**Abstract:** Recently, we have witnessed a booming development of composites and multi-dopant metal oxides to be employed as novel photocatalysts. Yet the practical application of photocatalysis for environmental purposes is still elusive. Concerns about the unknown fate and toxicity of nanoparticles, unsatisfactory performance in real conditions, mass transfer limitations and durability issues have so far discouraged investments in full-scale applications of photocatalysis. Herein, we provide a critical overview of the main challenges that are limiting large-scale application of photocatalysis in air and water/wastewater purification. We then discuss the main approaches reported in the literature to tackle these shortcomings, such as the design of photocatalytic reactors that retain the photocatalyst, the study of degradation of micropollutants in different water matrices, and the development of gas-phase reactors with optimized contact time and irradiation. Furthermore, we provide a critical analysis of research-practice gaps such as treatment of real water and air samples, degradation of pollutants with actual environmental concentrations, photocatalyst deactivation, and cost and environmental life-cycle assessment.

**Keywords:** Air pollution; Photocatalysis; Reactors; Wastewater; Water matrix; Scaling up

1. Introduction

Air and water pollution represents a serious concern for the human health and the livelihood of entire ecosystems. A vast range of priority pollutants (most important regulated pollutants) and pollutants of emerging concerns (pollutants with severe health and environmental concerns but not yet regulated) can be found in industrial wastewaters and exhausts, or are released to the environment during the end-use of chemical products [1–3]. Air pollution, both outdoor and indoor, represents a major threat to the human health, killing an estimated seven million people worldwide in 2016 [4], due to pollutants such as particulate matter, polyaromatic hydrocarbons, carbon monoxide, nitrogen oxides, and volatile organic compounds (VOC). Widespread water pollutants include perfluoroalkyl substances (PFAS), pharmaceuticals and personal care products (PPCPs), pesticides, and endocrine-disrupting compounds (EDCs) [5].

Although most of these pollutants are present in the aquatic environment in very low concentrations (usually in the range of μg.L⁻¹ and ng.L⁻¹), they have severe direct and indirect repercussions on the environment and human health [6]. For instance, very low concentrations of antibiotics may favor the development of antibiotic resistance in certain microorganisms [7].

Conventional pollutant removal technologies present numerous shortcomings. For instance, conventional biological wastewater treatment methods are able to break C-C bonds in organic pollutants, but they have limited ability to destroy other strong bonds in
complex micropollutants, especially when easily digestible organics exist as a favored food for microorganisms, such as in domestic wastewater [6]. Advanced oxidation processes (AOPs) have been recognized to be efficient for the degradation of persistent organic molecules through the generation of strong reactive oxygen species (ROSs). Among AOPs, photocatalysis is distinguished by its ability to generate diverse ROSs, durability, and oxidation efficacy towards numerous families of micropollutants [8–10].

Notwithstanding the myriad of studies reporting the degradation of diverse air and water pollutants by state-of-the-art photocatalysts, there is an increasing skepticism about the full-scale application of photocatalysis for environmental purposes [11–13]. Obviously, the recent research in photocatalysis was largely inspired by advances in materials science, nanotechnology, and characterization techniques [14]. The fascinating properties of novel nanomaterials such as quantum dots, metal-organic-frameworks (MOF), graphene, doped metal oxides, and their composites attracted many researchers to explore their photocatalytic activity at the expense of engineering aspects [15–17]. Consequently, the literature of photocatalysis research is overstuffed with novel nanocomposites and their advanced characterizations to prove the successful synthesis and unique properties. Photocatalytic experiments were often conducted by the dispersion of a photocatalyst in a single-pollutant solution under well-controlled conditions [11]. In contrast, fewer studies focused on the design of photocatalytic reactors or simulating real water/wastewater streams [18,19].

The benchmark photocatalyst, TiO$_2$, is distinguished by high thermal, chemical and photochemical stability, and low cost, but it lacks the sensitivity to visible light and is only activated under UV light [11,20], it presents low quantum yields [11] and its health effects have recently come under increased scrutiny [21]. Novel visible-light photocatalysts promise to overcome the limitations of TiO$_2$ in terms of activity range, but generally, there is a lack of knowledge about their cost and toxicity.

The photocatalyst particles are not consumed during the illumination, and hence they could be reused for several cycles until the active surface is blocked by the accumulation of organic matter [22]. However, the collection of the dispersed particles is a tedious process and may require prior magnetization [23]. To overcome these shortcomings, some attempts have been made to design photocatalytic reactors with retained catalysts but the full-scale potential of these approaches remains elusive [14,24–27].

The presence of multiple pollutants, electrolytes and other dissolved species in real water matrices is known to affect, often negatively, the photocatalytic performance [28]. Yet comparatively few studies reported the degradation of micropollutants in different water matrices to simulate real water/wastewater streams [29,30].

The application of photocatalysis for the removal of air pollutants suffers instead from mass transfer issues, which limit the process efficiency and can instead give rise to accumulation of undesired byproducts due to sub-optimal contact times between the pollutant and the active surface [28].

Overall, several research-practice gaps need to be tackled to encourage the investments in photocatalytic technology. This report provides a critical overview of the knowledge gaps that hinder the full-scale application of photocatalysis in air and water/wastewater purifications, such as reactor design and scale-up, cost estimation, indirect implications on the environment, photocatalyst lifetime, and treatment efficiency in the case of low pollutant concentrations and real water/wastewater matrices. Finally, we offer a perspective on some of the most promising, recent attempts for addressing these crucial issues.

2. Photocatalysis for water purification
2.1 Reactor design

The basic function of photocatalytic reactors is providing contact between the illuminated catalyst and pollutants. This can be easily and efficiently attained by dispersing the photocatalyst particles in a vigorously stirred vessel under an appropriate irradiation
source. This simple approach has been in fact employed in the majority of studies reporting the photocatalytic degradation of micropollutants or disinfection [31–34]. Notwithstanding the high photon absorption and efficient ROS interaction with pollutants in the case of dispersed catalysts, the photocatalyst reuse is hindered by the difficulty of recovering the nanostructured powder at the end of the process. To prove the stability and reusability of the dispersed photocatalysts, some researchers added drops of concentrated pollutants after the first photocatalytic cycle [7]; however, this approach is obviously not applicable in real-life. Furthermore, the potential release of photocatalyst powder represents another major drawback of setups using dispersed catalysts, because the toxicity of the nanoparticles and their repercussions on the environment are not yet fully understood.

Reactors employing photocatalysts in retained forms can facilitate reusability eliminating the need for powder recovery, which generally requires ultrafiltration, and, at the same time, they reduce the risks associated with nanoparticle release to the environment. We advocate for this strategy as a practical translation of bench-scale studies to full-scale water/wastewater treatment.

The fluidized-bed photocatalytic reactor is an example of photocatalytic systems that keep the photocatalyst within its boundary. In this system, the water flow is circulated with a proper velocity to keep the fluidized photocatalyst in a certain position inside the reactor [12]. In this sense, the catalyst remains in the reactor and thus there is no need for a collection step. However, the fluidized bed system was rarely used due to the low weight and high dispersibility of most photocatalysts [26]. Development of photocatalysts with bigger particle size to overcome the high dispersibility would be at the expense of the active surface area leading to lower light absorption. To attain appropriate photocatalytic suspensions, anchoring the photocatalyst on a porous substrate can also provide the additional benefit of promoting pollutant adsorption. For instance, Fang et al. prepared a composite macrostructure of TiO$_2$ nanotubes and graphene for the adsorption and degradation of bisphenol A in a fluidized bed reactor [35]. This system, using a flow rate of 1 mL/min, showed 86% and 50% pollutant removals for, respectively, 0.05 mg/L and 0.5 mg/L bisphenol A solutions; the removal performance remained constant during 1000 min tests.

The light source in fluidized-bed photoreactors can be placed at the center of the reactor or at the reactor walls, adopting either tubular UV lamps or LED lights [36,37] (Figure 1).

Figure 1. Fluidized bed type LED reactor with immobilized catalyst on polymer supports; reproduced with permission from [37].
Alternatively, reactors using photocatalysts immobilized on a solid, fixed support have been proposed as a solution allowing long operation periods with minimum catalyst loss [38]. Among them, reactors based on photocatalytic membranes have attracted increasing interest because immobilizing the photocatalysts at the membrane surface improves the mass transfer of pollutants to the photocatalytic sites [11]. The choice of the membrane materials is limited by the oxidative stress caused by the photocatalyst material: Suitable materials include polyethersulfone (PES) [39] or polyvinylidene fluoride (PVDF) membranes. Numerous types of photocatalyst immobilization procedures have been reported, such as dip coating [40], spray coating [41], layer-by-layer self-assembly [42] and blending with the polymer matrix [39]. Alternatively, porous photocatalyst morphologies can be used to obtain free-standing photocatalytic membranes [43,44]. During the operation of a photocatalytic membrane reactor, the contaminated water flows through the illuminated membranes for several cycles until the desired degradation is achieved, so the photocatalyst is kept in the reactor without the need for collection (Figure 2). Consequently, flow rate represents a crucial parameter for the operation of membrane reactor, as it affects mass transport of the reagents to the catalytic sites as well as contact time between the pollutant and the photocatalyst [45]. Liu et al. immobilized ZnIn$_2$S$_4$ on a PVDF membrane by phase inversion method, for the photocatalytic degradation of fluvastatin [46]. Almost complete degradation of 10 mg/L fluvastatin was attained in 180 min of irradiation and the reuse for six cycles retained about 91.5% of the initial efficiency. In another study, Wei et al. developed a reduced graphene oxide membrane loaded with graphitic carbon nitride (g-C$_3$N$_4$) for the degradation of 5 mg/L rhodamine B under visible light [47]. The recycle reactor removed 98.7% of the dye in 90 min and a high permeability rate was retained for 300 min, but reuse was not studied. Fischer et al. loaded TiO$_2$ on a PES membrane by dip coating and ultrasound modifications [48]. Interestingly, the produced membrane could achieve complete degradation of 13 mg/L methylene blue within 40 min for consecutive nine cycles.

![Figure 2. Photocatalytic membrane reactor operated in cross-flow filtration mode, where the feed solution is continuously recirculated tangentially to the membrane; reproduced with permission from [46].]

Other reactor configurations involving immobilized, fixed photocatalyst rely on the coating of internal reactor surfaces with the photocatalyst. Some examples of this strategy are reported in Figure 3. For instance, Behnajady et al. [49] reported a reactor design based on TiO$_2$-coated longitudinal glass plates (15 x 290 mm), illuminated by 30 W UV-C lamps (Figure 3a). The reactor was operated in a continuous-flow mode under different volumetric flow-rates and it could completely degrade 30 mg/L acid red 27 at a flow rate of 15 mL.min$^{-1}$. However, this type of reactor design is prone to photocatalyst deactivation due to the limited irradiated surface area [45]. In this respect, immobilization of the photocatalyst on substrates such as Raschig rings [50] can promote the overall photocatalyst surface area and mass transfer due to turbulent flow conditions within the reactor. Other concerns regard filming problems at the glazing/lamp surface due to accumulation of dirt from...
wastewater, and the need of air or oxygen purging to maintain aeration in the closed reactor.

Another alternative is represented by thin-film fixed-bed reactors, which are falling film recycle reactors using an immobilized photocatalyst. In these reactors, water flows in a laminar flow over an inclined flat plate, coated with the photocatalyst, and it is recirculated in a batch mode. This kind of setup does not require air/oxygen purging to maintain aerated conditions and can work using non-concentrated solar radiation [51]. For instance, Fouad et al. reported the use of W-TiO$_2$ coating on inclined stainless-steel plates illuminated by two metal halide lamps placed above the reactor (Figure 3d) [52]. By this configuration, complete degradation of 30 mg/L sulfamethazine was attained in 120 min and the reuse for five consecutive cycles showed that catalyst could retain 90% of its initial performance. A similar geometry was used for the disinfection of real surface waters collected from the intakes of water treatment plants by Ru-WO$_3$/ZrO$_2$ using visible light [53]. The photocatalytic system could disinfect different water samples of 300 to 5000 CFU.mL$^{-1}$ (CFU: colony-forming units) that include gram-negative and gram-positive bacteria and the coated plates kept their activity after four cycles of consecutive reuse. This reactor type was further developed by Samy et al. to include an additional vertical plate with a chamber illuminated from a lateral borosilicate glass side (Figure 3e) [54,55].

However, laminar flow adopted in thin film fixed bed reactors limits mass transfer, resulting in a slow treatment kinetics, hence large areas are required to attain an acceptable degradation efficiency. To solve this problem, thin film cascade photoreactors have been proposed. This setup uses turbulence introduced by waterfall to promote mass transfer (Figure 3b). For instance, Stephan et al. developed a falling film recycle reactor comprised of fiber steps coated by TiO$_2$, whereby the contaminated water flowed in a closed loop [56]. The reactor degraded 5 mg/L chlortoluron in less than 160 min, but reusability was not investigated. In this respect, thin film and cascade photoreactors require the development of affordable techniques for a highly stable immobilization of the photocatalyst on large flat surfaces.

In this respect, Sun et al. recently reported an interesting alternative, based on a magnetic-bed photocatalytic recycle reactor. In this study, magnetic photocatalyst particles of CoFe$_2$O$_4$-Ag$_2$O were anchored by an external magnet to the bottom of the reactor (Figure 3c) [57]. The magnetization of Ag$_2$O by CoFe$_2$O$_4$ was not only beneficial for holding the photocatalyst, but it also reduced the band gap so that the composite could be activated by visible light. This system degraded 92% of methyl orange in 60 min, but the degradation was reduced to 80% after three cycles of reuse. Despite the fact that the efficiency of this reactor is lower than those of many other photocatalytic systems in the literature, it is a very novel and promising that could be developed on larger scales. Table 1 lists some recent examples of reactors with retained photocatalysts and their application for the removal of water pollutants.
Despite the large amount of literature on the topic, there are still several issues that hinder the full-scale application of reactors with retained photocatalyst. First, reported processing capacities are generally limited, owing to mass transfer limitations and the inherent kinetics of the photocatalytic process. In order to promote degradation efficiency, higher residence time are needed, which however limits process throughput. Few investigations have reported on pilot scale reactors [51,58] and most of these studies have employed slurry based photo-reactors [59–61]. Moreover, numerous studies on reactor configurations focus merely on the main pollutant disappearance, without providing information on the reaction intermediates, which oftentimes are still toxic and poorly biodegradable compounds [62]. The evaluation of the long-term performance of the photocatalytic systems is also another scantily investigated point, as most studies report, at best, a few photocatalytic consecutive tests. In this respect, decreasing performance in consecutive tests is often indicative of photocatalyst leaching due to mechanical and thermal stress or to accumulation of pollutants and their transformation products on the active sites, which can translate in unsatisfactory system lifetime.

2.2 Photocatalytic activity in complex water matrices and real samples

In addition to considerations related to reactor design, other challenges regard the role of the water matrix. Most studies report photocatalytic experiments on ideal lab conditions such as pure water solutions of a single pollutant at an easily quantifiable concentration (from few mg.L\(^{-1}\) to even max solubility) [63]. While rigorously controlled conditions are adopted for the sake of the characterization of novel photocatalysts, they are far from the real scenario. In fact, real industrial wastewater streams always contain a mix of pollutants in complex matrices, which include numerous electrolytes and natural organic matter (NOM). Moreover, the concentrations of micropollutants in drinking and surface water is generally in the range of ng.L\(^{-1}\) to µg.L\(^{-1}\), hence far lower than in most of the literature studies about photocatalytic remediation.

2.2.1 Presence of interfering species and real water matrices

Most literature studies adopt photocatalytic tests involving a single pollutant at the time, in a synthetic water matrix to avoid the interfering effects particularly from unknown organic species. The photocatalytic degradation of pollutants in a background-free and transparent water is ideal for lab studies to investigate the interaction between the catalyst and pollutant and the contribution of different ROS in the oxidation. However, this is not the case in real practice like the treatment of surface water, industrial wastewater, or groundwater, whereby a wide variety of substances can be found [64]. The occurrence of organic or inorganic species other than the main pollutant may inhibit the photocatalytic degradation or requires additional amounts of catalyst [65]. Moreover, photocatalysts can exhibit largely different response to complex water matrices [62], which underscores the limited value of comparisons of photocatalytic activity in ultrapure water.

Some inorganic electrolytes, such as bicarbonates and chlorides, can have a detrimental effect on the photocatalytic activity by acting as radical scavengers [28]. However, the overall effect depends on the pollutant and on the relative concentration of the species.

Reposi et al. investigated the photocatalytic degradation of bisphenol A by Rh-TiO\(_2\) in ultra-pure water, humic acid solution, solution of inorganic salts found in bottled water, and secondary treated wastewater [66]. The presence of humic acid enhanced the degradation of bisphenol A in this study, which was imputed to the reduced aggregation of Rh-TiO\(_2\) particles by the repulsion forces induced by the accumulation of humic acid on their surface. On the other hand, the degradation was 30 times slower in the treated wastewater matrix despite the whole organic content (TOC= 6.2 mg.L\(^{-1}\)) was much lower than humic acid organic content (TOC= 9.2 mg.L\(^{-1}\)). Although the organic content of treated wastewater is unknown, it was expected to contain persistent organics that survived during the biological treatment and can scavenge the ROS during the photocatalytic reaction.

Awfa et al. examined the degradation of carbamazepine by a composite of carbon nanotubes (CNTs) and TiO\(_2\) in two-stages treated domestic wastewater, river water, and three commercial synthetic natural organic matter (NOM) solutions, viz., Suwanee River humic acid (SRHA), Suwanee River reverse-osmosis isolates (SRNOM), and Suwanee River fulvic acid (SRFA) [29]. The degradation of carbamazepine was reduced from 93% in ultra-pure water to 87% and 40% in river water and treated wastewater, respectively. Furthermore, inhibition by commercial NOM surrogates was in the order of SRHA, SRFA, SRNOM indicating that the inhibitory effect depends on the characteristics of NOM such as aromaticity (ratio of aromatic content to total organic content), molecular weight, and light absorption. In another study, Ren et al. investigated the inhibitory effects of a lake water and a synthetic solution of alginic acid sodium and citric acid on the degradation of clofibric acid [64]. The results revealed that the inhibition of photocatalytic activity was influenced by the molecular weight of NOM more than its concentration. It was also noted that increasing the dissolved oxygen could decrease the inhibitory effect due to the enhanced production of superoxide radicals, whereas changing the pH did not affect the degradation rates.
NOM can inhibit the photocatalytic degradation of micropollutants by different concurrent mechanisms according to the nature and concentration of existing organic substances. Firstly, the photocatalytic activity could be reduced by the inner filter effect, i.e., a lower effective irradiation of the photocatalyst, due to light absorption by organic compounds [29]. This effect is greatly dependent on the molecular structure of NOM, as complex organic structures absorb light on a broader range than simple organics and secondary by-products [67]. Specific UV absorbance (SUVA), which is the ratio of UV absorbance at 254 nm (UV254) to dissolved organic carbon (DOC), describes aromaticity of NOM based on the light absorption at 254 nm of the benzene rings. Higher SUVA values refer to existence higher content in aromatic organics regardless of the NOM concentrations [68]. Accordingly, water matrices with higher SUVA are expected to require higher light intensity to activate the surface of photocatalyst as a compensation for what will be absorbed by NOM.

The photocatalytic activity can be also inhibited by the accumulation of NOM on the surface of photocatalyst particles, which blocks the active sites and reduces the illuminated area [53]. This accumulation decreases the production of ROS even if the catalyst is well illuminated. NOM with high aromatic content is more likely to be hydrophobic, and hence it is more adsorbed at the photocatalyst surface [69]. Furthermore, aromatic NOM quenches the holes in the valence band of the photocatalyst, which not only reduces the degradation caused by the holes but also inhibits the production of hydroxyl radicals [70]. NOM and its transformation products further scavenge the generated ROS in the polluted water inhibiting the oxidation of the target pollutants.

Although several studies investigated the influence of NOM on the photocatalytic degradation of micropollutants, the effect of the photocatalytic process on the NOM composition still needs to be clarified. This may be attributed to the challenges associated with the characterization of molecular structure variations of NOM, which makes many studies limited to aromaticity, fluorescence, etc. [71]. This research gap can be filled by advanced analytical techniques based on high-resolution mass spectrometry (MS), such as Fourier transform ion cyclotron resonance (FT-ICR-MS), Orbitrap MS, and time-of-flight MS. Such techniques could identify the dominancy of certain organic compounds based on their molecular weights, which can shed light on the changes in the dissolved organic matter during the photocatalysis.

2.2.2 Degradation of pollutants at low concentration

Investigating the removal of micropollutants in the range of ng.L\(^{-1}\) to µg.L\(^{-1}\) to simulate natural water streams and groundwater is hindered by the accuracy and detection limit of the analytical methods. In the case of target analysis, photometric and chromatographic methods are often used to evaluate the photocatalytic degradation. In most cases, these methods are appropriate for the mg.L\(^{-1}\) scale because neither the accuracy nor the detection limit are adequate to work under 0.1 mg.L\(^{-1}\).

The environmental concentrations of emerging micropolllutants usually fall below this range and also in the case of several priority pollutants, threshold limits are getting more and more rigorous. For instance, the maximum allowed concentration of pesticides in drinking water in the European Union is 0.1 µg.L\(^{-1}\), while the maximum annual average concentration of perfluorosulfonic acid and its derivatives is 0.65 ng.L\(^{-1}\) [72].

Recently, gas or liquid chromatography coupled with tandem mass spectrometry (MS/MS) allowed the analysis of micropollutants with an accuracy of a few ng.L\(^{-1}\) and the identification of transformation products by suspect screening [2]. However, these technologies are not widely available due to their high cost. Researchers who have no continuous access to these technologies tend to choose model pollutants with high concentrations to get clear peaks in conventional liquid or gas chromatography.

Considering that water streams usually contain thousands of listed organic substances, it is impractical to use target analysis to confirm the suitability of water for certain
purposes [72]. This issue may be solved by nontarget analysis, whereby thousands of organic compounds could be detected with relative dominancy without the need for reference standards [73]. For instance, high-resolution mass spectrometry (MS) can detect the mass-to-charge ratios (m/z) with a precision of 10⁻³ Da allowing accurate identifications of organic compounds by computer-assisted data-processing tools [2]. With the spreading of these technologies, we expect to witness photocatalysis studies aiming at investigating the treatment of real water/wastewater based on non-target analysis and very low concentrations in the near future.

Another approach evaluates the photocatalytic degradation by the removal of dissolved organic carbon (DOC), chemical oxygen demand (COD), or detoxification. For instance, Arcanjo et al. used TiO₂ modified by iron oxide and hydrotalcite for the treatment of a textile industry wastewater [74]. Although the color removal reached 96%, the COD and DOC removals were not as high (less than 20% and 10% for the COD and DOC in 360 min respectively). The modest removal is imputed to the formation of recalcitrant by-products that may require a longer time for degradation. The toxicity was assessed by the 48 h immobilization test of Daphnia similis regarding EC₅₀ (dilution causing 50% immobilility) showing a decrease of toxicity (from EC₅₀=70% to EC₅₀=95% by pristine TiO₂ and to EC₅₀=79% by modified TiO₂). Comparable examples of real industrial and municipal wastewaters detoxified by photocatalysis were recently reviewed elsewhere [3,75]. In a different application, Fouad et al. studied the disinfection of real surface waters collected from the intakes of water treatment plants in the Nile Delta using Ru-WO₃/ZrO₂ [53].

2.3 Cost and environmental life-cycle assessment

Many researchers claim they developed the state-of-the-art photocatalyst but provide no information about its cost, toxicity, or life-cycle [11]. These issues are of crucial importance in terms of the actual full-scale applicability of any photocatalytic technology.

The economic sustainability of photocatalytic wastewater treatment on large scale is generally discussed in terms of electrical energy per order (EEO) values [76,77]. While several advance oxidation processes, including ozonation, UV/HzO₂, UV/persulfate, and UV/chlorine present median EEO values < 1 kWh/m³, hence are considered competitive for drinking water applications, the EEO for photocatalysis with UV activation are generally > 10-100 kWh/m³ [78,79]. To make photocatalytic water remediation a competitive approach for municipal wastewater treatment, this value needs to be reduced.

Although evaluating the energy efficiency of the process via EEO is encouraged, comparisons among different technologies using this single parameter can be misleading. Other factors should be considered, such as the embedded energy costs of consumable chemicals [11]. In this respect, life-cycle assessment (LCA) provides a more complete picture of the overall sustainability of a remediation process. LCA is an integrated procedure to compile the environmental impacts associated with a process due to the materials, energy consumption, and emissions from cradle-to-grave, based on a huge number of databases [80]. Despite the wealth of literature dedicated to new photocatalysts, the environmental impacts associated with the production and operation of these catalysts are usually ignored. Only a few studies compared the impacts of photocatalysis by TiO₂ for the removal of micropollutants with other treatment processes. Magdy et al. found that photocatalytic degradation of phenol by TiO₂ in a compound parabolic collectors (CPCs) reactor was more eco-friendly than electro-Fenton and activated carbon adsorption processes, whereas the photo-Fenton process in the same CPCs reactor had less environmental impacts [81]. The main contributors to the environmental impact were the production of TiO₂, electricity used for circulating the water in the reactor, and residual transformation products in the same order. Muñoz et al. when comparing solar Fenton and solar-based heterogeneous photocatalysis [10.1016/j.watres.2006.08.001] reported a similar conclusion. On the contrary, Pesqueira et al. found that the photo-Fenton process had higher environmental impacts than TiO₂ photocatalysis for degradation of a group of pharmaceuticals [82]. This dissimilarity may be attributed to the difference in the chemical dosages and
reaction times. It should be noted that LCA analyses of photocatalytic processes have been scarcely reported in the literature. A complete LCA analysis is indeed very challenging because most new complex photocatalysts are not included in LCA databases yet, so researchers have to build the LCA inventory to include the precursors and energy consumption used for the catalyst synthesis. Moreover, notable gaps still exist in our knowledge, particularly concerning the toxicity and environmental impact of novel nanostructures.

3. Photocatalysis for air purification

For more than three decades, the scientific community has devoted a great deal of effort to developing photocatalytic processes for the removal of a range of air pollutants [83–88]. Photocatalysis has demonstrated to be effective for the removal of pollutants in gas phase at relatively low concentrations [89]. Different photocatalytic materials and photoreactors have been proposed [85,89–91]. However, similar to the case of photocatalytic water treatment [10], the process scale-up for the photocatalytic air purification is still an open challenge [92].

When it comes to the application of photocatalysis in real air system, different approaches can be envisaged:

(i) Photocatalytic self-cleaning and antimicrobial materials to be used in indoor/outdoor areas: Under natural solar light (outdoor) or LED irradiation (indoor), the photoactive self-cleaning materials can initiate photocatalytic reactions able to clean continuously their surface and/or treat air pollutants [93–95]. This system is very promising and has received a lot attention from the industrial community [96–98]. Numerous types of self-cleaning coatings and building materials have been developed and commercialized for both indoor and outdoor applications. For instance, Bianchi et al. [98–100] reported a novel digital printing technology for the coating of tiles by visible light-responsive Ag nanoparticles-decorated TiO$_2$ (Figure 4). This scalable technology allows obtaining a homogenous coating without the loss of photoactivity.

![Figure 4. Photocatalytic self-cleaning tiles based on Ag nanoparticle-decorated TiO$_2$ (inset) for the purification of contaminated air and bacteria inactivation, reproduced with permission from reference [98].](image)

(ii) Photocatalytic purification of contaminated air in indoor, small spaces, such as aircraft cabins [101] and cold rooms [102]: while some air purifier devices based on photocatalytic materials are already on the market, this technology has some drawbacks. Since toxic by-products can be formed during the photocatalytic process if contact time are not properly tuned, the undesired accumulation of toxic byproducts in an enclosed environment can occur [103–105].

(iii) Photocatalytic reactors for the direct purification of industrial exhausts: photocatalytic reactors for this application have some scale-up issues and the gap between research at a laboratory scale and industrial needs is still substantial.
(iv) Giant solar photoreactors for CO\textsubscript{2} reduction have been suggested as possible strategy against climate change [106]; this approach has the additional benefit of producing value-added chemicals or fuels from the reduction process. However, research in this field is still in the early stages.

New applications are also emerging. In this respect, Horváth et al. [107] have recently reported a photocatalytic mask filter based on TiO\textsubscript{2} nanowires, which could be used as a protection against airborne viruses including covid-19, and could be photocatalytically sanitized under UV irradiation (Figure 5). Li et al. [108] fabricated a photocatalytic metal-organic framework (MOF) based personal mask which can be self-disinfected under visible light.

3.1 Photocatalytic reactors for air treatment

A successful photo-reactor ensures, on one hand, an excellent interaction between the gas pollutants and the immobilized photocatalyst by an enhanced surface-to-volume ratio, and on the other hand, an excellent irradiation of the photocatalyst surface [91,109–112].

Mass transfer and contact time are key parameters in photocatalytic air processing, since in air systems, only adsorbed pollutants can undergo degradation by direct oxidation by positive holes or surface photoproduced ROSs. While this issue is generally less felt in lab scale, batch reactors, where contact times range from seconds to minutes [113], the design of photocatalytic reactors for treating large air volumes requires a careful optimization of mass transfer issues [114] in order to achieve a fast degradation of pollutants without the accumulation of undesired by-products. In real applications, high flow rates are needed to maximize mass transfer but this comes at the cost of decreasing the contact time between the pollutant and the photocatalyst surface to less than 1 s, which often results in an incomplete degradation of the pollutant. To solve this problem, different strategies have been reported including modifications in the reactor geometry to decrease face velocity [105] or increase in the photocatalytic surface area and irradiance [109]. It should
be noted that the ideal contact time depends on the adsorption affinity between the reactants and the photocatalyst/support [115].

Costa Filho et al. [109] proposed a micro-meso-structured photoreactor for the removal of gas phase n-decane by simulated solar light (Figure 6). The adopted geometry allowed a uniform irradiance of the TiO₂ photocatalyst, yielding a degradation rate of 6.6 mmol m⁻³ s⁻¹ and no loss of activity after 72 h of consecutive use.

Fluidized bed photoreactors have also showed a great potential for the photocatalytic purification of contaminated air. Light irradiation can be external (Figure 7e) [116,117] or internal (Figure 7f) [118], and can also utilize LED lamps [115]. However, the leaching of photocatalysts from the bed was observed in this type of reactors [119].

Very recently, Saoud et al. reported a pilot scale reactor for gas phase VOC remediation and E. coli inactivation based on a photocatalytic textile, based on optical fiber, irradiated by UV LED [115]. A 66% degradation of 5 mg.m⁻³ butane-2,3-dione was measured when the system operated at 2 m³.h⁻¹.

More conventional geometries adopting honeycomb monoliths have been already commercialized for the photocatalytic purification of air (Figure 7a,b). Dijk et al. [120] have designed an internally illuminated honeycomb-based photoreactor for air treatment (Figure 7d) with high surface-to-volume ratio for air purification. This reactor is made for multiphase use [110], wherein the photocatalyst is coated via sol-gel in the inner walls of monolith channels. However, the drawback of this system is the need of separated illumination of each monolith channel. Transport cellulosic monoliths allow the penetration of artificial or natural solar light through all monolith channels (Figure 7c) [121–125].
Another reactor geometry for air treatment is tubular flow photoreactors enclosing lamps (Figure 7g,h) [126,127]; for enhanced mass transfer and surface-to-volume ratio, multi-walls based reactors have been constructed as shown in (Figure 7i) [128–130].

Hybrid techniques combining photocatalysis and other AOPs hold promise for the treatment of large volumes of air due to synergistic effects. Filho et al. [131] have combined O$_3$/UV/TiO$_2$ for the oxidation of VOC in air streams in NETmix micro-photoreactor system (Figure 8a). While single ozonation exhibit fast oxidation towards n-decane but very slow mineralization, the hybrid system O$_3$/UV/TiO$_2$ showed a synergistic removal and mineralization. Zadi et al. [102] combined non-thermal plasma and photocatalysis for the oxidation of propionic acid and benzene in refrigerated food chambers (Figure 8b). By the use of photocatalysis as a single process, the authors reported serious gas toxicity. The combination of photocatalysis with non-thermal plasma overcomes such a toxicity issue, and on top of that, an enhanced photocatalytic efficiency was observed together with an excellent regeneration of the photocatalytic surface.

3.2. Tests in realistic conditions

The efficiency of air purification by photocatalysis depends on a series of operational parameters and environmental conditions. However, comparatively few studies considered these all important parameters in photocatalytic tests [105,109] and even less report actual field tests of pilot scale reactors [133].

First of all, the role of relative humidity should be considered. Water vapor is a ubiquitous component of air and industrial exhaust. The relative humidity of the treated effluent can vary greatly depending on the environmental conditions and process parameters, but it is generally present in concentrations far higher than those of the pollutants are. Water vapor is also known to greatly affect the photocatalytic process [113]. However, there is no consensus on the role of air humidity on the photocatalytic performance [115]. Water vapor seems to play different, conflicting roles on gas phase photocatalysis and the overall beneficial or detrimental effect depends on parameters such as the type of pollutant and its concentration, the photocatalyst adsorption capacity and air relative humidity. It is worth to mention that water competes for adsorption at the photocatalyst active sites, which can lead to a detrimental effect in terms of pollutant adsorption and hence photocatalytic activity [133]. Competition for adsorption between the reaction intermediates and water can also result in a detrimental effect in terms of mineralization [133]. On the
other hand, water can react with photogenerated charges to generate reactive radicals, promoting the photocatalytic degradation. The injection of water vapor can enhance the formation of HO• species on the surface of the photocatalyst [134]. Conversely, in dry air system, the yield of photoproduced ROS can be reduced and it is mostly related to O2• species.

Air samples also contain a mixture of pollutants, generally with individual concentrations in the order of the ppbv. Most literature studies involve photocatalytic tests with a single gas pollutant, often with concentrations in the ppm range. Higher pollutant concentrations are generally associated with improved reaction rates (until rate reaches its plateau), poorer efficiency of removal and lower mineralization [115]. In the case of pollutant mixtures, the individual components are generally simultaneously degraded when the individual concentrations are in the ppbv range. However, the co-presence of some species, such as SO2 [133] and NOx [133], can lead to detrimental effects on the degradation of VOCs.

3.3 Photocatalyst deactivation

The deactivation of photocatalyst systems is a serious issue that should be solved for a continuous processing [34]. It takes place during the photocatalytic reaction due to irreversible adsorption of recalcitrant by-products or due site blocking by carbonaceous residues or dust particles on the surface [120]. In gas phase photocatalysis, deactivation is a more pressing concern than in liquid phase, as there is no water solvent to help to remove products and intermediates from the surface.

Deactivation is most severe in the presence of aromatic compounds [135,136], however it has been reported for a wide range of species [137]. For instance, van Dijk et al. reported photocatalyst deactivation within 80 min of photocatalytic operation for the oxidation of cyclohexane [120]. Despite the importance of this topic for the commercial application of photocatalytic technologies, comparatively few studies have investigated the mechanisms of deactivation, regeneration and the photocatalyst lifetime.

Several strategies to reactivate the photocatalyst have been proposed, including treatment with water vapor [120], high temperature treatment [120,137], oxidation with H2O2 [137] and UV irradiation [138]. The use of a more oxidizing atmosphere and better mass transfer have been reported to slow down deactivation [136].

Combining photocatalysis with another AOP generally promotes the lifetime of the photocatalyst. Zadi et al. [102] reported that the introduction of non-thermal plasma to the photocatalytic system can lead to continuous regeneration of the photocatalyst in air system. It was found by Ribeiro et al. [139] that addition of ozone allows the use of TiO2 without deactivation up to 77 h.

4. Conclusions

Notwithstanding the myriad of studies on the application of photocatalysis to air and water purification, this technology is still far from full-scale, commercial application.

To avoid concerns about leaching in the environment of the photocatalysts and its toxicity, several attempts to design photocatalytic reactors with retained photocatalysts have been presented. The designs involve the immobilization of the photocatalyst on a suitable support or in monoliths. Numerous studies showed photocatalytic reactor designs suitable for reusing the same catalyst for a few cycles with minimal loss of performance; however, more extensive tests on the photocatalyst lifetime should be performed and photocatalyst leaching should be more systematically determined.

Another critical issue is related to the adopted water matrix and the use of more realistic test conditions. Studies reporting the photocatalytic degradation of micropolllutants in different water matrices (including treated municipal wastewaters, river waters, and commercial NOM) showed that the photocatalytic activity was inhibited due to the absorption of light and scavenging of ROS by the organic backgrounds. Tests in ultrapur
water often provide indications that are not transferable to such complex systems. There is the need for robust photocatalyst able to retain its activity in a complex water matrix and in multi-pollutant conditions.

The commercial viability and environmental sustainability of the photocatalytic technology require more attention to the determination of the costs and LCA analysis of the developed materials and processes. The application of photocatalytic remediation to municipal wastewater treatment has been so far hindered by scale-up difficulties and costs uncompetitive with conventional technologies and other AOPs. However, niche applications, such as water treatment in remote locations or the treatment of waste streams from aquaculture and hydroponics, are more promising for short-term applicability of the photocatalytic technology.

Photocatalytic air purification offers a range of applications, some already at the commercial stage. However, issues remain in terms of reactor design, especially for the treatment of large volumes of air without the emission of undesired reaction intermediates. Also, in this case, tests in more realistic conditions should be performed, including considerations about relative humidity, multi-pollutant interactions, and photocatalyst deactivation.

In general, there is the need of pilot scale studies and tests on real samples to revamp industrial interest in the technology.

**Funding:** This research was funded by The Fonds de recherche du Québec – Nature et technologies (FRQNT), grant number 2021-PR-284416”. The authors thank Velux Stiftung Foundation for the financial support through the project 1381 “SUNFLOAT – Water decontamination by sunlight-driven floating photocatalytic systems”. This research was undertaken, in part, thanks to funding from the Canada Research Chair program.
