Abstract: Although cooperative social networks are considered key to human evolution, emphasis has usually been placed on the functions of men's cooperative networks. What do women's networks look like? Do they resemble or differ from men's and what does this suggest about evolutionarily inherited gender differences in reproductive and social strategies? In this paper, we test the 'universal gender differences' hypothesis positing gender-specific network structures against the 'gender reversal' hypothesis that posits women's networks looking more 'masculine' under matriliney. Specifically, we ask whether men's friendship networks are always larger than women's and we investigate measures of centrality by gender and descent system. To do so, we use tools from social network analysis and data on men's and women's friendship ties in matrilineal and patrilineal Mosuo communities. In tentative support of the gender reversal hypothesis, we find that women's friendship networks in matriliney are relatively large. Measures of centrality and generalized linear models otherwise reveal greater differences between communities than between men and women. The data and analyses we present are primarily descriptive given limitations of sample size and sampling strategy. Nonetheless, our results provide support for the flexible application of social relationships across genders and clearly challenge the predominant narrative of universal gender differences across space and time.

Keywords: social relationships, descent systems, female autonomy, matriliney, gendered networks

Introduction:

In summary, we propose that men and women are equally social, but their sociality is directed differently. To caricature, female sociality is dyadic, whereas male sociality is tribal. In other words, men seek social connection in a broad group with multiple people, particularly by competing for a good position in a status hierarchy; women, in contrast, seek social connection in close personal relationships based on mutual, dyadic intimacy. - (Baumeister & Sommer, 1997, p. 39)

Humans are a deeply cooperative species. Indeed, many have gone so far as to argue that humans cannot reproduce without the assistance of others (Hrdy, 2009; Kramer, 2010). Social relationships are sources of information, resources, and other support that promote reproductive success (Apicella et al., 2012; Page et al., 2017). Research suggests that males and females build, maintain, and leverage networks differently in ways that correspond with gender-specific reproductive and cooperative strategies (Benenson, 2019; Seabright, 2012). Prior work, however, in large part underrepresents low- and middle-income nations and participants from non-industrialized settings (see David-Barrett et al., 2015), and has predominantly relied on young children and adolescents rather than adult participants (see Vigil, 2007). Thus, the generalizability of observed gender differences in the properties of social networks is potentially limited, as little attention has been focused on how gender differences in social relationships may vary across broader social contexts. This is despite well-characterized variation in population structure and household demography, which shape individuals' interactions and formation of social ties (Power & Ready, 2019). In this paper, we compare gendered social networks in two villages - one matrilineal and one patrilineal - among Mosuo agriculturalists of Southwest China to test two hypotheses: gender differences in social network structure are universal versus gender differences in social structure are shaped by the social environment, including kinship.

Evolutionary hypotheses positing universal gender differences are based on the premise that male and female reproductive and cooperative strategies diverge (Geary, 2006; Trivers, 1972) and that social relationships therefore serve different purposes for men and women (e.g., Baumeister & Sommer, 1997; Geary, 2006). In particular, because females experience obligate parental investment in the form of pregnancy and lactation and tend to spend more time in direct childcare, women are generally expected to invest effort more intensively in relationships that enhance or do not conflict with childcare (Low, 2005). By contrast, men are hypothesized to use social networks more frequently to achieve status-oriented objectives, and/or to facilitate typically male dominated activities such as hunting, collective defense, or collective aggression (David-Barrett et al., 2015; Rose & Rudolph, 2006; von Rueden et al., 2018). Some hypothesize that male philopatry over human evolutionary history exacerbates these gender differences by providing men greater access to kin (Campbell, 2013; but see Dyble et al., 2015). These hypothesized universal gender differences have generated the following specific predictions: 1. men's social networks will be larger than women's and will include a higher proportion of casual and opportunistic 'weak' ties (e.g., Baumeister & Sommer, 1997; Benenson, 1990; Vigil, 2007); 2. higher quality relationships in

women's networks will manifest in more frequent communication ties, whereas higher quality relationships in men's networks will be demonstrated through participation in joint activities (e.g., Pearce et al., 2021; Roberts & Dunbar, 2015); 3. men will show a higher threshold for relationship conflict and will achieve post-conflict reconciliation sooner than women (e.g., Benenson et al., 2018; Benenson & Christakos, 2003; Dunbar & Machin, 2014); 4. men will preferentially socialize in larger and more hierarchically organized groups while women will gravitate towards more intimate, often 'dyadic' relationships (e.g., Baumeister & Sommer, 1997; Benenson, 2019; David-Barrett et al., 2015).

Taken together, these predictions, associated with what we call the 'universal gender differences' (UGD) hypothesis, have garnered a fair amount of support across a range of studies. For example, women have been reported to treat friends more like kin, and men to treat friends more like strangers and to pursue status-oriented relationship goals (Ackerman et al., 2007). In a study of American university students, men reported more friendships than women, and were more willing to sacrifice intimacy to secure more friends (Vigil, 2007). In a study of American high school and middle school students, boys had more friendship connections than girls, while girls' networks showed more small-group clustering (Lindenlaub & Prummer, 2021). In another university sample, Friebe et al. (2021) documented that women's initial friendships remained highly stable over time, whereas men's friendship connections showed more opportunism and flexibility. In a large study of Facebook friendships, David-Barrett et al. (2015) found evidence consistent with women preferring same-sex dyadic relationships and men favoring larger, same-sex cliques. Similarly, an experience-sampling study of Dutch and American participants found that women engaged in collective activities in dyads more than men (Peperkoorn et al., 2020). In addition, studies of same-sex groups suggest boys and men tend to organize their groups hierarchically more than women, whereas women are more likely to enforce egalitarianism (Benenson & Abadzi, 2020; Berdahl & Anderson, 2005).

In a review of available evidence, Rose and Rudolph (2006) concluded that girls were more likely than boys to engage in prosocial relationships and were motivated by 'connection-oriented' goals, whereas boys had larger, more hierarchical networks, with 'dominance' and 'self-interest' goals at the fore. These differences are generally thought to solidify in adolescence (Benenson, 1990). However, some studies observe mid- to late-age gender reversal. A study of Europeans found that men have more social contacts than women, particularly in young adulthood, but then this gender difference reverses in middle age as the number of contacts for both genders declines and as reproductive priorities shift (Bhattacharya et al., 2016). There are also studies that find no gender difference in network structure (e.g., Mengel, 2020) or find a higher number of network contacts in women compared to men, such as in the context of an online game (Szell & Thurner, 2013) or online communication more generally (Psylla et al., 2017).

Similarities to the human studies can be found in non-human primates. Observations suggest that baboon females build relationships to benefit infant survival (Silk, 2007), and that female chimpanzees and bonobos build coalitions to defend kin and friends against male aggression, whereas males are more likely to build relationships to compete for high rank and the mating opportunities it affords (Newton-Fisher, 2006; Tokuyama & Furuichi, 2016). Many evolutionary arguments appeal to male philopatry as a primary reason for gender differences in social networks on the premise that philopatry was common, long enough, or universal during much of human (or primate) evolutionary history (e.g., Campbell, 2013; David-Barrett et al., 2015; Vigil, 2007). In chimpanzees, male social networks are based strongly on

maternal kinship relationships (Mitani, 2009), and, in gorillas, male philopatry results in more dispersed networks for males (Bradley et al., 2004). However, philopatry is variable among non-human primates, where the benefits of social bonds to females have been argued to be a causal driver of female philopatry in a majority of non-human primate species (e.g., Wrangham, 1980). Even in non-human primates most closely related to humans, where male philopatry prevails, it appears that the importance of female social bonds has been under-emphasized (Emery Thompson, 2019) and that males and females show less divergent use of social bonds than sometimes reported (Langergraber et al., 2009; Psylla et al., 2017). Among humans, contemporary hunter-gatherers are highly flexible in residence (Kramer & Greaves, 2011; Wood & Marlowe, 2011). More generally, although male philopatry and female exogamy are modal among human societies (Murdock & White, 1969), humans are remarkably flexible in post-marital residence across cultures (e.g., Surowiec et al., 2019), creating varying constraints on the social relationships available to men and women (Power & Ready, 2019). In sum, several lines of evidence in humans and non-humans suggests that sex-biased philopatry is neither ancestral nor universal among humans; therefore if philopatry influences the nature of sex-biased social relationships, we should expect flexibility rather than universals in gendered relationships (Langergraber et al., 2009; Power & Ready, 2019; Rodseth & Novak, 2006).

In general, conditions that decrease the differences between men's and women's reproductive capacities may result in less divergence in their use of social relationships to achieve reproductive goals. Monogamy, for example, limits men's reproductive success so that it more closely matches women's (e.g., Brown et al. 2009, Fortunato & Archetti, 2009). In monogamous contexts, men's interests should be more closely (if not perfectly) aligned with their partners' and their social relationships more tightly focused on household concerns. Differences in the means of subsistence are also associated with variation in the divergence of men's and women's reproductive success (Holden et al., 2003; Low, 2005; Mattison, 2011). Forms of subsistence such as pastoralism are generally conducive to supporting men's reproductive agendas because animals can be converted into reproductive success at higher rates for men than for women, e.g. via polygynous unions. In such cases, coalition-building and status-enhancing relationships may enhance men's chances to attain disproportionate reproductive success. In many societies, men may accrue more exchange partners than women due to public displays of wealth, e.g., in highland New Guinea (Lederman, 1990), resulting in increased status and mating opportunities. Other forms of subsistence, such as foraging or horticulture, are less likely to produce surpluses that support disproportionate reproduction among men, while others such as offshore fishing may remove men from their households for long periods of time. In these cases, women often contribute significantly to household production, or run their households with less consistent involvement from men (Mattison et al., 2019). A relatively high degree of women's autonomy amidst a limited ability among men to convert resources to reproductive success should be associated with less divergence in men's and women's relationship-building strategies.

Because subsistence differences alter the possible divergence in men's and women's reproductive success, they have been tied to variation in kinship systems, whereby son-biased inheritance (patriliney) is favored when men's reproductive interests can be effectively supported, and female-biased inheritance (matriliney) when reproductive returns are greater via daughters than via sons (e.g., Cronk, 2000; Fortunato, 2012; Holden et al., 2003; Mattison, 2011). Matriliney is also frequently, though not exclusively, associated with female philopatry (matrilocality; Fortunato, 2019; Surowiec et al., 2019).

Differences in the ecological conditions thought to give rise to matriliney are thus likely to alter the costs and benefits of gender-specific social strategies in ways that limit – and maybe reverse – the differences anticipated by the UGD. There are numerous pathways by which this might arise: first, men's absences in matrilineal systems may constrain the extent to which they can build large local networks; second, the relatively limited ability to convert resources to reproductive success may affect men's status differentials by limiting wealth differentials; and, third, women may adopt more 'masculine' social strategies as the opportunity costs of childcare are lessened by local kin support (i.e., increased presence of local allocarers). Such reversals are often deemed impossible in anthropology, where it is axiomatic that matriliney still involves men in authority (see Mattison et al., 2019). Yet, economic games in matrilineal communities have shown reversals in, e.g., risk taking (Andersen et al., 2008; Gong et al., 2014; Gong & Yang, 2012), that support the view that matrilineal women may take on roles often assumed to be 'masculine'.

Forms of subsistence can also impact gender-specific social networks via their influence on culturally transmitted gender norms, particularly norms related to gendered divisions of labor. While highly variable, gendered divisions of labor are cross-culturally ubiquitous and tend to shunt women towards more intra-household labor and direct childcare, which may constrain women's socializing beyond the household depending on family size (von Rueden et al., 2018). For example, women's group-level influence in the Mekranoti of the Brazilian Amazon was negatively associated with their parenting demands (Werner, 1984), and in the Tsimané of the Bolivian Amazon the number of women's but not men's cooperation partners was negatively associated with the number of dependent offspring (von Rueden et al., 2018). Women in many small-scale societies may tend to build larger social networks as they near menopause, in part due to fewer childcare demands. (Brown & Kerns, 1985). Subsistence practices may affect women's mobility and therefore their opportunities to form networks. For example, the transition to the plow may have made agricultural labor more strength-intensive and less compatible with childcare, thereby decreasing women's labor value outside of the home and decreasing their bargaining power in community-level politics (Alesina et al., 2011). Similarly, societies of historically pastoralist origins are more likely to promote norms restricting women's mobility and therefore their social influence (Becker, 2019). Specifically, econometric analyses suggest these restrictive gender norms arose from men's fear of nonpaternity due to periodic absence from their communities for herding or war (Becker, 2019). Warfare can also promote greater gender differentiation in social networking, due to male coalition-building (Rodseth, 2012). In contrast, some local norms encourage women's work, and therefore social connections, outside the home. Among Shodagor fisher-traders in Bangladesh, for example, some women travel to rural villages to trade with ethnic Bengali women, whose religion restricts their interaction with unrelated men (Starkweather et al., 2020). These studies suggest that gender norms related to current and historical means of subsistence influence the relative sizes and natures of gendered social networks.

In this paper, we leverage variation in kinship norms and institutions among the Mosuo of Southwest China to investigate differences and similarities in gendered social networks. Evolutionary anthropologists have hypothesized that kinship systems are shaped by social and environmental circumstances (Alvard, 2011; Shenk & Mattison, 2011) in ways that alter the costs and benefits associated with gender-specific reproductive strategies (Holden et al., 2003; Mattison, 2011; Mattison et al., 2016). We have argued previously that Mosuo matriliney is driven by limited reproductive differentiation

between the genders due to a resource base (agriculture) that is expansive and not particularly productive and that does not therefore support a strongly divergent male reproductive agenda (see also Alesina et al., 2013; Brown et al., 2009), as well as norms and institutions that allow some men to limit investment in reproductive partners and parenting activities (Mattison, 2011; Mattison et al., 2019; see also Fortunato, 2012). By contrast, patriliney, which predominates in the Mosuo villages located in more rugged, mountainous terrain, appears to be reinforced by monogamous unions and the need for stable support from men of spouses and children (Mattison et al., 2021). This context presents an ideal test of the UGD hypothesis in humans—if men tend to pursue divergent strategies due to fundamental sex differences, which they inherit as part of humans' evolutionary legacy, then we would expect to see differences between men and women even among the matrilineal Mosuo. If typical gendered differences in social networks are due instead to flexible strategies that are sensitive to local socioecological circumstances affecting the costs and benefits of different social strategies, then we are unlikely to see the typical gendered differences among the Mosuo. We pay particular attention to matrilineal Mosuo women, who may, in their socioecological circumstances, build social ties in ways that are considered typically “masculine” in the existing literature.

In a case study of two villages, one matrilineal and one patrilineal, we compare the universal gender differences hypothesis (UGD) and gender reversal hypothesis (GRH) with the following predictions: UGD: Men have larger networks (higher degree) across matriliney and patriliney; women's greater focus on intimacy and 'dyadic' relationships results in smaller networks (lower degree). GRH: Women will have larger networks (higher degree) than men in matriliney and men will have larger networks (higher degree) than women in patriliney.

Methods and Study Site:

Population: The Mosuo are a population of roughly 40,000 agriculturalists residing in the Hengduan Mountains on the border of Sichuan and Yunnan Provinces in Southwest China. They are famous among anthropologists for their matrilineal traditions, involving inheritance that effectively moves through lineally related household women (Mattison, 2011), prominent roles for grandmothers and maternal uncles (Shih, 2010), and lack of consistent involvement in parenting by some, but not all, fathers (Mattison et al., 2014, 2019). Less well known are a geographically distinct population of Mosuo, who are patrilineal and whose norms involve transmission of wealth and status from parents to their sons, monogamous marriage, and more limited, if still relatively strong, autonomy for women (Mattison et al., 2021). Evidence suggests that the patrilineal Mosuo separated from the matrilineal region 500 years ago or earlier, establishing separate norms and institutions while continuing to identify as Mosuo and maintaining a variety of shared customs, language, religion, and attire (Mathieu, 2003; Mattison et al., 2021). We have shown previously that these differences in kinship norms and institutions are associated with reversals in child gender preference (Mattison et al., 2016) and gender disparities in health (Reynolds et al., 2020). We speculated that some of this arises via more limited social support for women in patriliney (Reynolds et al., 2020), a pathway we begin to investigate here.

While little has been published about cooperation among the patrilineal Mosuo, ethnographic and quantitative evidence suggests that cooperation is extensive among the matrilineal Mosuo. Mosuo people routinely come together to help each other during planting and harvesting seasons, for example, and

cooperate in the construction and repair of homes, preparations and costs of religious and cultural ceremonies, and joint economic ventures (Shih, 2010; Thomas et al., 2018). Large households help with domestic activities such as childcare, and household sisters are said to reproduce as a communal effort toward ensuring lineage and household longevity (Ji et al., 2013; Shih & Jenike, 2002). At the same time, tourism and acculturation have led to an increasing fraction of households adopting non-normative institutions and plausibly acting more autonomously than might otherwise be expected (Blumenfield et al., 2018; Mattison, 2010; Walsh, 2001; see also Wu et al., 2015). The villages sampled in this study were both relatively far removed from sites of tourism and are locally considered to be relatively ‘traditional’.

Data collection: We carried out social network interviews as part of the [ENDOW project](#) in an attempt to capture full networks of households in one matrilineal (N=40 households) and one patrilineal (N=30 households) community of Mosuo in the summers of 2017 and 2018. Accompanied by local guides, we walked from house to house and asked any available adult member of the household, man or woman, who could also comment on the networks and kin relatedness of other adult members of the household, to participate. We explained the study to potential participants and addressed their questions before obtaining their informed consent for the interview (UNM IRB 06915). We employed a name generator approach in which respondents were asked to free list individuals with whom they had various kinds of social ties (Marsden, 2005). We focus here on a question that asked respondents to identify whom they considered close friends (*‘pengyou’*) with whom one would hang out or ‘chat’ (*‘liaotian’*) after dinner, a common activity among friends. Our goal was to obtain responses to interview questions for one adult man and one adult woman of each household. In cases where the opposite-gender respondent was not available at the time of interview, the main respondent answered in their stead. We did not note the names of any additional people present during the interview. Because data collection included a complete household census, we were able to infer the identity of the opposite gender respondent in most cases (with certainty if they were the only adult member of opposite gender residing in the household and with high confidence if the friendship network consisted mainly of similar-age peers). In some cases, additional cues were available, such as the respondent indicating that friends were ‘my son’s’. For cases where multiple opposite-gender individuals of similar age resided in the same household, we did not assign an identity for the second household respondent. A census of households allowed us to identify and verify individual-level attributes for egos, inferred egos, and alters who were present in the census; we also collected some individual-level data on egos and alters at the time of social network interview.

Data Analysis: The populations of interest in this study are all adults in two geographically distinct communities: 312 adults in the matrilineal area and 219 in the patrilineal area. In order to estimate the patterns of friendship ties in each location, we constructed social networks as follows. First, we included each individual who was either interviewed directly or whose friendship ties were identifiable from an interview, an ego, as a node in a location-specific network regardless of gender. Second, we drew an undirected edge between each ego and any other individual (an alter)¹ named in response to the question, ‘With whom do you/women/men hang out after dinner?’ Multiple edges, indicating that both termini of the edge were egos and had nominated each other (6.0% of raw edges in the matrilineal location and 9.5% of raw edges in the patrilineal location), were treated as a single undirected edge. Although the results of

¹ This modification to standard use of the terms ego and alter is used in this study to reflect the fact that our sampling strategy resulted in individuals having systematically more or less opportunity to have their friendship edges represented in the network.

the name generating process could have been considered a directed network, undirected edges were used because not all nodes had the same opportunity to be associated with both in- and out-edges.

Networks were characterized according to standard metrics (Wassermann & Faust, 1994). Our sampling procedure resulted in the exclusion of 57% of possible nodes in the matrilineal area and 58% in the patrilineal area—these individuals and any edges connecting to them are considered to be missing. Although these levels of missingness are relatively high, reasonable estimates of many network features may still be possible (Smith & Moody, 2013). Furthermore, our strategy of interviewing heads of households and their closest household partners likely included individuals who were relatively more central to the overall network, potentially reducing the effects of missingness on estimation (Smith et al., 2017). Differences between the central tendencies of node-level statistics were tested with Wilcoxon rank-sum tests and differences between distributions tested with Kolmogorov-Smirnov tests; pairwise comparisons between categories of egos are reported here with equivalent analyses of all nodes reported in SI.

We constructed a generalized linear model to test the primary hypotheses using the degree of each node as the outcome variable. Degree was approximately Poisson-distributed and was not zero-inflated. All nodes were considered in the GLM analysis, with controls included for whether the node was an ego and whether, if an ego, the node was not the primary interviewee. These controls capture the fact that we did not interview all individuals represented by nodes and therefore not all nodes had the same chance to declare edges and were thus expected to have lower observed degree.

All analyses were conducted in R (version 4.0.5) using the ‘igraph’ package (version 1.2.6, <https://igraph.org>); network visualization was done in Gephi (version 0.9.2, <https://gephi.org>).

Results:

Table 1. Sample characteristics.

All respondents	Matriliny		Patriliney	
	Women	Men	Women	Men
N	31	32	29	29
<i>Individual characteristics: mean (standard deviation)</i>				
Age (years)	48.9 (9.1)	45.9 (14.4)	43.5 (11.4)	47.4 (13.3)

Descriptive Statistics: We interviewed 17 men and 23 women in the matrilineal area who provided information for an additional 15 men and 8 women, for a total of 32 men and 31 women. We interviewed 18 adult men and 12 adult women as primary respondents in the patrilineal area. In addition to their own information, these respondents provided information about 11 co-resident men and 17 co-resident women, for a total of 29 men and 29 women respondents (Table 1). We were unable to identify the second household respondent in 8 (20.0%) cases in matriliney and 2 (6.7%) cases in patriliney; we treated this information as missing. The full discovered network (all nodes) included 55 women and 78 men in the matrilineal community and 45 women and 47 men in the patrilineal community. The mean age of all nodes was 50.0 years versus 42.8 years for women versus men in the matrilineal community; and 46.8 years versus 47.8 years for women versus men in the patrilineal community. Mean years of education was slightly lower for both men and women in the matrilineal community.

Qualitatively, the matrilineal friendship network appeared to be more connected and contained many more cross-gender friendships than the patrilineal network (Figure 1a). By contrast, the patrilineal friendship network (Figure 1b) was markedly gender-segregated, with distinct clusters of friends, linked loosely to each other. In the patrilineal network, 2 (1.8%) discovered edges were cross-gender; in the matrilineal network, 24 (14.0%) discovered edges were cross-gender. There were five isolates reporting no friendships in the matrilineal area and three isolates in the patrilineal area.

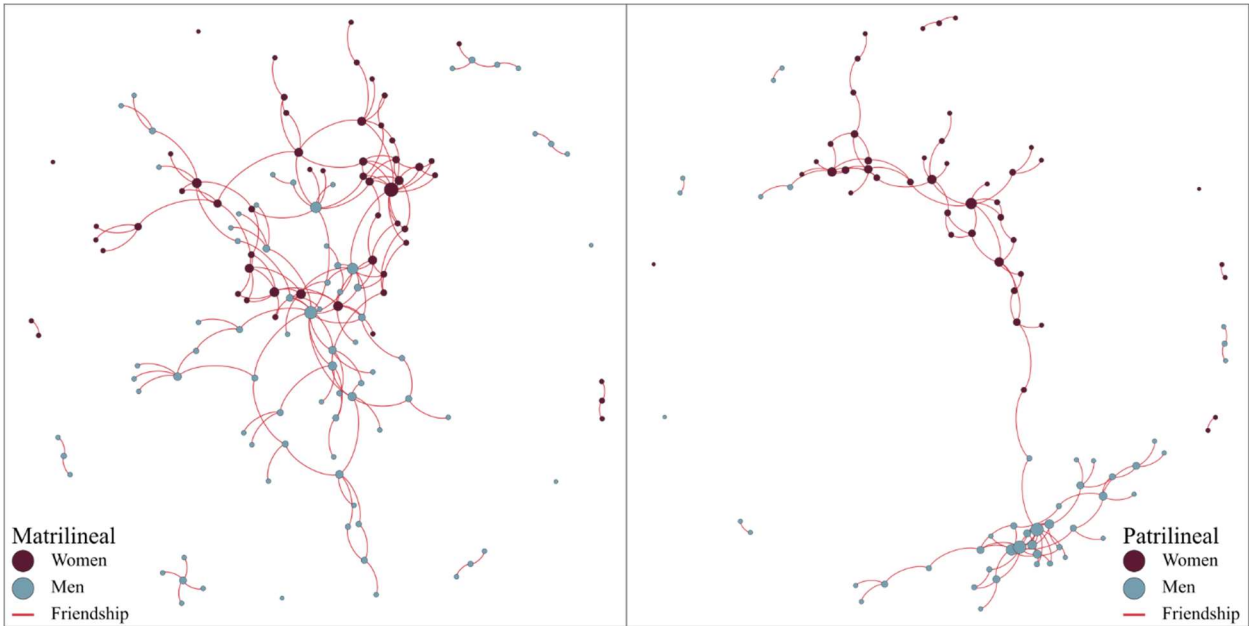

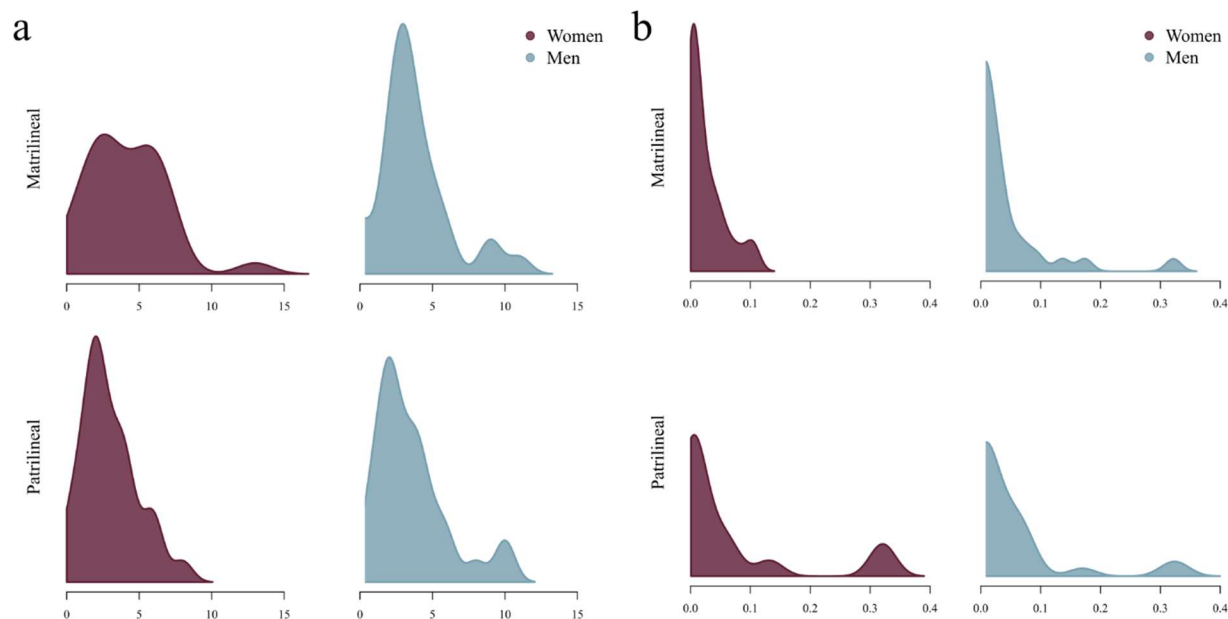

Figure 1. Social networks of men (blue) and women (purple) in matriliney (a, left) and patriliney (b, right). The size of each node corresponds to its degree.

Among respondents, the degree (i.e., the number of reported friendships for an individual, whether by that individual or by others) distribution of matrilineal women was distinct from the others (Figure 2a; Table 2); particularly, median degree was higher among matrilineal women. Men's degree distributions were roughly similar, with long right tails, which is consistent with a few men having relatively more friendships than the bulk of men and women. The degree distribution for matrilineal women stood out as being relatively flat, with a higher median reported degree. The modal degree for respondents of both genders in both contexts was two to three. The direction of differences was similar when all nodes were considered (Table 1; SI Figure 1a).

Additional measures of centrality revealed few strong differences between men and women. Betweenness centrality, which measured the extent to which a node fell on the geodesic paths of others in the network, depicted an individual's potential to bridge among disparate network clusters. The importance of one cross-gender edge in bridging the largely gendered clusters in the patrilineal community was apparent in Figure 2b; nodes along this path had correspondingly high levels of betweenness centrality. The distribution of betweenness centrality was similar among men in matrilineality. Matrilineal women, however, demonstrated low levels of betweenness centrality, potentially suggesting matrilineal women were generally more connected within that network. None of these differences was statistically significant (Table 2). Patterns in betweenness centrality were similar when all nodes are considered (Table 1; SI Figure 1b).

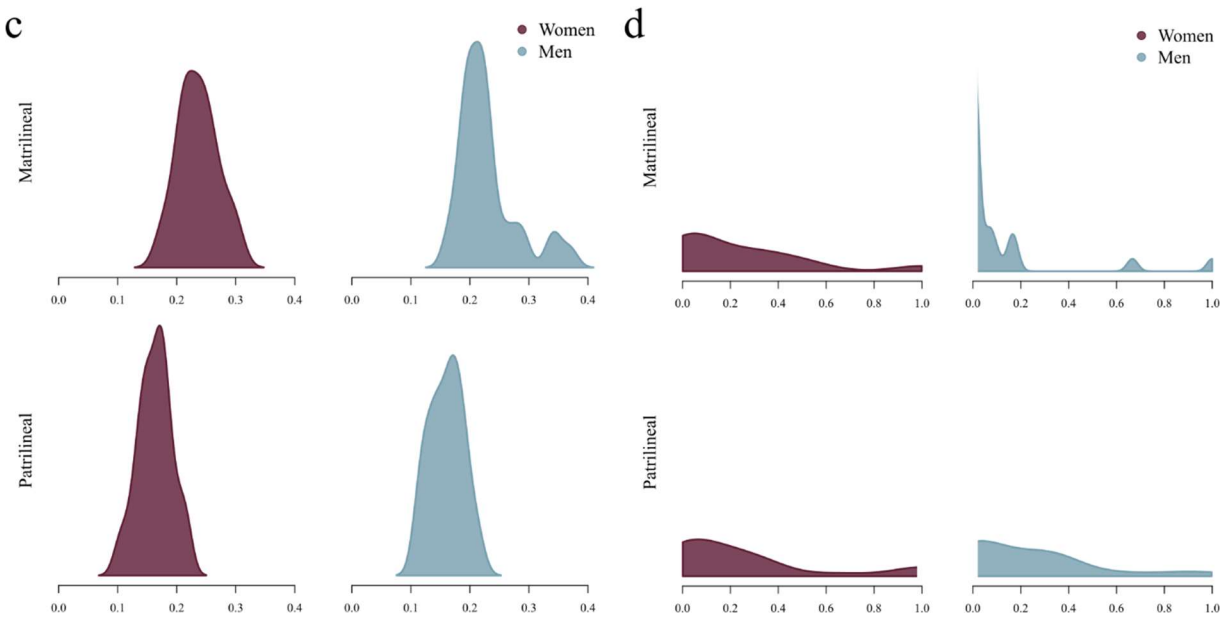

Figure 2. Kernel density plots for men (blue) and women (purple) in matriline and patriline, as labeled for (a) degree, (b) betweenness centrality, (c) closeness centrality, and (d) transitivity.

Table 2. Results of Wilcoxon rank sum (WRS) and Kolmogorov-Smirnov (K-S) tests comparing degree, betweenness, closeness, and transitivity distributions for patrilineal (pat.) and matrilineal (mat.) Mosuo respondents.

Closeness centrality measured the number of edges between a focal node and all other nodes in a network; it was undefined for nodes without at least one path between them. Nodes with high closeness centrality had relatively short distances to all other nodes. Under matriliney, the range in closeness centrality was wider for men than for women, although the medians of the distributions were not obviously different (Figure 2c; Table 2). Among respondents from the patrilineal area, closeness centrality distributions were similar between men and women. There were no statistically significant differences in closeness by gender within either community; however, higher closeness in the matrilineal community was apparent upon both visual inspection (Figure 2c) and pairwise tests (Table 2). This was consistent with higher connectivity in the matrilineal friendship network and increased average distance between nodes in the patrilineal network due to the single set of edges connecting the two main clusters of nodes. Consideration of all nodes does not alter this conclusion (Table 1, bottom; SI Figure 1c).

Transitivity, or the number of a node's complete triads (a case in which three nodes were connected by edges between each of the three possible pairs) as a proportion of its connected triads (a case in which three nodes were connected by two edges such that one pair of nodes was not connected by an edge), reflected clustering in a network—the extent to which friends tended to nominate the same individuals as friends. The modal transitivity for both women and men respondents in both matriliney and patriliney was

Table 3. Poisson generalized linear model of network degree by primary household survey respondent status, secondary household survey respondent status, age, gender, and community for all nodes of matrilineal and patrilineal Mosuo adults (n = 225).

Variable	Coefficient	Standard Error	<i>p</i>

zero. Matrilineal women had a higher median transitivity and more matrilineal women had non-zero transitivity (25, 47.2%) compared to matrilineal men (9, 11.8%). The median transitivity for men and women in patriliney was similar. Patterns were similar when all nodes were considered (Table 1; SI Figure 1d). Both centrality and transitivity scores indicated that matrilineal women were relatively more connected than patrilineal women.

The node-level characteristics described above reflected corresponding differences in network-level metrics between the two locations (SI Table 1). Although network density (the number of observed edges as a proportion of possible edges), degree centralization (the extent to which centrality is concentrated in a small number of nodes), and betweenness centralization were roughly equivalent between the two networks, measures of network distance diverged. In particular, although all nodes were on average closer to each other in the matrilineal network, there was more concentration of closeness centrality in the matrilineal network than in the patrilineal network.

Generalized Linear Models: Modeling degree as a function of gender and community (matrilineal or patrilineal), with controls for respondent status (i.e., primary respondent, inferred respondent, or discovered node) and age did not reveal differences by gender ($p = 0.62$; Table 3). There was marginal evidence for a positive association between matriliney and degree ($p = 0.095$). There was no evidence for an interaction between gender and community (Coef: -0.214 ; $p = 0.23$), which would have been expected if the gender reversal hypothesis were supported. The control variable for survey respondent was, as expected, positively associated with degree ($p < 0.0001$), as respondents had more edges than non-respondents; the control variable for inferred respondent was inversely associated with degree ($p = 0.065$), suggesting fewer ties may have been reported for secondary respondents within a household. Finally, although the interaction term was not significant, the predicted probabilities from this model supported a mild gender reversal in degree by descent system, providing tentative, suggestive evidence for a gender reversal in network size (Figure 3).

Figure 3. Predicted probabilities for network degree by gender and descent system controlling for survey respondent status and age.

Discussion:

In this paper, we strove to test what we have called the universal gender differences (UGD) hypothesis, which posits, among other things, that men have larger networks than women, here operationalized as degree in an undirected social network. We tested this in two communities – one patrilineal and one matrilineal – that are organized differently in terms of gender, inheritance, descent, and ecology, but otherwise similar (Mattison et al., 2021). This variation presented the opportunity to investigate whether the UGD might hold in some ecologies, but not others, and whether gender reversals in node degree (a measure of network size) might be present in matrilineal communities where women are relatively autonomous (Mattison et al., 2019; Reynolds et al., 2020).

We find no evidence in either patriliney or matriliney in support of the UGD hypothesis. In patriliney, there are no marked gender differences in network metrics. In matriliney, there are some gender differences: although these differences are not substantial, they are generally in the opposite direction to predictions of the UGD hypothesis. Specifically, matrilineal women may have larger networks than matrilineal men. Additionally, both descriptive results and our generalized linear model suggest that matrilineal friendship networks are larger and more connected than patrilineal networks, with matrilineal friendship networks including more hetero-gendered social relationships and patrilineal ones clustering more strongly on gendered lines. In addition to rejecting the UGD in these contexts, we interpret this evidence as consistent with variation being structured by local socioecologies. These inferences are tempered by limitations of sample size (only two networks were sampled) and sampling strategy (not all relevant individuals were interviewed). Nonetheless, we believe this is a useful case study if it prompts additional research in small-scale settings where local gender norms and ecological variation may be likely to reveal additional nuances in the ways that men and women structure and use social support.

These findings suggest that local socioecological circumstances should be incorporated into understandings of women's and men's constraints, decision-making, and associated outcomes (Winterhalder & Smith, 2000). More specifically, the assumptions that underlie hypotheses of universal differences in men's and women's social and reproductive strategies are unlikely to be met across contexts. We highlight two such assumptions here, as neither is likely to characterize both subpopulations of the Mosuo. First, the UGD hypothesis assumes that reproductive variance is higher in men than in women and that this motivates men to cultivate larger ('diffuse') networks as a means to gain status (and, as a result, more mating opportunities). Furthermore, sexually selected motivations contribute to gendered divisions of labor, and these tend to anticipate more intra-household labor by women, which effectively constrains women's social-networking opportunities relative to men's (von Rueden et al., 2018). Among the patrilineal Mosuo, monogamy and the consistent need for men's labor (Mattison et al., 2021) likely constrains men who would otherwise attempt to pursue multiple reproductive partners (see, e.g., Fortunato & Archetti, 2009; Kokko & Jennions, 2008). More generally, although variance in reproductive success is higher, on average, for men than for women among humans, there is substantial population-level variation (Brown et al., 2009), with variance in female reproductive success occasionally outstripping male. Monogamy characterizes the bulk of relationships among both patrilineal and matrilineal Mosuo (Mattison et al., 2021), but exists within the context of relatively small, mostly nuclear domestic units in patriliney, suggesting that status-oriented pursuits may have more limited impact on male reproductive success among the Mosuo – even in patriliney – than it might in contexts where polygyny prevails.

Second, the UGD hypothesis often references male philopatry and female emigration as an ancestral pattern of community organization to which men and women adapted differently. Specifically, scholars have argued that general tendencies toward male-biased philopatry in humans should lead to stronger, kin-based coalitionary networks in men versus a focus on fewer, more intimate relationships in women (Vigil, 2007; Wrangham, 1980). Although patrilocality is the modal form of human social organization in contemporary societies (Murdock & White, 1969), it is far from universal (Surowiec et al., 2019) and is unlikely to have been the single emigration pattern of Pleistocene foragers, who most likely displayed flexibility in residence (Dyble et al., 2015; Kramer & Greaves, 2011; Wood & Marlowe, 2011)—and in fact it has been argued that modern low levels of matriliney and high levels of patriliney may be in part due

to the impact of colonialism on the ethnographic record (Shenk et al., 2019). In our study communities, patrilineal women initially have more limited access to social support than patrilineal men. By contrast, matrilineal women and men normatively reside in their natal communities throughout their lifetimes. Our findings provide preliminary evidence that matrilineal friendship networks are larger than patrilineal ones and are also more likely to involve hetero-gendered relationships. This pattern of natalocal residence may contribute to that (He et al., 2016; C. Shih, 1993), as may the relative ease with which individuals travel from house-to-house in this relatively traversable terrain (Mathieu, 2003; Mattison et al., 2021). This result, even if tentative, reinforces the importance of differences in the social and demographic constraints imposed by kinship systems in structuring access to social support and the costs and benefits to men and women of gender-specific strategies (Koster Jeremy et al., 2019; Low, 2005; Power & Ready, 2019; Starkweather et al., 2020), with important implications for understanding strategies across diverse contemporary settings (David-Barrett, 2019; Mattison & Sear, 2016).

Our qualitative assessment of degree distributions suggests differences between genders, by descent system, offering very tentative support for our hypothesis that the ‘typical’ pattern of larger degree for men would be reversed in the matrilineal setting. Our analyses did not bear out the predicted interaction between gender and community, potentially due to our fairly small sample size. Although our qualitative assessment hardly stands on its own, in the context of other studies showing gender reversals in aspects of behavior (Gong et al., 2014; Gong & Yang, 2012; Liu & Zuo, 2019) and outcomes (Mattison et al., 2016; Reynolds et al., 2020) among matrilineal Mosuo relative to other patrilineal populations, we suspect that future work in a larger sample may bear out this prediction.

Our findings provide additional motivation to reexamine existing dogma stipulating the absence of matriarchy and limits to women’s roles in matriliney (Leonetti et al., 2005; Parkin, 2021; Schneider, 1961). Women in matriliney are often implicitly or explicitly assumed to never fully take on roles analogous to those of men in patriliney, particularly as societal leaders. However, a variety of evidence points to the importance of women’s leadership and status in securing evolutionarily relevant benefits, such as their own and their children’s health and welfare, even if women’s influence *on average* in the range of societies that generate the ethnographic corpus may be less overt than men’s within their communities (Alami et al., 2020; Reynolds et al., 2020). Matrilineal women’s social relationships as depicted here do not fully mirror men’s; still, their relatively large network size suggests that aspects of women’s social strategies can resemble men’s when women are more central and have more authority and social support (Hrdy, 2000; Mattison et al., 2019; Smuts, 1994). The large households characteristic of the matrilineal Mosuo are likely to free many women from the demands of childcare by providing ample and capable allocarers (often women), whereas the nuclear households characteristic of patrilineal Mosuo are likely to be conducive to more domestic-oriented activities among women, as suggested by our ethnographic observations. In other small-scale societies, women’s time spent in childcare and domestic labor more generally can contribute to greater opportunity for men to socialize broadly within and between communities and to gain community-wide social influence (Werner, 1984; Brown & Kerns, 1985; von Rueden et al., 2018). Differences in network characteristics according to social and ecological contexts underscore the importance of general, rather than gender-specific, models of reproductive and cooperative strategies that consider social, demographic, and ecological constraints affecting the potential for complementarity and divergence between men and women (Bliege Bird & Bird, 2008; Mattison, 2016; Starkweather et al., 2020).

Our study is subject to a number of important limitations. Our sampling strategy resulted in a network that is not complete in that we did not interview every person residing in the two communities, but rather members of, to the best of our ability, every household in each community. Households often included more adults than the two about whom friendship information was sought. Our expectation is that if more individuals had been interviewed, the number of nodes and edges would have increased as well, affecting, for example, the maximum observed degree. Furthermore, although node degree and transitivity in networks of a similar number of nodes as our potential networks (250 – 350 nodes) is relatively consistently estimated across a wide range of percent missingness, metrics such as betweenness and closeness are more sensitive (Smith & Moody, 2013). This sensitivity may be problematic in the networks we studied because betweenness and closeness are driven in large part by the small number of cross-gender friendship ties, particularly in the patrilineal network. However, the difference in proportion of cross-gender edges between the two locations is stark: although our precise estimates of, for example, betweenness and closeness may differ from values that would have been obtained in the complete network, cross-gender ties would have to be substantially undersampled in the patrilineal network to approach the proportion of cross-gender ties in the matrilineal network. That said, a sampling strategy that focused on younger or older adults, or a more random sample of individuals (and thus less systematically likely to include higher centrality nodes (Smith et al., 2017), may have found different patterns. Moreover, this is a static, descriptive portrait of social relationships, which are known to change across the life course (David-Barrett et al., 2016; Palchykov et al., 2012; Bhattacharya et al., 2016). Stability of relationships may have important implications for health, well-being, and reproductive success (Cheney et al., 2016) that we cannot capture here, perhaps particularly for women in patriliney where many relationships are established subsequent to marriage. Our ability to capture spatially and temporally diverse friendships that characterize humans and distinguish us from non-humans (Rodseth et al., 1991) is incomplete. Nor do we have information on the intimacy or specific exchanges implied by observed relationships that might help to test differences in the quality and intensity of relationships anticipated by some of the hypotheses reviewed in the introduction (e.g., Rose & Rudolph, 2006; Vigil, 2007). This, too, would provide important insights on how the strength of relationships relates to fitness and well-being (Scelza, 2011; Silk et al., 2010), and whether this varies by gender across different social systems. Finally, we characterized networks based on self-reported, often unreciprocated ties. Although we have no reason to suspect biases in any particular direction, we also have no observation of benefits transferred along the reported ties. Observations of specific types of cooperation (e.g., working on someone's farm (Thomas et al., 2018) would help to verify the importance of the patterns we describe here.

Certainly, the fact that respondents' social networks are larger than alters' suggests the need for more complete sampling. Comparing our results to prior network studies based on more complete networks drawn from other settings, e.g., classrooms (Benenson, 1990; Vigil, 2007) or even relatively clearly bounded networks (Apicella et al., 2012; Nolin, 2012; Page et al., 2017), is difficult. Considering the limitations of network methods and metrics in field settings, especially with loose boundaries among communities (Gerkey & Cronk, 2014), will be important in future studies of gender differences in social relationships. Finally, the comparison between individuals residing in two communities that differ in terms of descent system is interesting, but also effectively a case study. Comparative networks studies will facilitate attempts to generalize results beyond this particular site.

Conclusion: Despite the demonstrated importance of social relationships to human and non-human primate reproductive success and well-being, there has been remarkably little work in evolutionary anthropology investigating how social relationships may be structured and used differently by men and women in varying contexts. Our study is the first of which we are aware to compare men's and women's social networks in two very different kinship contexts: matriliney and patriliney. Because these contexts are part of the same culture yet differ in the extent to which they support divergent reproductive strategies, they are ideal for understanding how fixed (or flexible) gendered social relationships are. Women provide important forms of support that often go unrecognized in evolutionary studies of cooperative networks. We have shown here that gender differences in social network size can reverse in matriliney compared to patriliney. This suggests the need to evaluate common assumptions undergirding universal models of gender differences in social and reproductive strategies, which are only likely to be met in some socioecological circumstances, and which were unlikely to have fully characterized ancestral human environments. Our point is not to say that men and women never diverge or that they do not pursue complementary strategies, or that the patterns found by previous researchers are incorrect, but rather to suggest that more general models of human evolutionary strategies that incorporate non-gender-specific constraints and consider diverse socioecologies will offer a broader understanding of human flexibility. Given the links between social support, health, and well-being across species (Cheney et al., 2016; Power & Ready, 2019; Silk et al., 2003), this is not merely a theoretical exercise.
