Abstract:

Background: Although persistent systemic inflammation is considered to be predictive for future cardiovascular events, it remains unclear whether or not C-reactive protein (CrP) plays an active role in coronary-plaque instability. Here, we report a case of a patient with failed and super-infected renal allograft as a source for systemic inflammation presenting with repeat acute coronary syndromes.

Case presentation: A 52-years-old male type-2 diabetic with a failed kidney transplant who was hospitalized for acute urinary-tract infection. In the presence of other, classic cardiovascular risk factors, peak values of CrP coincided with episodes of unstable angina treated by cardiologic interventions. Besides pyelonephritis, the histological examination of the kidney transplant revealed signs of chronic rejection and the presence of a renal cell carcinoma *in situ*. Once the renal allograft has been removed, systemic inflammation was attenuated, the patient was not rehospitalized for acute-coronary syndrome within the next 12 months.

Conclusion: In this case, systemic inflammation was paralleled by instability of coronary plaques as documented by repeat coronary angiograms.

Key Words: coronary artery disease, acute coronary syndrome, inflammation, case report

Background

C-reactive protein (CrP), a surrogate of systemic inflammation, is considered to be a predictor for cardiovascular risk in the general population (1-3) as well as for the outcome in patients with acute myocardial infarction (4) or unstable angina [5]. However, it remains unclear, whether or not CrP plays an active role in atherothrombosis or solely represents an epiphenomenon (6).

Here we report a patient with end-stage renal disease (ESRD) due to a failed, super-infected renal allograft hospitalized for repeat episodes of acute coronary syndrome. The role of systemic inflammation for coronary-artery disease outcomes is discussed.

Case presentation

A 52-years-old, obese male patient with ESRD due to diabetic nephropathy was admitted to a nephrology department of a tertiary referral hospital because of haematuria, leukocyturia and oligo-anuria in the presence of a failed renal allograft. The patient received the renal allograft of a deceased donor 4 years earlier after 7 years of hemodialysis treatment. Hemodialysis treatment had to be resumed 6 months prior to hospitalization. Comorbidities include the full range of type-2-diabetes complications, rheumatic arthritis, secondary hyperparathyroidism, an epoetin-resistant anemia (haemoglobin at admission: 5.4 mmol/l, ferritin: 1302 ng/ml), and a history of multiple invasive cardiologic interventions for myocardial revascularization in the preceding six years. Left-ventricular systolic function was preserved. The patient received an intensive insulin treatment in addition to standard cardiovascular medications including angiotensin converting enzyme inhibitor, statin, low-dose aspirin and beta-blocker agent and epoetin alpha.

The eve prior to admission, the patient had chest pain. However, no action was taken. At admission, troponin T was slightly elevated (0.15 µg/L), creatinine kinase was normal. CrP (155.1 mg/L) and procalcitonin (1.38 ng/mL) were elevated. The ECG remained unchanged showing pre-existing T-wave inversions in I and aVL. Transthoracic echocardiography revealed a moderate left-ventricular hypertrophy and a new inferoseptal and basoapical hypokinesia. Consecutively, a coronary angiography and bare-metal stent deployment into a right-coronary-artery stenosis were performed. An intravenous antibiotic was administered for urinary-tract infection, CrP levelled off at 52 mg/L. However, because of nephrotic syndrome, haematuria, and persistent infection, an elective renal allograft-removal surgery was scheduled within 4 weeks, once dual anti-platelet therapy for direct stenting was changed to monotherapy with acetylic salicylic acid.

Three weeks later, the patient was readmitted with coronary syndrome. The ECG revealed a new significant Q wave in III and prominent T waves in the precordial leads V2 and V3. Transthoracic echocardiography showed a new akinesia of the posterior wall. The subsequent coronary angiography revealed a new unstable

plaque in the first branch of the left circumflex coronary artery (Figure 1B) being absent 3 weeks earlier (Figure 1A). There, a direct bare-metal stent was deployed.

One week later, the kidney-transplant removal surgery had to be performed urgently due to urosepsis. Within the explanted renal allograft, the histological analysis revealed abscess formation and a prevalent vasculitis as sign of chronic vascular rejection (Figure 2A). As a new finding, a moderately differentiated renal-cell carcinoma (G2, pT1a, pN0, L0, V0) with a diameter of 2.5 cm was found (Fig. 2B and 2C). The tumor was restricted to the renal transplant showing no signs of invasion. In abdominal and thoracic computed tomographies, lymph-node or organ metastases were not found. Euglycemia and normotension were maintained before and after surgery. HbA1c was 5.3 %.

However, within six days following surgery, the patient experienced a third troponin-positive, unstable angina when inflammation was unprecedentedly high with a CrP of 200 mg/L. Creatinine kinase remained normal. Echocardiography showed no change, in spite of new negative T waves in the precordial ECG leads V4 – V6. Under conservative therapy including intravenous heparin and antibiotics, cardiac situation stabilized, post-surgery infection consolidated. Within 10 days after renal-transplant removal surgery, albumin plasma concentration increased from 25.5 g/L to 32.9 g/L. During hospitalization 4 months after surgery, a scheduled coronary angiography was unrevealing. However, at that time, CrP still was elevated (60 mg/L) suggesting the presence of additional sources of inflammation. The clinical examination including a sonographic exam of arteriovenous fistula for hemodialysis access was unrevealing. After discharge, the patient was not rehospitalized for acute-coronary syndrome within the next 12 months.

Discussion and Conclusion

This case suggests that peak systemic inflammation may coincide with acute coronary syndromes. Once the renal allograft ceased to function due to pyelonephritis and due to chronic allograft rejection, increased systemic inflammation may have facilitated the occurrence of plaque ruptures leading to acute coronary syndromes. This view is supported by sequential coronary angiograms within 3 weeks. As soon as systemic inflammation was consolidated, the patient remained event-free, as far as acute coronary syndromes are concerned. After kidney transplantation, medical immunosuppressive therapy may predispose to infections. Once the main source of infection has been identified, other secondary sources of infection, e.g. hemodialysis catheter (7) and/or infective endocarditis need to be ruled out, if systemic inflammation still persists. In the present case, there was no clinical sign of arteriovenous-fistula infection, no secondary source of inflammation was found.

As a limitation, no cause-consequence relationship between inflammation and acute coronary syndromes may be established from a single case. However, the timely coincidence points to the possibility of a contribution of systemic inflammation to the occurrence of cardiovascular events. Coronary plaque rupture is known to be facilitated by pro-inflammatory cytokines (8). Besides local inflammatory processes leading to coronary-plaque instability, a more generalized inflammatory response may affect the whole coronary tree. There, CrP synthesized in the liver upon interleukin-6 stimulation, represents a candidate mediator linking inflammation with occurrence of acute coronary syndromes (9). In an animal model of atherosclerosis, CrP transgene expression accelerated aortic atherosclerosis (10), while therapeutic inhibition of CrP improved outcome of experimental myocardial infarction (11). Functional studies on neutrophils and human endothelial cells indicate that monomeric CrP, but not pentameric or native CrP, leads to neutrophil-granulocyte (12) and to endothelial-cell activation (13). Increased systemic inflammation adversely affects mortality in patients with chronic kidney disease, stage 3 or 4 of (14). In addition, overall and cardiovascular

mortality correlate with the estimated glomerular filtration rate (15). Future research needs to determine the individual roles and mechanisms of uremic toxins and inflammation for cardiovascular outcomes. To contain a possible role of CrP on acute coronary-artery disease progression, adsorptive techniques to therapeutically lower plasma CrP may be employed on an individual basis (16).

In summary, from this case a contributory role of inflammation on acute progression of coronary heart disease is assumed. Anti-inflammatory strategies, such as the removal of a failed, super-infected renal allograft, need to be considered in patients with therapy-resistant systemic inflammation to avoid cardiovascular complications.

Declarations

Ethics approval and consent to participate

Not applicable

Consent for publication

Written informed consent to publish patient-related information was obtained from the patient. The signed informed consent is on file. A copy of the consent form is available for review by the Editor of the journal.

Availability of data and material

All relevant data were included in the manuscript.

Competing interests

None of the authors has competing interests.

Funding

Not applicable

Acknowledgement

The authors wish to thank the patient for providing his consent for the publication.

Authors' contributions

RUP and SSD were attending doctors of the patient. RUP drafted the paper.

SSD gave critical input. AT critically contributed to contents concerning the histological specimen. All authors contributed to the discussion and approved the content of this manuscript.
