty}^{\infty} dP \frac{\partial}{\partial t} \frac{f^W(X, P, t)}{f^W(X, P, t)} \]

\[
= -\int_{-\infty}^{\infty} dP \left[ \int_{-\infty}^{\infty} dX \left( \frac{\partial}{\partial X} f^W(X, P, t) \right)^2 - \frac{\partial}{\partial X} f^W(X, P, t) \right] \leq 0.
\]

(30)

In the transformation from the second line to the third line, we substituted Eq. (2) and then performed integration by parts over \( X \) with the boundary conditions (26) and (27). It is clear that the inequality in Eq. (30) holds from the conditions (24) and (28). Hence, this functional satisfies the H-theorem.

In the time derivative of the H function (30), the contribution of the convection term with \( \sigma(P) \) in Eq. (2) disappears and only the contribution of the diffusion term with \( D(P) \) remains. In other words, only the diffusion term in Eq. (2) is essential for the decrease of the H function.

When we consider the time evolution of the Wigner distribution function of a free particle which has no interaction with the phonons, there is no diffusion term in the transport equation. Therefore, the time derivative of the H function (29) is zero. This is consistent with the fact that free particle propagation is a reversible process and there is no entropy production.

From the above discussion, when the Wigner distribution function obeys the convection-diffusion equation (2), the H-theorem holds. That is to say, there is no entropy reduction in the exciton propagation at the local equilibrium in this one-dimensional quantum system. It should be emphasized that it is essential for the H-theorem that the diffusion coefficient \( D(P) \) derived from the microscopic theory is always positive.

4. Example of the exciton propagation with apparent negative diffusion coefficient

As explained in Sec. I and II, the transport coefficients have momentum dependence due to the one-dimensionality in this system. Because of the momentum dependence of the hydrodynamic sound velocity, a wave packet spreads in time not only due to the diffusion processes but also due to the effect of the phase mixing. As a result, the phenomenological time-dependent diffusion coefficient \( D^{(x)}(t) \) increases linearly with time in this 1D quantum system.

Surprisingly, for particular initial distributions, the phenomenological time-independent diffusion coefficient \( D^{(x)}_{\text{const}} \) can be negative. However, as we proved in the previous section, the H-theorem holds for any initial distribution since the diffusion coefficient \( D(P) \) is always positive.

In this section, we give an example of the initial distribution with which the constant term of the phenomenological diffusion coefficient \( D^{(x)}_{\text{const}} \) is negative. We also illustrate the physical picture of apparent negative diffusion.

First, let us show that the first term \( \tilde{D} \) in Eq. (4) is always nonnegative. Although the Wigner distribution function, which is a quasi-probability function, can take negative values, when integrated over \( X \), it becomes the true momentum probability distribution.
and takes non-negative values \[19\]. In addition, the diffusion coefficient \(D(P)\) is always positive as shown in Eq. (24). Thus, we obtain

\[
D \equiv \langle D(P) \rangle_{eq} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} D(P) f_W(X, P, t \gtrsim \tau_{rel}) \textrm{d}X \textrm{d}P \geq 0,
\]

where

\[
f_P(t) \equiv \int_{-\infty}^{\infty} f_W(X, P, t) \geq 0.
\]

Therefore, in order for \(D_{\text{const}}^{(x)} < 0\) to be satisfied, the second term in Eq. (4) should be negative. The reason why the second term in Eq. (4) can be negative is that the hydrodynamic sound velocity \(\sigma(P)\) can take either positive or negative values as shown in Eq. (23).

As an example of the initial distribution for \(D_{\text{const}}^{(x)} < 0\) to be satisfied, we consider the case where the initial state is given as a superposition of two Gaussian wave packets, as follows:

\[
|\psi_0 \rangle = |\psi_{0;1} \rangle + |\psi_{0;2} \rangle,
\]

where, for each \(\alpha = 1, 2\),

\[
(X|\psi_{0;\alpha}) \equiv N_{\alpha} \left( \frac{1}{2\pi \Delta X_{\alpha}^2} \right)^{\frac{1}{4}} \exp \left[ -\frac{(X - X'_{\alpha})^2}{4(\Delta X_{\alpha})^2} + i \frac{P'_{\alpha}}{\hbar}(X - X'_{\alpha}) \right].
\]

The notations \(X'_{\alpha}\) and \(P'_{\alpha}\) indicate the coordinate and momentum of the peak position of the Gaussian wave packet. The normalization constants \(N_{\alpha}\) satisfy

\[
N_1^2 + \gamma N_2 N_1 + N_2^2 = 1,
\]

where

\[
\gamma \equiv \left( \frac{2 \Delta X_1 \Delta X_2}{(\Delta X_1)^2 + (\Delta X_2)^2} \right)^{\frac{1}{2}} \exp \left[ -\frac{1}{4} \frac{(X'_1 - X'_2)^2}{(\Delta X_1)^2 + (\Delta X_2)^2} \right]
\]

\[
\times \exp \left[ -\frac{(P'_1 - P'_2)^2}{\hbar^2} \frac{(\Delta X_1 \Delta X_2)^2}{(\Delta X_1)^2 + (\Delta X_2)^2} \right]
\]

\[
\times 2 \cos \left( \frac{(X'_1 - X'_2) P'_1(\Delta X_1)^2 + P'_2(\Delta X_2)^2}{\hbar} \frac{\Delta X_1 \Delta X_2}{(\Delta X_1)^2 + (\Delta X_2)^2} \right).
\]

The momentum representation of the wave function (34) is written as

\[
\psi_{0;\alpha} (P) \equiv (P|\psi_{0;\alpha}) = N_{\alpha} \left( \frac{1}{2\pi \Delta P_{\alpha}^2} \right)^{\frac{1}{4}} \exp \left[ -(\Delta X_{\alpha})^2 \frac{(P - P'_{\alpha})^2}{\hbar^2} - iX'_{\alpha} P_{\alpha} \hbar \right].
\]

For simplicity, we assume that both of the two Gaussian wave packets \(\alpha = 1, 2\) are the minimum uncertainty wave packets, which satisfy

\[
\Delta X_{\alpha} \cdot \Delta P_{\alpha} = \frac{\hbar}{2}.
\]
In this case, the Fourier component of the initial Wigner distribution function is given by (see Eq. (15))

\[
\begin{align*}
 f_k^{\text{init}}(P) &= (P + \frac{\hbar k}{2}) |\psi_0\rangle \langle P - \frac{\hbar k}{2} | \\
 &= \sum_{\alpha=1,2} \psi_{0,\alpha} (P + \frac{\hbar k}{2}) \psi^{\ast}_{0,\alpha} (P - \frac{\hbar k}{2}) + \sum_{\alpha \neq \alpha'} \psi_{0,\alpha} (P + \frac{\hbar k}{2}) \psi^{\ast}_{0,\alpha'} (P - \frac{\hbar k}{2}).
\end{align*}
\]  

(39)

By substituting this into Eq. (17), the initial Wigner distribution function is obtained as follows:

\[
\begin{align*}
 f_k^{\text{init}}(X, P) &= \sum_{\alpha=1,2} \frac{N^2}{\pi \hbar} \exp \left( -\frac{(X - X_\alpha')^2}{2(\Delta X_\alpha)^2} - \frac{(P - P_\alpha')^2}{2(\Delta P_\alpha)^2} \right) \\
 &\quad + \frac{N_1 N_2}{\pi \sqrt{\hbar} \{4\Delta X_1 \Delta P_1 + \Delta X_2 \Delta P_2\}} \exp \left( -\frac{1}{2} \frac{(P - P_1')^2}{2(\Delta P_1)^2} - \frac{1}{2} \frac{(P - P_2')^2}{2(\Delta P_2)^2} \right) \\
 &\quad \times \exp \left( -\frac{1}{2} \frac{\{X - X_\alpha' + X_\alpha''\}^2}{(\Delta X_1)^2 + (\Delta X_2)^2} + \frac{\hbar^2}{2} \left\{ \frac{P - P_1' - P_2'}{2(\Delta P_1)^2 - 2(\Delta P_2)^2} \right\} \right) \\
 &\quad \times 2 \cos \left( X_\alpha' - X_\alpha'' \right) \frac{P}{\hbar} + \hbar \frac{X - X_\alpha' + X_\alpha''}{(\Delta X_1)^2 + (\Delta X_2)^2} \left\{ \frac{P - P_1'}{2(\Delta P_1)^2} - \frac{P - P_2'}{2(\Delta P_2)^2} \right\}.
\end{align*}
\]  

(40)

Each term of the summation in the first term of Eq. (40) represents an isolated Gaussian wave packet, and the second term comes from the cross term of the two Gaussian wave packets. It can be seen that the second term can take negative values. We note that the sign of the initial momentum \(P_\alpha'\) determines the direction of the sound (See Eq. (23)).

By substituting the initial distribution (39) into Eq. (20) and performing the Fourier transform (17), we obtain the Wigner distribution function at local equilibrium. We then calculate the average values of the phenomenological diffusion coefficient (1). We have calculated numerically the transport coefficients \(\sigma(P)\) and \(D(P)\) using Eqs. (63) and (64) in Ref. [10].

In Fig. 1, we display the time evolution of the phenomenological diffusion coefficient \(D^{(x)}(t)\). The constant term of the phenomenological diffusion coefficient \(D^{(x)}_{\text{const}}\) is given by \(D^{(x)}(t = 0)\). This figure clearly shows that the constant term \(D^{(x)}_{\text{const}}\) is negative, and that \(D^{(x)}(t)\) increases linearly with time, which is consistent with Eq. (3).

To draw this figure, we chose the positions of the two peaks of the Gaussian wave packet in the initial distribution as \((X_1, P_1) = (0, 0.7)\) and \((X_2, P_2) = (40, -0.7)\). Note that we have chosen opposite signs for the momenta at the two peaks. This is the condition for the two peaks to approach each other (See Eq. (23)).

Therefore, the situation where apparent negative diffusion occurs with \(D^{(x)}_{\text{const}} < 0\) can be understood by the physical picture as follows. The width of each Gaussian distribution increases due to the diffusion process and the phase mixing process. Nevertheless, the width of the entire distribution function decreases because the two Gaussian distributions approach each other. As a result, the mean-square displacement \((\langle (X - \langle X \rangle)^2 \rangle)\) decreases in the first stage of the time evolution. After the two Gaussian distributions pass each other, the variance of the displacement increases monotonically.

In Fig. 1, the value of \(D^{(x)}(t)\) increases linearly with time and changes from negative to positive value around \(t = 20\). We confirmed by drawing numerically the time evolution of the Wigner distribution function that the two peaks of the Gaussian packets approach each other and pass around \(t = 20\).
We should note that the occurrence of the apparent negative diffusion is because of the approaching of the peaks each other in the initial distribution rather than the existence of the negative region in the Wigner distribution function.

We can say that the apparent negative diffusion occurs because of the competition between the effect of diffusion process and the effect of the phase mixing which leads to approaching of the two Gaussian wave packets. Because the phase mixing occurs due to the one-dimensionality of the system, this competition is unique to 1D quantum system.

Even in the presence of the negative phase mixing process which reduces the mean-square displacement, there is no entropy reduction in this system since the phase mixing is a reversible process. On the contrary, the entropy in this system monotonically increases due to the diffusion process.

Figure 1. Time evolution of $D^{(x)}(t)$ when the constant term $D^{(x)}_{\text{const}}$ is negative in units where $m = 1$, $c = 1$, $\hbar = 1$, $g\Delta_0 = 1$, and $\rho_M = 1$. The transport coefficients $\sigma(P)$ and $D(P)$ are calculated at the temperature $T = 1$. The initial conditions $\Delta X_\alpha = 1, 2 = 3$, $(\bar{X}_1, \bar{P}_1) = (0, 0.7)$, and $(\bar{X}_2, \bar{P}_2) = (40, -0.7)$ are chosen. Note that the origin of time $t$ is $\tau_{\text{rel}}$.

4.1. Summary and Conclusion

We have shown the interesting anomaly of the diffusion process with an apparently negative diffusion coefficient in a one-dimensional quantum molecular chain model. Indeed, the usual definition of the phenomenological diffusion coefficient through the time evolution of the mean-square displacement of the exciton leads to a negative value of the “diffusion constant.” Nevertheless the system satisfies the H-theorem and hence the second law of thermodynamics. However, since the Wigner distribution function may have a negative value because it is a quasi-distribution function and is not the true probabilistic distribution function, we have needed a subtle extension of the usual H-function as shown in Eq. (29).

The reason why the usual phenomenological diffusion coefficient through the mean-square displacement becomes negative is that the hydrodynamic sound velocity depends on the momentum, which is a characteristic result of the one-dimensionality of our system. As a result, there is a process of the phase mixing that leads to both a positive effect and a negative effect for spreading the total mean-square displacement of the exciton in addition to the positive true diffusion process. We should emphasize that this anomaly does not occur in the ordinary convection-diffusion equation with a similar form to Eq. (2) but with the momentum independent sound velocity.

Then, we have shown an example of the situation where negative value of the phenomenological diffusion coefficient can be temporally achieved for the initial condition. This situation is achieved where the two Gaussian wave packets are approaching each other. For this situation the negative effect of the phase-mixing is larger than the...
positive effect of the spreading of the wave packets due to the diffusion process and the phase mixing. However, since the H-theorem is satisfied during all time evolution, the entropy of the system monotonically increases, and the system approaches to the thermal equilibrium state.

References

11. In addition to this definition, there is another phenomenological definition in which the mean-square displacement is divided by time \(t\) and the long-time limit is taken \([20,21]\). However, the results of this paper are essentially the same regardless of which definition we use.
12. The second term of Eq. (4) does not appear in our previous paper \([10]\) where we have considered a special case of the initial condition of the distribution with a single Gaussian called the minimum-uncertainty wave packet.
