Abstract— Many corporations and governments aspire to become Net Zero Carbon Dioxide by 2030-2050. Achieving Net Zero CO₂ requires understanding where energy is produced and consumed, the magnitude of CO₂ generation, and the Carbon Cycle. It is unreasonable to assume that fossil fuel can be completely replaced, and thus, atmospheric CO₂ will continue to accumulate. Many prior proposed solutions focus on reducing *future* CO₂ emissions from continued use of fossil fuels. Examination of these technologies exposes their limitations and shows that none offer a complete solution. Direct Capture technologies are needed to reduce CO₂ *already* in the air. However, some of those already proposed would lead to a very high cost of Carbon Capture, Use, and Storage (CCUS). Biofuels can help achieve reduction goals. However, two of the six carbons in sugar fermented to bioethanol produce CO₂ per the stoichiometry of the reaction. Four carbons go to ethanol, which go back to the atmosphere upon burning in an engine. Thus, without CCUS, which most current bioethanol plants do not practice, bioethanol would at best be sustainable.

The only way to permanently remove CO₂ *already* in the atmosphere is to break the Carbon Cycle by growing biomass from atmospheric CO₂ and permanently sequestering that biomass carbon. Permanent sequestration can be achieved in landfills modified to discourage biomass decomposition to CO₂ and methane. Sequestration of biomass carbon is proposed as a simple and natural means of Direct Capture. Tree leaves are proposed as a good source of biomass for this purpose. Left unsequestered, leaves decompose with a short Carbon Cycle time constant releasing CO₂ back to the atmosphere. Leaves can represent a substantial fraction of the total biomass generated by a tree when integrated over a tree's lifetime. High yield crops, such as switchgrass would also be a good source of biomass. The cost for growing switchgrass and sequestering it in a landfill is estimated to be on the order of \$120/mt CO₂ for a conservative yield of 3.5 tons/acre and may be reduced to as low as \$88/mt CO₂ if the development of high yield switchgrass is successful. This compares to an estimated cost of CCUS from the Steam Reforming of Methane to produce hydrogen of about \$190/mt. Thus, sequestration of biomass is shown to be a natural, carbon efficient, and low-cost method of Direct Capture.

Keywords— Carbon Dioxide, Net Zero, Sequestration, Biomass, Direct Capture, Global Warming.

1. Introduction

Carbon dioxide is the dominant greenhouse gas component leading to Global Warming. If man does nothing to intervene, atmospheric CO₂ levels are projected to more than double to over 900 ppmv by 2100 [1]. Many corporations and governments have set goals of Net Zero CO₂. A CO₂ material balance indicates: In – Out = Net Rate of Accumulation. In order to achieve a Net Zero CO₂, CO₂ removal must equal CO₂ generation. Preferably CO₂ removal from the atmosphere exceeds generation to reduce the level of CO₂ already in the atmosphere, which is already leading to Global Warming. Many new technologies for confronting CO₂ accumulation and fuels decarbonization are under rapid development. These include technologies for renewable energy, biofuels, hydrogen production from fossil fuels with Carbon Capture, Use, and Storage (CCUS), and CO₂ removal and sequestration from large point source industrial furnaces. Most focus on reducing *future* CO₂ emissions. The advantages and challenges of some of these technologies were reviewed in an unpublished preprint [2].

Methods for removing CO₂ *already* in the air are known as Direct Capture methods. In one direct air capture technology, being developed by companies such as Climeworks and Carbon Engineering, large fans blow air through an adsorbent or absorbent [3,4]. The CO₂ must then be released by adding heat, followed by CO₂ compression to liquify to allow it to be transported for industrial uses or permanent storage underground. There are numerous issues with this technology that put current estimates of the cost of recovered CO₂ as high as \$800/tonne [5]. First, an enormous amount of air with 400 ppm CO₂ must be moved the adsorbent to remove even a small amount of CO₂. The fans have high capital and operating cost. There is the cost of heat required to release the CO₂, and high capital and operating cost to compress, transport and store the captured CO₂.

One issue for decarbonization by CO₂ recovery is what to do with the recovered CO₂. CO₂ has value for certain markets, such as carbonation of beverages and tertiary oil recovery. However, the markets where the CO₂ has value are small compared to the current 36 giga tonnes/yr (Gt/yr) generated. Beyond those markets, recovered CO₂ has negative value.

A 2005 Energy Information Authority (EIA) report estimated that the markets where CO₂ has value extend out to about 700 million metric tonnes per year (MMt/yr) [6]. That compares to about 36 Gt/yr total generation. EIA identified geological formations having a total storage capacity of about 3800 Gt CO₂. The mean cost for storage in deep saline aquifers was estimated to be about \$12.5/t CO₂ in 2005, which is \$17/t CO₂ in 2020 when escalated using the US Consumer Price Index (CPI).

There is a lot of focus on the use of hydrocarbons to produce hydrogen as a clean burning CO₂-free fuel. However, the carbon must go somewhere. The carbon ends up as CO₂ that must be recovered and disposed.

Hydrogen can be produced by steam reforming or partial oxidation of hydrocarbons. For natural gas, the preferred route is steam reforming (Steam Reforming of Methane (SRM)). In a first step, methane is reacted with steam at high temperature to form a synthesis gas (CO + H₂):

This reaction is strongly endothermic: ΔH_r = 206 kJ/mol

In a second step, the CO is reacted with more water via the water-gas shift reaction to form more hydrogen plus CO₂:

This reaction is mildly exothermic: $\Delta H_r = -41 \text{ kJ/mol}$.

The net reaction is:

The overall reaction remains strongly endothermic:
 $\Delta H_r = 165 \text{ kJ/mol}$.

Thus, a large amount of heat must be put into the process. That heat generally goes into the reformer process furnace by burning additional natural gas. Of course, the furnace flue gas contains CO_2 . For hydrogen from steam reforming to be a “ CO_2 -free” fuel, both the CO_2 produced by the reactions and CO_2 in the flue gas must be recovered and sequestered.

For low molecular weight hydrocarbons with low C:H ratio, steam reforming is preferred. For hydrocarbons with high C:H ratios, such as coal, or even elemental carbon, partial oxidation is preferred, as shown in Equation 4 for carbon:

Theoretically, any hydrocarbon can be steam reformed or undergo partial oxidation and the CO reacted with water to produce hydrogen and CO_2 via Reaction 2.

The steam reforming or partial oxidation of biomass can produce “Green Hydrogen.” The use of biomass to produce hydrogen represents an alternate Direct Capture technology, since the biomass carbon is produced from atmospheric CO_2 via photosynthesis. Thus, “Green Hydrogen” production from biomass with CCUS represents one form of Direct Capture.

An understanding of the Carbon Cycle indicates that the only way to remove CO_2 already in the air is to grow biomass from atmospheric CO_2 and then permanently remove that biomass carbon from the Carbon Cycle. Steam reforming or partial oxidation of biomass, followed by water-gas shift and CO_2 capture and storage is one way. However, it is expensive, since it requires high capital, energy and other operating and fixed costs for the hydrogen plant, and CCUS. The cost of CO_2 capture and sequestration from an SRM hydrogen plant will be calculated in this manuscript.

In this manuscript, we propose a simple and more natural method of Direct Capture. Furthermore, this method will be shown to have a lower cost of CCUS than an SRM hydrogen plant.

In the proposed method, biomass is grown from atmospheric CO_2 via photosynthesis and the biomass carbon is sequestered (permanently removed from the Carbon Cycle) by secure burial in landfills modified to discourage biomass degradation. Thus, this is *Carbon Sequestration* as opposed to *CO_2 Sequestration*.

Tree leaves had been proposed as a good source of biomass for sequestration [2]. Leaves have a short Carbon Cycle time constant on the order of one year and they are renewable every year. Leaves are shown to represent a significant portion of the total biomass generated by a tree when integrated over the life of a tree. Left unsequestered, leaves decompose and release their carbon as CO_2 back to the atmosphere to complete their Carbon Cycle. Sequestering leaves as opposed to tree trunks and branches would have certain advantages. Sequestering leaves would leave the underlying forests undisturbed. Furthermore, trees have a very long Carbon Cycle time constant on the order of decades to centuries, as opposed to leaves which are renewed every year and have a short decomposition time constant on the order of a year.

Of course, other sources of biomass should be considered, such as crops or grasses grown for the purpose of carbon sequestration, or municipal waste. The cost to grow and sequester the carbon in switchgrass in a landfill will be used as a proxy to estimate the cost of CO₂ capture for the proposed biomass carbon sequestration, and that cost will be compared to the cost for CO₂ capture and storage from an SRM hydrogen plant.

In fact, growing and sequestering switchgrass for the purpose of direct CO₂ capture may have certain advantages over gathering leaves. Growing switchgrass is very analogous to growing hay which is well established farm technology practiced on a massive scale. The cost of harvesting hay is well known [7]. The cost of harvesting switchgrass should be very similar.

2. The energy scene

Before discussing the proposal, it is helpful to examine the current energy scene, i.e., what fuels are used, where they are used, and to examine the current world energy consumption by fuel source, and the amount of CO₂ currently being generated each year to understand the magnitude of the problem and show that prior proposed technologies will fall short of the goal of achieving Net Zero CO₂ by 2050.

The US Energy Information Authority (EIA) provides a database that tracks primary energy production and disposition for the US, and other world regions [8]. BP provides its yearly Statistical Energy Review [9].

Fig. 1 shows the US 2016 (pre-pandemic) primary energy source and sector in which the energy is used [10]. The three largest sources are petroleum (37%), natural gas (29%), and coal (15%). In 2016 only about 10% of primary energy came from renewables.

U.S. primary energy consumption by source and sector, 2016

Total = 97.4 quadrillion British thermal units (Btu)

Fig. 1. US Primary energy consumption by source and sector, 2016 Source: EIA (2017) [10]. All rights reserved.

The numbers on the left of the lines connecting sources to usage sectors show the percentage of a source that goes to a corresponding sector. The major sectors are transportation (29%), industry (22%), and electric power (39%). Industrial use accounts for 22% and residential and commercial accounts for 11%.

The numbers on the right of **Fig. 1** show the percentage of energy used in a sector that comes from the corresponding source. Thus, 71% of petroleum goes to the transportation sector with most of the balance (23%) going to industry, and only minor amounts to residential and commercial and electric power sectors. Natural gas usage is split almost evenly amongst industrial, residential and commercial, and electric power, with very little to transportation. Coal and nuclear are almost exclusively used to generate power.

In 2016, CO₂ emissions were 36 Gt [10]. The world has a huge CO₂ problem that is going to take a variety

of huge solutions to solve. **Fig. 1** shows the US energy demand. World energy demand is different. In particular, coal represents a much higher fraction of energy demand in China. China dominates world energy demand. Asia and Oceania account for almost half of total energy demand. Thus, it is not surprising that coal and coke (a heavy-end solid refinery byproduct that can be substituted for coal) represent about 44% of total energy demand. Petroleum and other liquids represent about 36%, and natural gas about 20%. Coal usage in China exceeds that in the rest of the world combined, as shown in **Fig. 2**. Thus, while coal usage is declining worldwide, it will continue to play a major role in China, and a solution is needed for the CO₂ coming from coal.

Fig. 2. Coal demand in select countries/regions

Data Source: (EIA, 2017). All Rights Reserved. [10]

The EIA provides a projection for the shift in all energy sources for electricity production (**Fig. 3**), and further granularity for the sources of renewable energy for electricity production out to 2050 (**Fig. 4**) [11]. Coal is expected to decline from 24% to 13%, and nuclear is expected to decline from 19% to 12%. Renewable energy is projected to double but will still be under 40% of the total energy sources. -

Fig. 3. Shift in all sources of energy for electricity.
Source: (EIA, 2020). All Rights Reserved. [11]

Fig. 4. Shift in source of renewable energy for electricity.
Source: (EIA, 2020). All Rights Reserved. [11]

The absolute amount of electricity from wind is projected to double. Solar is projected to increase by a

factor of 9. One question to ask is: Is that a reasonable projection? Natural gas has become cheap and abundant in the US after the advent of fracking. The EIA projects that the fraction of electricity coming from natural gas remains about constant near 36 to 37% out to 2050. This is still a very significant percentage and a significant percentage of CO₂ production. Thus, a means to sequester CO₂ during the production of electricity from natural gas is needed, especially if the projected increase of electricity from solar falls short.

The energy for transportation is distributed between passenger cars, long haul trucks, aviation, and rail. US passenger cars are currently fueled primarily by gasoline. Thus, in the US, gasoline represents about 47% of refined products [12]. Distillates represent about 30%, with LPG (7%) and Other Petroleum Liquids (chemical feedstocks, etc.) representing the balance. US distillate fuels represent about 20% of US refined products with about 67% of distillates used for on-highway diesel mainly for long haul trucks). Jet fuel is about 8% of US refined products [13]. Diesel cars are more popular in Europe. Thus, for example in Germany, distillate fuel oils represent about 46% -and gasoline only about 18% of refined products [12].

US gasoline currently contains about 10 vol% bioethanol. Thus, bioethanol represents only a trivial amount of total US energy consumption (29% x 47% x 10% = 1.4%), and that comes at great economic and social cost. Currently about 40% of the US corn crop is devoted to fuel ethanol [14]. Furthermore, the stoichiometry of the fermentation reaction converts only 4 of the 6 carbons in glucose sugar formed by hydrolysis of corn starch to ethanol and 2 carbons to CO₂:

Most US ethanol plants currently vent the CO₂ to atmosphere. The 4 out of 6 sugar carbons that go to bioethanol represent renewable carbon that will displace *future* fossil fuels from continued gasoline production. They will not reduce CO₂ *already* in the atmosphere. Only the 2 of 6 carbons that go to CO₂ during fermentation will represent Direct Capture CO₂, and only if bioethanol plants are fitted with CCUS. Bioethanol is not break-even sustainable, when the energy used to produce the corn and within the process is considered. Water removal from the ethanol fermentation beer is energy intensive [2].

Bioethanol from cellulosic biomass has been a long-term goal due to potentially cheap feedstock and no diversion of food to fuel. A Sandia study indicated that 70 billion gallons of cellulosic ethanol should be “possible” by 2030 [15]. However, only about 15 MM gal were produced in 2018 [16]. The reality is that continued economic and technical challenges remain.

Biodiesel penetration into the total diesel market is even lower than bioethanol penetration at about 6% of diesel for on-highway use (only about 4% of total US distillate oils), and that consumes about 30% of US soybean oil [17,18]. It also consumes corn oil in a ratio of about 27 liters corn oil to about 73 liters soybean oil [17,18]. Corn oil is the most valuable product from corn wet mill plants, and thus is an expensive feedstock.

The future for zero CO₂ emission passenger cars is electric vehicles. Powering them by renewable electricity would make them truly net zero CO₂ emitters (not counting CO₂ related to their manufacture and battery production). The reality is that electric vehicles represented only 1.5% of new vehicle sales in Q1 2019 [19]. Also, recall that EIA projections are that natural gas will still account for 36% of electricity generation in 2050 needed to power them (**Fig. 3**). Also, electric passenger cars represent only a portion of energy for transportation, which accounts for only about 30% of total energy consumption. Long haul trucks, rail and aviation represent a significant fraction of transportation energy. Currently there are no practical electric drives for those modes.

Clearly, other solutions are needed to achieve net CO₂ emission goals by 2050.

3. Understanding the Carbon Cycle

The Carbon Cycle is misunderstood by many. There are those who believe planting more trees will lead to a reduction in atmospheric CO₂. It is true that deforestation and burning of trees leads to a *temporary* large release of CO₂, and reforestation leads to *temporary* reduction of atmospheric CO₂. However, if one follows trees through their entire life cycle, trees are sustainable. They pull CO₂ from the air during their life. However, in unmanaged forests, tree biomass eventually decomposes and a tree's stored carbon is released to the atmosphere as CO₂. Trees lose their leaves every year, which decompose and release their stored carbon back to the atmosphere on a time scale of approximately one year. At the end of their life, trees die, decompose, and release the carbon stored in their trunks and branches. Thus, trees are sustainable. Over their entire life and death cycle, planting trees will not lead to a net reduction in CO₂ that is *already* in the atmosphere.

Plants get all of their carbon for their growth from CO₂ in the atmosphere via photosynthesis, forming carbohydrates [20]. The photosynthesis reaction can be represented crudely by the reaction:

The simplest formula representation of carbohydrates is CH₂O, Thus the amount of CO₂ plants pull from the atmosphere can be calculated roughly from plant mass using the ratio of molecular weights: (44.01 gm/mol CO₂)/30.03 gm CH₂O).

Plant matter is fed to animals and plants and animals are fed to humans. Animals and humans respire the bulk of the carbon in their food as CO₂ when they exhale. Animals and humans grow and thus serve as temporary storage vessels for some of the carbon. However, plants, animals, and humans eventually die and decompose and release their carbon back to the atmosphere as CO₂, completing their part of the Carbon Cycle. Plant matter left on the ground decomposes via the action of worms, fungi, and bacteria. They feed on the decomposing biomass, and respire CO₂, and thus, play an important role in the Carbon Cycle. Normally there is no net buildup of carbon in the soil. Soil carbon generally reaches a steady state carbon level of 1-4 weight percent (wt%) [21]. Yes, depending on farming practices, there can be a small increase or decrease of plant matter carbon in the soil. However, it is small and limited. If there were a large net movement of carbon to the soil, mountains would spring up in the US corn belt, and that is clearly not the case.

While plants receive all of their carbon from the atmosphere, they draw water as a source of hydrogen, nitrogen, phosphorous and other nutrients such as potassium from the soil. The enzyme that catalyzes photosynthesis contains both nitrogen and phosphorous [21]. In the natural Carbon Cycle, dead plant material returned to the soil feeds the worms, bacteria, and fungi that decompose it releasing the needed N, P, K, and other nutrients back into the soil. That is part of the Carbon Cycle. Intensive farming requires artificial fertilizer to provide some of the nutrients removed with the farm products.

Thus, the normal Carbon Cycle is sustainable. Over time, there is no net movement of CO₂ to the atmosphere and no net movement of carbon into the ground. The only way to remove CO₂ *already* in the atmosphere is to break the cycle. Biomass must be grown from CO₂ in the atmosphere and the biomass itself must be sequestered (*Carbon* sequestration, not CO₂ sequestration).

4. Sequestration of biomass carbon

As noted earlier, renewable energy, biofuels without CCUS, and CO₂ sequestration will reduce *future* CO₂ from continued use of fossil fuels entering the atmosphere. However, doing it on a scale needed to

meet current and future energy demands is daunting. Furthermore, these are not a complete solution to achieve Net Zero CO₂, so other solutions are needed.

Per an understanding of the Carbon Cycle, the only way to remove CO₂ *already* in the atmosphere is to grow biomass and remove that biomass from the Carbon Cycle by permanent sequestration.

If the biomass in the entire corn plant from the 40% of the US corn crop that is now devoted to bioethanol production were sequestered and removed from the Carbon Cycle, instead of just the starch in the corn kernels going to bioethanol, that would be the equivalent of removing 407 MMt/yr of CO₂ per year compared to the 36 Gt/yr CO₂ generated [2]. Something else is needed to achieve Net Zero CO₂ to the atmosphere.

In this manuscript, secure burial of biomass from other sources, including municipal and yard waste and biomass generated in forests (tree leaves and wood) or from growing high yield crops, such as switchgrass is proposed as a supplemental solution. Secure burial means permanent burial with provisions taken to prevent decomposition and release of the CO₂ to the atmosphere. Thoughts on how to achieve secure sequestration with minimal or no CO₂ to the atmosphere are provided in the next sections.

Permanent sequestration of municipal and yard waste in permanent landfills would remove that carbon from the Carbon Cycle and would remove CO₂ *already* in the atmosphere that would feed the growth of the organic materials in those waste sources. In addition, it would remove CO₂ going to the atmosphere from refinery and petrochemical processes used to produce plastics, if plastics are included in the waste to be buried. Systems are in place to collect yard and municipal waste in most large cities in the US, and elsewhere in the world, so part of the cost is already sunk.

Most municipal yard waste is buried in landfills. Some municipal waste is now burned to generate renewable power. One issue for that application is that even after separation of recyclables, average municipal waste still contains about 20% non-organics (glass, metal, etc.), as shown in **Fig. 5** that must be separated before the organics can be burned [22]. Secure landfilling to sequester all of the waste would not require this stringent and costly separation.

How big of a difference could secure sequestration of municipal and yard waste make? The US EPA provides statistics on municipal and yard waste generated, and how much is ultimately landfilled [22]. In 2017, the total amount of US municipal and yard waste generated was 267.8 MM tons. Some is separated and recycled, and some is currently burned to generate renewable power, leaving the amount landfilled at 139.6 MM tons, with composition provided in **Fig. 5**. The organic component was 112.5 MM tons. That corresponds to 149.6 MM metric tonnes of CO₂ if allowed to completely decompose. This compares to the 6480 MM tons per year CO₂ generated in the US and is far short of the 36 Gt/yr CO₂ currently being generated worldwide. Participation by other countries would help, but clearly not enough to solve the daunting CO₂ problem.

Other biomass is needed for pulling CO₂ from the atmosphere: trees, both tree leaves and/or wood, and high yield crops. The USDA has provided allometric equations for urban tree growth parameters for many species and at numerous locations in the US [23]. The growth equations have been programmed into EXCEL files which are available in **SI.1** (Supplemental Input). Dry leaf biomass is calculated for most species and regions where data are available.

Fig. 5. US 2017 Municipal and Yard Waste Landfilled
Source: (EPA, 2020) [22].

Dry leaf biomass for some species of maple trees at various locations in the US are shown in in **Fig. 6**, as an example. Data for other tree species are provided in **SI.1**. Dry leaf biomass can be over 100 kg/yr for some of the maples and over 400 kg/yr for some of the oaks depending on location and age.

Leaves currently fall to the ground and decompose every year. Assuming a conservative average of 50 kg/yr dry weight of leaves per tree, if forests were managed, the leaves gathered and permanently securely buried, this would be the equivalent of over $(50 \text{ kg/yr dry wgt}) \times (44.01 \text{ gm CO}_2 / 30.03 \text{ gm CH}_2\text{O}) = 73 \text{ kg/yr CO}_2$ removed from the atmosphere per tree every year.

According to the latest estimate, there are over 3 trillion trees in the world [24-25]. However, only about 30% of the trees are deciduous. At 73 kg/yr-tree CO_2 equivalent per tree that is the potential to remove 66 Gt/yr CO_2 , compared to 36 Gt/yr CO_2 generated each year. Thus, theoretically sequestering tree leaves could provide a complete solution to our CO_2 fossil fuel problem. The potential is enormous but sequestering all of those leaves would be daunting.

One secondary issue for sequestering biomass will be the replacement of P, N, and K nutrients needed for photosynthesis. This can be done via chemical fertilization. This will generate CO_2 , but this can be compensated by additional biomass sequestration.

Mature tree wood weights can be several metric tonnes per tree, as shown in **Fig. 7**. Removal and secure burial of tree wood would help. However, there are several issues. First, tree trunks and tree branches have a much longer Carbon Cycle time constant (on the order of decades or centuries) compared to leaves (on the order of one year). However, it is not needed. Harvesting leaves would suffice. While the mass of leaves dropped in a particular year is much less than that of the tree trunk and branches, leaf mass becomes appreciable relative to the latter when integrated over the life of the tree. Also, harvesting leaves alone would not disrupt the forest itself, and leaves are renewed every year. It is best to leave the wood for its current uses (construction, furniture, etc.). Managing new forest plantings should be considered with access provided for leaf collection. In Brazil, secure burial of bagasse should be considered instead of burning it to produce power, which releases the bagasse CO_2 back to the atmosphere, albeit renewable CO_2 . The bagasse is already at the ethanol plant. It could be buried in a site nearby to minimize

transportation costs. Sequestration of other biomass, such as underbrush should also be considered.

Fig. 6. Yearly dry leaf biomass generation by some maple tree species in various regions of the US
Source: McPherson, van Doorn, and Peper (2016) [23].
The US regions include: LoNdWst=Lower Midwest;
MidWst=Midwest; NMtnPr=North: No East = North East;
CenFla=Central Florida; GulfCo=Gulf Coast; Piedmt=South.

Figs. 6 and 7 represent calculations from the regression equations for the allometric tree growth equations provided by McPherson, van Doorn, and Peper (2016) [23]. Twelve equation forms were used for different species and different locations, including quadratic, cubic, quartic, exponential and ln(ln). Some are not well behaved for extrapolation. Thus, they were not extrapolated beyond the limits provided. However, even within the limits, some projections showed declines in mass with age, and thus, were truncated at the point where that happened.

Fig. 8 provides calculated cumulative leaf biomass as a percentage of total tree biomass generated (including tree trunk and branches) up to a given tree age. Note that the calculations show some erratic behavior from the combining of two ill-behaved correlations in some cases. Considerable scatter is observed depending on species and location. Nonetheless, this figure shows that the cumulative leaf mass can be a significant fraction of the total tree biomass generated over the life of the tree. In certain cases, the regressed percentage of leaf biomass exceeds 50% to over 70% of the total biomass generated over the life of the tree.

5. Modified landfills for biomass carbon sequestration

Permanent sequestration of municipal waste and plant biomass will require rethinking how landfills are designed. Currently, landfills are designed to allow or even encourage some decomposition of the waste to minimize volume. Permanent sequestration requires discouraging waste degradation in landfills.

Fig. 7. Above ground biomass for some Maple tree species in various regions of the US. Source: McPherson, van Doorn, and Peper (2016) [23].

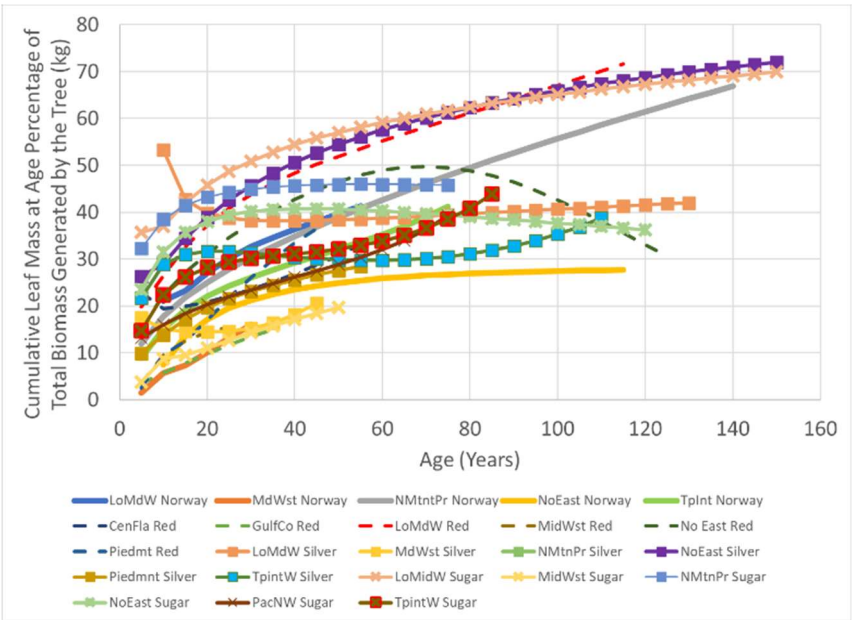

Fig. 8. Calculated cumulative leaf biomass as a percentage of total biomass generated over the life of various species of Maple trees at various locations in the US.

Municipal waste is buried in landfills, where a portion slowly decomposes. It undergoes a combination of aerobic and anaerobic decomposition to produce a biogas. Modern landfills undergo several distinct stages [26-28].

Phase I (Initial Adjustment)

During the first phase of decomposition, aerobic bacteria that require oxygen to live consume oxygen while breaking down the complex carbohydrates, proteins, and lipids that comprise organic waste. The primary byproduct of this process is carbon dioxide. Nitrogen content is high at the beginning of this phase, due to nitrogen in the air that supplies the oxygen for aerobic decomposition. Nitrogen content continuously declines as the landfill moves through the phases. Phase I continues until available oxygen is depleted. Phase I decomposition can last for days or months, depending on how much oxygen is present when the waste is disposed in the landfill, which can vary depending on how compacted the waste was when it was buried.

Phase II (Acid Phase)

Phase II decomposition starts after the oxygen in the landfill has been depleted. Anaerobic bacteria then convert compounds created by aerobic bacteria into acetic, lactic, and formic acids and alcohols such as methanol and ethanol. The landfill becomes highly acidic. With the presence of moisture, the acids cause certain nutrients to dissolve, making nitrogen and phosphorus nutrients available to the bacteria present during this phase. The biogas comprises mainly carbon dioxide and hydrogen during this phase.

Phase III (Methane Formation)

Phase III decomposition starts when anaerobic bacteria consume the organic acids produced in Phase II and form acetates. This process causes the landfill to become a more neutral environment in which methane-producing bacteria establish themselves. Methane- and acid-producing bacteria have a mutually beneficial relationship. Acid producing bacteria create compounds for the methanogenic bacteria to consume. Methanogenic bacteria consume the carbon dioxide and acetate, too much of which would be toxic to the acid-producing bacteria.

Phase IV (Stable Phase)

Phase IV decomposition begins when both the composition and production rates of landfill gas remain relatively constant. Phase IV landfill gas usually contains approximately 45% to 60% methane by volume, 40% to 60% carbon dioxide.

Phase V (Mature Phase)

Landfills eventually enter a mature phase. The rate of microbiological activity slows during this phase as the supply of nutrients and/or moisture limits the chemical reactions, e.g. as bioavailable phosphorus becomes increasingly scarce. CH₄ production almost completely disappears. Thus, complete decomposition may take hundreds to thousands or even millions of years.

The anaerobic decomposition phase produces a biogas. On average, about half of the volumetric concentration of landfill gas is methane and slightly less than half is CO₂. Methane has a climate change potential that is 25 times more powerful than CO₂. Thus, anaerobic decomposition is to be discouraged in the landfills proposed for biomass sequestration.

Landfills are now designed with underground collection systems, and the gas is typically routed to flares, and burned as a renewable fuel. Thus, the carbon in the gas is converted to CO₂ which goes back to the atmosphere. Some landfills now route the gas to boilers for power generation (renewable power generation), or other uses.

How can landfills be redesigned to minimize or eliminate biomass degradation? By understanding the degradation chemistry, there are opportunities to interrupt the process at each phase. Phase I degradation could be minimized by minimizing the landfill working volume as material is moved to the

non-working volume which is moving towards later phases. The working volume may be covered by tarps at night or covered by foam. This is already being done in some landfills. Nitrogen blanketing could eliminate the oxygen needed for aerobic decomposition.

Simplified equations for anaerobic degradation of cellulose are:

Hydrolysis (depolymerization) of cellulose to release sugars.

Anaerobic digestion to form methane and CO₂.

Water is needed to first depolymerize the cellulose to release the sugars that serve as food for the anaerobic bacteria. Thus, one key to reducing or eliminating anaerobic degradation is to keep water out, i.e., preferably to dry the biomass in drying fields, and sealing the landfill as it moves beyond Phase I.

Another way to discourage anaerobic decomposition is to exploit known inhibitors of anaerobic bacteria [29]. These include among others, pH adjustment, high concentration of alkali or alkaline earth metals, etc.

Municipal waste used to be accumulated in open piles. Modern landfills with daily, intermediate, and final covers only began in the 1940s and accelerated in the 1960s and 1970s. None of the modern landfills have gone through their full life cycle, which can take hundreds to thousands or even millions of years. The evidence is the huge mounds that are left by modern landfills that have had their final earthen caps installed and are then abandoned.

Can secure permanent sequestration of biomass carbon really be achieved? The answer is: Yes, it can. Can some leakage be tolerated during the five stages? The answer is: Yes. However, it will increase the amount of material that needs to be sequestered to compensate for these losses. Some biogas can be allowed and collected and burned to generate renewable power to displace fossil fuels as is currently done at many landfill sites.

Thus, secure permanent landfills are envisioned that are modifications of current landfills. These landfills may also be located near the source of biomass to minimize transportation cost.

6. Are Steps to Prevent Degradation in a Landfill Absolutely Necessary?

Steps to reduce or eliminate biomass degradation are desirable but will add cost. Are they absolutely necessary?

Coscuner, et al. [30] modeled landfill gas generation in a landfill in Bahrain. using the US Environmental Protection Agency's Landfill Gas Emission Model software [31]. The data in Tables 1 and 2 of that manuscript allow the calculation of the fraction of the fraction of decomposable waste that is predicted to decompose after 120 years following landfill closure. That landfill opened in 1987 and closed in 2019. The total amount of waste deposited was about 23,000 tonnes. The MSW (Municipal Solid Waste) was comprised of 35.2% food waste, 11.6% paper and cardboard, 4.1% textiles, and 18.4% plastics.

The model requires input of DOC=Degradable Organic Carbon.

$$DOC = 0.4 (A) + 0.17 (B) + 0.15 (C) + 0.3 (D) \quad 11)$$

where A is the fraction of MSW that is paper and textile wastes, B is the fraction of garden/park wastes or another non-food organic degradable waste, C is the fraction of food waste and D is the fraction of wood and straw wastes.

For the case of the Bahrain landfill, A=0.157, B=0.028, C=0.352, and D=0.018, i.e., the total fraction of

decomposable waste = 0.555. The fraction of plastic film and other plastics in the MSW was 0.184. Per the US EPA model this material does not decompose, as it should not, per the stoichiometric equations for anaerobic decomposition (Equations 9 and 10), because petrochemical plastics such as PET, or polyolefins do not contain oxygen atoms.

The EPA model predicts an exponential decline in biogas generation (methane and CO₂) for 120 years after landfill closure. **Fig. 9** shows that if the model were extrapolated to 500 years, the percentage of decomposable material that would have decomposed reaches an asymptote of about 18%. The calculations are provided in **SI.2**. Thus, if one were to take no additional action to prevent biomass degradation, over 80% of the decomposable biomass would never decompose, thus proving the premise of this manuscript that secure landfilling of biomass is a viable way to pull CO₂ from the atmosphere to offset CO₂ from continued use of fossil fuels.

Fig. 9. Percentage of degradable biomass that would decompose calculated by extrapolating the US EPA Landfill Gas Emissions Model (LandGEM) for a landfill in Bahrain [30-31]

7. The Cost of CCUS for a SRM Hydrogen Plant

There is much interest and many recent papers and webinars related to hydrogen production, because hydrogen is a carbon-free fuel. The steam reforming of methane (SRM) is technology that has been practiced for almost 100 years as a means of producing hydrogen for refineries and chemical plants.

In this section, the cost of CO₂ sequestration from an SRM hydrogen plant will be considered as a basis for comparison to the proposed method.

A schematic of a typical SRM hydrogen plant is provided in **Fig. 10**.

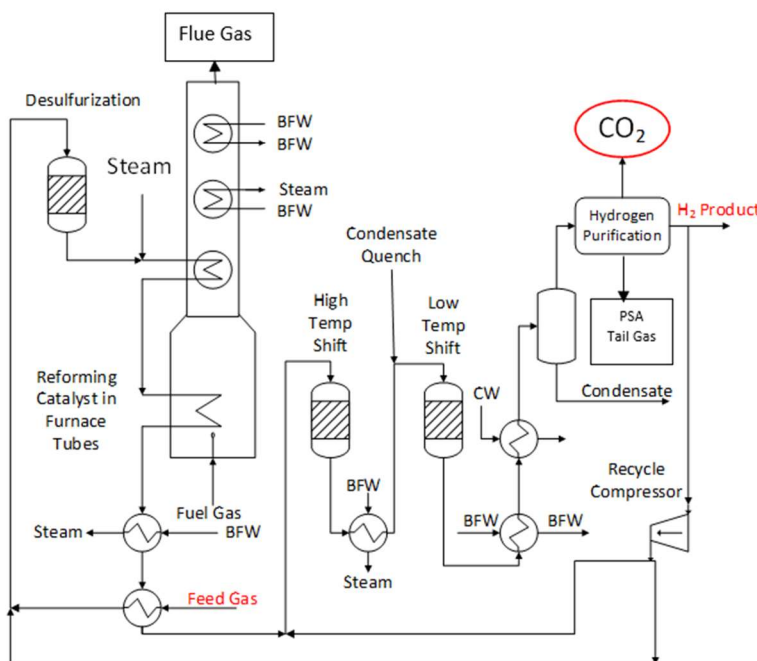

Fig. 10. Process Flow Diagram for a Hydrogen Plant
BFW = Boiler Feed Water; CW = Cooling Water

Feed gas is preheated and pretreated to remove sulfur. The pretreated gas is mixed with steam (and some recycled hydrogen product) and reformed over a catalyst at high temperature. For small hydrogen plants, the reforming “reactor” is catalyst packed right into furnace tubes. The feed is first preheated by heat exchange with hot flue gas. Heat is recovered from the hot flue gas by generating steam. The hot effluent from the steam reforming reactor is cooled and passed to water-gas shift reactors. Equilibrium conversion to CO_2 and H_2 in the water-gas shift reactors is favored by low temperature. Water-gas shift conversion is limited by thermodynamics, which favors higher conversion at lower temperatures. Thus, the shift may be done in two steps. A first high temperature shift reactor is used to provide faster reaction kinetics. A second low temperature shift reactor is used as a trim reactor to provide high conversion.

The hydrogen atoms in the methane are converted to water. The water is mainly removed by cooling and separation in a condensate drum.

CO_2 separation and hydrogen purification and separation is shown as a block (Hydrogen Purification) in Fig. 10. Within that block, hydrogen separation and purification is commonly done by a pressure swing adsorption (PSA) unit. The PSA unit produces the purified hydrogen product and a PSA tail gas that contains unreacted CH_4 , unrecovered H_2 , unconverted CO , and CO_2 . The CH_4 , H_2 , and CO give the tail gas a heating value. This gas is burned in the reformer furnace. However, since the reforming reaction is so endothermic, additional natural gas is needed.

CO_2 is typically removed from the PSA tail gas by absorption in an amine solution followed by CO_2 removal from the rich amine solution in a stripper distillation column. CO_2 stripping is energy intensive. The stripped CO_2 is compressed to liquify for export.

Note that steam is generated in multiple places in the process. That steam can be used to turn turbines to generate electricity in a combined cycle power plant, in which the hydrogen product can be burned to produce more steam and more power, or it can be exported for use in a refinery or chemical plant or elsewhere (the basis for a hydrogen economy). In a hydrogen plant dedicated to H_2 production for a

refinery or chemical plant, net steam is produced, that must find a home. Receiving value for export steam is very important for the economics of these units.

A block flow diagram for an SRM hydrogen plant with CCUS is shown in **Fig. 11**, which shows where CO₂ must be recovered to make this hydrogen “CO₂-free.” This figure assumes that CO₂ produced in the process is recovered from the PSA tail gas. It could be recovered ahead of the PSA unit, but this generally leads to lower recovery and higher cost, since the CO₂ is more dilute ahead of the PSA.

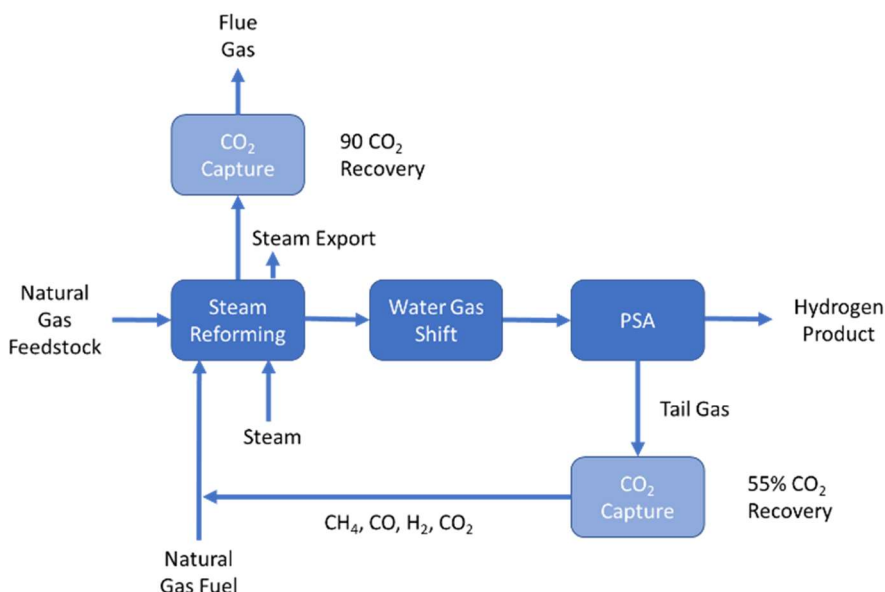

Fig. 11. SRM Hydrogen Plant Block Flow Diagram

IEA provided estimates for H₂ production cost for an SRM with and without CCUS for various world regions [32]. H₂ cost is broken down into natural gas cost, CAPEX and OPEX. These costs came from an engineering study performed by Foster-Wheeler [33] for a large 100,000 Nm³/hr SRM H₂ plant. For reference, the world’s five largest single train SRM plants range from 151,000 Nm³/hr to 240,000 Nm³/hr.

The modeled plant produces 100,000 Nm³/hr H₂ = 9.0 t/hr H₂, and 23.7 t/hr CO₂ (combined furnace flue gas and PSA tail gas). The IEA incremental CAPEX (with CCUS vs. no CCUS) is \$0.26/kg H₂ and the incremental OPEX is \$0.24/mt H₂, which correspond to \$99/mt CO₂ and \$91/t CO₂ respectively, assuming 100% CO₂ recovery. Thus, total cost for CCUS is \$190/t CO₂, or higher depending on CO₂ recovery efficiency.

8. The Cost of CCUS for Biomass Sequestration in a Landfill

The cost of CCUS for biomass sequestration will be comprised of two components: 1) the cost of harvesting leaves, or the cost of growing and harvesting cultivated biomass such as switchgrass; and 2) the cost of landfilling.

Growing and landfilling switchgrass will be considered first. Farm-Energy (2019) estimated the cost of producing switchgrass in the US Upper Midwest at \$65/short ton dry matter (\$72/mt) [34]. This assumes a switchgrass yield of 3.5 ton/acre. New varieties of switchgrass are being developed that could increase yield to 6 ton/acre, which would lower production cost to about \$38/ton (\$42/mt).

Bagchi provided a cost estimate for landfilling municipal waste at \$20/ton [35]. This estimate in the third edition of his book is the same as in the first edition published in 1990. In a private conversation, he

suggested inflating that cost by the Consumer Price Index, which when converting to metric units brings the cost in 2020 to \$46/mt.

Thus, the total cost for growing and sequestering switchgrass in a landfill would be \$118/mt at a conservative yield of 3.5 ton/acre, or as low as \$88/mt for a yield of 6 ton/acre. Thus, growing and sequestering switchgrass would be a low-cost Direct Capture option.

The cost for harvesting and bailing hay is well known [7], and thus the cost of producing switchgrass should be accurate. The cost for harvesting tree leaves would have more uncertainty. Harvesting leaves from established forests would have no growing costs. However, harvesting costs would be expected to be higher for leaves due to lower compacted density. The density of hay is about 150-250 kg/m³ [36], compared to a density of about 113 kg/m³ for compacted leaves. The latter value is from a private email dated April 27 2021 from the Commissioner of Streets and Sanitation for the city of Batavia, Illinois.

How much CO₂ capture potential does growing and sequestering switchgrass provide? The following numbers use the ratio of CO₂/CH₂O MW of 44.0/30.03, a conservative switchgrass yield of 3.5 tonne/acre, and assumes 80% permanent capture in an unmodified landfill. Corn is the primary feed grain, accounting for more than 95% of total feed grains in the US. In 2019, greater than 90 MM acres of corn were planted in the US [37]. If the 40% of that crop devoted to bioethanol were replanted with switchgrass and sequestered, the CO₂ capture potential is 148 MMt/yr. In 2019, 89.1 MM acres of soybeans were planted in the US [38]. If half of that land were devoted to switchgrass, that CO₂ capture potential would be 183 MM tonnes. In addition, range and pastureland accounts of 27% of total land in the contiguous US, or 528 MM acres [39]. If half of that land were devoted to switchgrass, the CO₂ capture potential would be 1.1 Gt/yr. If high yield switchgrass providing a yield of 7 tonnes/acres were to be developed, these numbers would double. Of course, this is just in the US. The world potential is enormous. Combined with energy conservation, renewable energy, CO₂ sequestration from large point sources, and leaf and other biomass sequestration, and other carbon capture innovations, Net Zero CO₂ could be within reach.

9. Secondary Issues and Practicality

The main secondary issues include:

- 1) For leaf gathering, the main issue is accessibility. While theoretically, there are enough leaves in the world to achieve Net Zero CO₂ if they were gathered and sequestered, trees are distributed with many being in remote areas that are not accessible. Reforestation is a popular current topic. New forests should be planted structurally with leaf gathering in mind.
- 2) Resupply of nutrients pulled from the ground is another issue. As noted above, plants receive all of their carbon from CO₂ in the air via photosynthesis. However, the enzyme that catalyzes photosynthesis required nitrogen and phosphorous. For trees in mature forests, those can come from decomposition of leaf and dead trees. In addition to N, P, and K, there are other micronutrients such as B, Fe, etc. There is nothing in the list of nutrients that cannot be supplied by external fertilization with a proper mix. Note that natural forests are sustainable without external fertilization. There are nitrogen fixing plants, such as soybeans. Crop rotation between corn and soybeans is practiced reducing the need for external fertilization. Also, nitrogen fixation is carried out naturally in soil by microorganisms termed diazotrophs that include bacteria such as *Azotobacter* and archaea. Perhaps research and commercial development of these bacteria could lessen fertilizer requirements.

Would it be practical to achieve full Net Zero CO₂ by sequestering tree leaves and growing and sequestering high yield switchgrass? The answer is likely not. However, these methods can play an

important role in supplementing energy conservation, renewable energy, and CO₂ sequestration from existing and future large point sources. First, let us remember that to achieve Net Zero CO₂, emissions need to be reduced by about 36 Gt/yr.

The issue of practicality will be addressed in two ways: 1) The volume of leaves and switchgrass that would need to be sequestered to pull 1 Gt/yr CO₂ from the air will be compared to the volume of coal that is currently removed from the ground each year; and 2) The practicality of pulling an equivalent amount of CO₂ from the air by sequestering biomass will be compared to the amount of CO₂ that may be removed by low-carbon hydrogen production of historical, announced and in the Sustainable Development Scenario of the IEA for the period 2010-2030 [40].

Historical data provided by IEA indicates that world annual coal production peaked at about 8 Gt in 2013, and after a dip to about 7.3 Gt in 2016 recovered to about 7.9 Gt in 2019 [41]. Using 8 Gt/yr and an average compacted coal density of 881 kg/m³ (the average for anthracite and bituminous) [42], that is about 9 billion m³/yr. The average compacted density of leaves is about 113 kg/m³. The ratio of coal to leaf density is about 7.8. Thus, burying 1 Gt/yr of leaves would occupy about the same volume as the amount of coal mined in 2013. Remember that the amount of CO₂ removed from the air for burying 1 Gt leaves or other biomass is about (44.01 gm/mol CO₂/30.03 gm CH₂O) = 1.47. Thus, achieving 1 Gt/yr reduction of CO₂ by burying leaves seems within the realm of possibility. The density of large round hay bales is about 177 kg/m³ [43], and switchgrass density should be about the same. Thus, the ratio of coal density to hay density is about 5. Thus, burying 1 Gt/yr of switchgrass would require about 63% of the volume of coal mined in 2013 and would be the equivalent of removing about 1.47 Gt/yr CO₂.

IEA has provided a recent update of low-carbon hydrogen production projects, historical, announced and in the IEA Sustainable Development Scenario, for the period 2010-2030. Through 2023, only about 6-7 Mt/yr H₂ are installed or planned. IEA projects another 8 Mt/yr may be installed out to 2030. That is Mt/yr, not Gt/yr! Per the rough H₂ plant material balance in Section 9.0, that corresponds to (7+8 Mt/yr H₂)*(23.7 t CO₂/9 t H₂) = 39.5 Mt/yr CO₂ sequestered if the plants are built with CCUS. While there is high hopes for a hydrogen economy contributing to the reduction of CO₂ emissions, this is no where near the 36 Gt/yr that needs to be eliminated. That is reality. For comparison, this would require growing and sequestering about 29.6 Mt/yr biomass, requiring a volume of just 2% of the volume of coal mined in 2013. Surely, sequestering biomass can do better than this.

10. Final Comments

Here are some final comments regarding the proposal of permanent biomass sequestration as a means of removing CO₂ already in the atmosphere (Direct Capture).

- Theoretically can it achieve Net Zero CO₂? Yes, there are enough leaves that it can on its own independent of other technologies.
- Is it technically sound? Yes. Landfills can be designed to prevent biomass degradation to CO₂ and/or methane. In fact, encouraging degradation may be a more difficult problem as evidenced by the huge mounds left by traditional landfills. Also, as shown above, very little degradation of biomass occurs without modifications to further reduce degradation.
- Is it actionable? Yes. It could be put into practice in the timeframe required (before 2035-2050).
- Are there secondary issues? Yes: 1) Designing new managed forests with leaf collection in mind; 2) Soil nutrient replacement, etc.; and 3) Designing secure leaf landfills with no or minimal decomposition and leakage. However, it is thought that these issues can be addressed by gathering the right group of people (experts in forestry, soil chemistry, landfill management).
- The potential for carbon capture via tree leaf collection and growing and sequestering switchgrass is

enormous as shown in Sections 4 and 8.

- Is it still a daunting problem? Yes. To achieve Net Zero CO₂ for the current 36 Gt/yr of CO₂ using this technique alone would require sequestering an enormous amount of material. Of course, this would be reduced, perhaps in half, by energy conservation, renewable energy, CO₂ sequestration, other carbon capture innovations, etc. Even at incomplete implementation, it can play a role in reducing net CO₂ to the atmosphere.

- Can any of the other proposed technologies achieve Net Zero CO₂ on their own? No.

- How would biomass landfill projects be funded? Carbon credits are currently being traded. The business model for this proposal would be: Corporations would invest in the landfills and leaf or biomass growth and collection. Farmers would grow high yield crops for Direct Capture carbon sequestration. Carbon credits would be sold to recover investments.

11. Conclusions

Carbon dioxide from fossil fuels is the main culprit of Global Warming. The problem is massive; 36 Gt/yr CO₂ are being released into the atmosphere. Finding a solution requires an understanding of where energy is produced and consumed and a proper understanding of the Carbon Cycle. While renewable energy is growing rapidly, it remains a very small part of overall energy. Other solutions are needed.

Bioethanol and biodiesel remain a small part of energy for transportation, which itself is less than 30% of overall energy consumed. Corn ethanol is at best be sustainable, but not when energy for production is considered. Two of the six carbons of glucose are converted to CO₂ during fermentation, which most facilities release to the atmosphere before any useful work is done in an engine. Cellulosic ethanol promises cheap feedstock, but still faces a number of technical and economic challenges. This has slowed implementation. The reality is that only about 15 MM gallons of cellulosic were produced in 2018 compared to 16,868 MM gal of corn ethanol.

CO₂ sequestration can target CO₂ produced in large industrial furnaces, including those used to generate electric power. Industrial and power plant furnaces account for about half of CO₂ generated. This is significant, but CO₂ sequestration will not be a complete solution.

There is much recent attention on the steam reforming of natural gas to produce hydrogen. SRM can indeed produce clean burning "CO₂-free" hydrogen fuel, if CCUS is added. Coal can undergo partial oxidation to CO, followed by shifting CO by reaction with H₂O to CO₂ and H₂ via the water-gas shift reaction. With CCUS, coal has the potential to be converted to a "CO₂-free" fuel. One issue for CO₂ capture is what to do with the CO₂. The markets where CO₂ has positive value are limited. Beyond that, CO₂ must be buried underground in spent oil or gas wells or underground saline formations.

Renewable energy, biofuels without CCUS, and CO₂ sequestration from industrial furnaces can displace *future* CO₂ from continued use of fossil fuels. The only way to reduce CO₂ *already* in the atmosphere is to grow biomass from atmospheric CO₂ via photosynthesis and permanently sequester that biomass. Rather than spending capital and energy to convert that biomass to biofuels, which is both energy inefficient and an inefficient use of biomass carbon, permanent sequestration of biomass *carbon* from tree leaves, crops, and municipal and yard waste is proposed. Permanent sequestration can take place via landfills modified to prevent aerobic decomposition to CO₂ or anaerobic decomposition to CO₂ and methane. Theoretically, sequestration of only a fraction of the world's tree leaves can bring the world to Net Zero CO₂ and without disruption of the underlying forests. Thoughts are put forth on how to redesign landfills to achieve secure permanent biomass sequestration.

The cost of Carbon Capture, Use, and Storage (CCUS) is calculated to be about \$190/mt CO₂ for an SRM hydrogen plant. The cost of CCUS for growing switchgrass and burial in modified landfills is calculated to

be about \$120/mt CO₂ for a conservative yield of 3.5 tons/acre switchgrass. Development of high yield switchgrass (6 mt/acre) could lower that cost to about \$88/mt CO₂. Thus, growing and sequestering switchgrass would be a low-cost Direct CO₂ Capture option.

ACKNOWLEDGMENTS

Amelse received a Ph.D in Chemical Engineering from Northwestern University, Evanston, IL USA. He worked for Amoco Chemical Company R&D (now BP Amoco Chemical Company Petrochemicals Technology, Naperville, IL USA, for 35 years, mainly on paraxylene catalyst and process technology. He retired in April 2017 and joined CICECO, Aveiro Institute of Materials, Department of Chemistry, University of Aveiro, Portugal as Invited Principal Investigator to continue collaborating with Dr. Luis Mafra on the characterization of molecular sieve catalysts and adsorbents via Solid State NMR, work started while he was at BP. He has published numerous papers and is co-inventor on 17 issued or pending patents. He was recently extended a 3-year unpaid position as Invited Associate Professor, so he can continue to teach on-line and collaborate on several projects following his return to the U.S.

Paul Behrens received a Ph.D. in Chemical Engineering from the University of Delaware. He joined Amoco Chemical Company R&D and spent 28 years there, supporting a number of chemical processes, including para-xylene, PTA, polybutene, 2,6-naphthalene dicarboxylic acid, and efforts to commercialize cellulosic bioethanol. He continues as an independent consultant with expertise in process modeling, design, and economics. Since his semi-retirement, he purchased a farm near Indianapolis, IN where he grows hay.
