Abstract

Glucocorticoids (GCs) have been the mainstay of immunosuppressive therapy in solid organ transplantation (SOT) for decades due to their potent effects on the innate immunity and tissue protective effects. But, some SOT centers are reluctant to administer GCs for long-time due to the various side effects. This review summarizes advantages and disadvantages of GCs in SOT. PubMed and Scopus databases were searched from 2011 to April 2021 using search syntaxes cover “transplantation” and “glucocorticoids”.

GCs are used in transplant recipients, transplant donors, and organ perfusate solution to improve transplant outcomes. In SOT recipients GCs are administered as induction and maintenance immunosuppressive therapy. GCs are also the cornerstone to treat acute anti-body- and T-cell-mediated rejections. Addition of GCs to organ perfusate solution and pretreatment of transplant donors with GCs are recommended by some guidelines and protocols to reduce ischemia-reperfusion injury peri-transplant. GCs with low bioavailability and high potency for GC receptors such as budesonide, nanoparticle-mediated targeted delivery of GCs to specific organs, and combination use of dexamethasone with inducers of immune-regulatory cells are new methods of GC usage in SOT patients to reduce side effects or induce immune-tolerance instead of immunosuppression. Various side effects on different non-targeted organs/tissues such as bone, cardiovascular, neuromuscular, skin, and gastrointestinal tract have been noted for GCs. There are also potential drug-drug interactions for GCs in SOT patients.

Key words: Corticosteroids; Glucocorticoids; Solid organ transplantation; Liver; Kidney; Heart; Lung
Core tip: Due to their potent immunosuppressive and anti-inflammatory effects, glucocorticoids (GCs) are widely used in solid organ transplantation (SOT). We herein review the current status of GC usage in SOT including their different clinical uses in transplant recipients and donors, new strategies for targeted organ delivery of GCs, and enhancing their immune-tolerance versus immunosuppressive effects. Major concerns about GCs such as their adverse effects on various organs and their potential drug-drug interactions in SOT patients are also discussed.

Introduction

Glucocorticoids (GCs) have long been used as induction and maintenance immunosuppressive therapy as well as treatment of acute allograft rejection in solid organ transplant (SOT) patients. However, complications of GCs make them undesirable for long-term use. Therefore, steroid sparing regimens have been used in different types of SOT[1-3].

French insurance data in 2014 showed that only 54% of patients who received kidney transplantation in 2012 were taking prednisolone[4]. A large cohort study on adult liver transplant patients who were transplanted between 2006 and 2014 showed that during six months after transplantation approximately 43% of the liver transplant recipients were treated with three immunosuppressive drugs including prednisolone, a calcineurin inhibitor (CNI), and mycophenolate/azathioprine, while 15.4% of the patients were on steroid sparing regimens; however, approximately 34% of the patients on triple therapy changed to steroid sparing regimen between months 7 to 12 after liver transplantation[2]. It should be kept in mind that this data underestimates the number of patients who discontinued steroid because patients who received only tacrolimus has been categorized as antimetabolite sparing not steroid sparing group.

Regarding heart transplantation, a report from International Society of Heart and Lung Transplantation Registry on adult heart recipients who were transplanted between 2000 and 2008 indicated that long-term use of steroids (use for more than 5 years after transplantation) has declined over time from 60% in the year 2000 to 43% in the year 2008, and early GC withdrawal (discontinuation between 2 to 5 years after transplantation) has increased from 19% to 33% during these years[3]. Here, we review different advantages and disadvantages of GCs in SOT (Figure 1).
Figure 1: Advantages and disadvantages of glucocorticoids in solid organ transplantation

**GC in SOT**

**Advantages**
- Induction and maintenance of immunosuppression
- Treatment of acute rejection
- Treatment of recurrent autoimmune/inflammatory diseases after transplantation
- Treatment of PTLD
- Maintaining immunosuppression in patients with allograft loss who listed for retransplantation
- Treatment of GVHD
- Treatment of hyperbilirubinemia after liver transplant
- Maintenance of immunosuppression during pregnancy and lactation
- Management of other complications after transplantation
- New horizons in GC use in SOT:
  * GC nanoparticles for targeted immunosuppressive therapy
  * GC-enhanced immunoregulatory cells induction

**Disadvantages**
- Infections
- Bone disorders
- Growth retardation in pediatrics
- Metabolic complications and cardiovascular risks
- Neuropsychiatric side effects
- Muscular side effects
- Adrenal insufficiency
- Gastrointestinal side effects
- Dermatologic side effects
- Other complications

**Organ perfusate solution**
- Amelioration of IRI and maintaining allografts quality

**Transplant recipients**

**Drug interactions**
- 3A4 inducers
- 3A4 inhibitors
- CNIs

**Transplant donors**

CNI: calcineurin inhibitor; GC: glucocorticoid; GVHD: graft versus host disease; IRI: Ischemia-reperfusion injury; PTLD: post-transplant lymphoproliferative disorder; SOT: solid organ transplantation
Method

PubMed and Scopus databases were searched from January 2011 to April 2021 using search syntaxes: (transplantation [Title/Abstract] OR transplant [Title/Abstract]) AND (corticosteroid* [Title/Abstract] OR glucocorticoid* [Title/Abstract] OR steroid* [Title/Abstract] OR prednisolone [Title/Abstract] OR prednisone [Title/Abstract] OR methylprednisolone [Title/Abstract] OR dexamethasone [Title/Abstract] OR hydrocortisone [Title/Abstract]). Articles’ references were reviewed for relevant publications.

Mechanisms of actions of corticosteroids in solid organ transplantation

For many years adaptive immunity system (T and B cells) has been focused for preventing allograft rejection. However, innate immune system (dendritic cells, phagocytes (monocytes, macrophages, neutrophils), and natural killer (NK) cells) also play major roles in peritransplant immunologic process. Innate immunity is activated peritransplant by donor brain death, ischemia-reperfusion injury (IRI), non-adherence to immunosuppressive therapy, and infections. Innate immune activation ultimately induces acute allograft rejection and chronic allograft damages[5]. GCs exert a wide range of anti-inflammatory and immunosuppressive impacts mainly through their genomic and partly via their non-genomic effects. Their genomic effects that usually have prolonged onset of action, are mediated by binding of GCs to their cytosolic receptors, entering the nucleus and activating GC response elements that induce anti-inflammatory genes (transactivation) while repressing elements that induce expression of inflammatory factors such as nuclear factor kappa-light-chain enhancer of activated B-cells (NF-KB) and activator protein-1 (AP1) (transrepression). Anti-inflammatory effects of GCs are related to both transactivation and transrepression effects, while their adverse effects mainly correlated to their transactivation impacts. Genomic effects usually depend on cumulative dose over duration of GC administration[1, 5, 6]. Non-genomic mechanism of GCs has been less known and are partly mediated by membrane receptors that modulate anti-inflammatory and anti-oxidant effects. Their non-genomic effects are of rapid onset, short duration of action, and happens with high or pulse doses (prednisolone doses of more than 30mg/day)[1, 6, 7].

Regarding the effects of GCs on innate immunity system, in dendritic cells GCs decrease the production of inflammatory cytokines (tumor necrosis factor (TNF)-α and interleukin (IL)-1β) in response to CD40L and lipopolysaccharide (LPS). GCs also inhibit upregulation of costimulatory molecules (CD40, CD80, CD83, CD86 and MHC-II) in response to LPS. In monocytes, GCs increase the expression of anti-inflammatory cytokines (IL-10) and repress production of inflammatory cytokines (TNF-α, IL-1β, IL-12), reduce expression of CD80 in response to inflammatory stimuli, impair monocyte antigen presenting activity, down-regulate expression of TLR4 on the surface of monocytes and subsequent monocyte hypo-responsiveness to endotoxin. In neutrophils, GCs inhibit neutrophil activation (by reducing the expression of NADPH oxidase, inducible nitric oxide synthase (iNOS), and cyclooxygenase 2), reduce chemotaxis,
phagocytosis and cytokine secretions, increase the expression of some receptors for ILs and proinflammatory leukotrienes (IL1R1, BLT1), and reduce neutrophil sensitivity to apoptosis that leads to increased neutrophil life span. GCs reduce NK cell cytolytic activity and increase their production of pro-inflammatory cytokines[8]. By repressing the expression of IL-1, IL-2, IL-3, TNF-α, and IFN-γ, T-cell activation process (a part of adaptive immunity) is inhibited by GCs[5]. These mechanisms have been summarized in Figure 2. Considering above-mentioned mechanisms, GCs have various advantages and disadvantages in SOT patients that are reviewed here.

Figure 2. Effects of GCs on immune system

Advantages of GCs in SOT

GCs are administered pre-transplant in potential donors and organ perfusate solution to decrease IRI and preserve organs quality, and GCs are given peri- and post-transplant to recipients as induction or maintenance immunosuppression, treatment of acute rejection, or for management of some post-transplant complications.

1. Transplant recipients

1.1. GCs as induction and maintenance immunosuppressive therapy

GCs are commonly used as induction and maintenance immunosuppressive agents in SOT patients\textsuperscript{[1-3]}. As maintenance immunosuppressive therapy, some centers are shifting toward steroid sparing maintenance immunosuppressive regimens by different steroid withdrawal or avoidance protocols\textsuperscript{[1-3]}. Steroid sparing means rapid, early, or late steroid discontinuation (within one week to several months after transplantation), while steroid avoidance refers to avoiding steroid use in regimens with or without initial high corticosteroid induction therapy\textsuperscript{[3, 9-12]}. Although old studies on steroid sparing regimens that usually were GC minimization or discontinuation after 3 months of transplant surgery showed higher rates of acute rejection and graft loss, in those studies immunosuppressive regimens contained cyclosporine as a CNI\textsuperscript{[13]}. Nowadays, induction therapies with thymoglobulin or IL2 receptor antagonists and new maintenance immunosuppressive regimens such as tacrolimus instead of cyclosporine as CNI or mTOR inhibitors in combination with low doses of CNIs and/or mycophenolate provided the opportunity for successful steroids sparing immunosuppression regimens\textsuperscript{[1, 9-11, 14, 15]}. Although firstly steroid sparing immunosuppressive regimens were used for low immunologic risk patients, an analysis of 169479 renal transplant patients using SRTR exhibited that rapid discontinuation of steroids can be used in all adult and pediatric first kidney transplant recipients from deceased or living donor and even in second kidney transplant recipients from living donor or patients at risk for rejection or recurrence of underlying diseases, without decreasing patients’ or graft survivals. Only in adult patients with second kidney transplantation from deceased donor, rapid steroid withdrawal was associated with worse graft survival\textsuperscript{[9]}. Another systematic review and meta-analysis consisting 7 cohort studies that included even high-risk kidney transplant patients such as re-transplant patients, African-American ethnicity or recipients with panel reactive antibody (PRA) of 20% or more found that acute rejection episodes and graft loss were comparable between patients maintained on steroids compared with steroid withdrawal or avoidance group. Steroid withdrawal was done within 1 week after transplantation in many of these patients. Based on this meta-analysis, steroid withdrawal within 1 week after transplantation was associated with significant reduced risk of patient death\textsuperscript{[10]}. Steroid withdrawal regimens are used in most liver transplant patients. A Cochrane systematic review consisting 1347 liver transplant patients revealed that early steroid
withdrawal or steroid avoidance (excluding intraoperative GC use) have been beneficial in some patients especially those at risk for hypertension or diabetes mellitus\[\text{[11]}\]. Although steroid avoidance after using high intraoperative dose may be beneficial in liver transplant recipients, data showed that complete steroid avoidance (even avoiding intraoperative use) led toward decreased patient and graft survival\[\text{[12]}\].

Most centers of simultaneous kidney and pancreas transplantations are also shifting toward steroid avoidance, or early or late steroid withdrawal\[\text{[16]}\].

Long term GC therapy had been conventionally the cornerstone of immunosuppressive therapy in heart transplant patients. However, a report from International Society of Heart and Lung Transplantation Registry on adult heart recipients who were transplanted between 2000 and 2008 showed that early or late GC withdrawal has increased among heart transplant patients. Comparing to long-term steroid users (GC use for more than 5 years after transplantation), 10-year patient survival was significantly higher among early (GC discontinuation between 2 to 5 years after transplantation) or late (GC discontinuation after year 5 of transplant) steroid withdrawal (73%, 82% and 80%, respectively)\[\text{[3]}\]. Steroid discontinuation during 1 week after transplantation has also been applied in low-risk heart transplant pediatrics with acceptable 1-year outcomes\[\text{[17]}\].

Corticosteroids are usually a part of maintenance immunosuppression in lung transplant patients as well. Glucocorticoid receptor (GR) in lung epithelia is essential for lung development, and GCs are widely used to treat certain lung diseases\[\text{[18]}\]. It seems that there is a difference in lung transplant outcomes between patients with different variants of glucocorticoid-induced transcript 1 gene (GLCCI1) that modulates GC sensitivity. A study on 71 lung transplant recipients showed that compared with those with the CC variant (wild type allele), patients with the TT variant (homozygous for mutant allele) had lower total lung capacity and forced expiratory volume in 1 second at 3 years after transplantation and also had significantly decreased chronic allograft dysfunction-free survival at year 3 after transplantation\[\text{[19]}\].

Despite available data regarding efficacy of steroid sparing regimens in SOT patients, systemic steroids are still used at least for several weeks in maintenance immunosuppression regimens even in low immunologic transplant types such as liver transplantation\[\text{[20]}\]. Budesonide is a synthetic corticosteroid with minimal systemic bioavailability of about 10% due to extensive first pass hepatic metabolism that result in its lower side effect\[\text{[21]}\]. On the other hand, compared to methylprednisolone and prednisone, budesonide possesses strong local anti-inflammatory effect in the liver due to approximately 15-times higher affinity to GR\[\text{[22]}\]. A phase 2 clinical study in first liver transplant recipients compared budesonide (tapering from 9 to 3 mg over 12 weeks) with prednisolone in the maintenance immunosuppressive regimen containing CNI and mycophenolate. Patients were followed for two years. Biopsy proven acute cellular rejection was the same between the two groups (5% in each group), while PTDM (0% versus 15%) and infection rates (0% versus 30%) were significantly lower in the budesonide taking group\[\text{[23]}\].
1.2. Treatment of acute rejection

High doses of intravenous (methylprednisolone or dexamethasone) or oral (prednisolone, prednisone) GCs have been historically administered for the treatment of acute cellular and antibody mediated rejections in different types of SOT[24-28].

Recently, a US center retrospectively assessed the 6-month outcomes of 29 pediatric liver transplant who were prescribed oral budesonide at outpatient setting for treatment of biopsy proven (19 patients) or presumed (based on blood biochemistry tests; 10 patients) mild to moderate acute cellular rejection. In these patients, budesonide was administered at daily doses of 6 to 9 mg for several weeks and tapering down thereafter. Only 3 patients needed switching to systemic GCs (methylprednisolone or prednisone). All other patients experienced significant decreases in liver transaminases without progressive graft injury or chronic allograft rejection[29].

1.3. Post-transplant malignancies

A main complication after solid organ transplantation is post-transplant malignancies including post-transplant lymphoproliferative disorders (PTLD). Immunosuppression reduction or changes is recommended in patients with PTLD. However, GCs are a basis of chemoimmunotherapy in some malignancies including PTLD and are usually remained in immunosuppressive regimen of solid organ transplant recipients with PTLD[30]. Sometimes under the umbrella of corticosteroids, other chemotherapeutic agents with some concerns in SOT recipients are administered. Although immune checkpoint inhibitors are increasingly shown to be successful in treating multiple types of cancer, there are some concerns about the risk of allograft rejection with these drugs in SOT patients[31]. A pilot study showed that immune checkpoint inhibitors along with prophylactic steroids may be a safe and effective treatment for some solid organ transplant patients with advanced cutaneous squamous cell carcinoma[32]. While a Danish historical cohort study revealed a tendency toward higher occurrence of post-transplant cancer in a kidney transplant center that applied steroid-free immunosuppressive regimen compared to centers that adhered to GC-containing immunosuppressive protocols[33], another Danish registry analysis on over 59000 patients found a standardized incidence risk of 1.32 (95% 1.09-1.59) for cutaneous squamous cell cancer among GC users, however, this increased risk was seen across all patients in that study not just transplant patients[34].

1.4. Prevention or treatment of recurrent autoimmune diseases

Diverse de novo autoimmune diseases in different organs can happen after SOT and are usually treated as patients in the general population that is out of the scope of this review. Recurrent glomerulonephritis (GN) after renal transplantation is the fourth common cause of allograft loss with reported recurrence rate of 2.6% to 50% and average graft loss risk of 8.4% over 10 years. Data from Australia and New Zealand Dialysis and Transplant Registry over 30 years reported that focal segmental glomerulosclerosis (FSGS), IgA nephropathy, membranous GN, and membranoproliferative GN (MPGN) showed
recurrence after renal transplantation. Different risk factors have been reported for these GN recurrence. Regarding the role of GCs, when all GNs were totally included, multivariate analysis exhibited that baseline steroid use in maintenance immunosuppression had a protective effect (adjusted HR: 0.54; 95% CI 0.37-0.76, P<0.001). When FSGS and IgA nephropathy were analyzed separately, baseline steroid use was a protective factor only for transplant recipients with IgA nephropathy[35]. Another study also revealed that the rate of recurrence of IgA nephropathy after kidney transplantation was higher among patients with steroid withdrawal at any time after transplant[36]. There is paucity of enough evidence for treatment and outcomes of recurrent GN after transplantation. Recurrent GN after transplantation is usually managed similar to de novo ones in the general population, although sometimes with some different protocols and responses. GCs are usually a part of GN management regimen[37, 38]. Recurrent IgA nephropathy after renal transplantation is treated with GCs[39].

Autoimmune liver diseases (autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC)) may recur after liver transplantation with varying rates of 10% to 50%. Recurrence of PBC or PSC has not been associated with dose or duration of CGs administration or discontinuing of GCs. Recurrent PBC is traditionally treated with ursodexycholic acid with varying results. Recurrent PSC usually causes progressive allograft damage and need for repeat liver transplantation. Although overall dose and duration of GC treatment pre- and post-liver transplantation were not related to AIH recurrence, rapid weaning of GC after liver transplantation has been associated with higher AIH recurrence rate. AIH recurrence is usually treated with GCs[40, 41].

1.5. Maintaining immunosuppression in patients with graft loss who listed for re-transplantation

Although maintenance of low dose CNI after kidney allograft loss can decrease the development of donor-specific antibody and repress the rise in PRA in patients listed for repeat kidney transplantation, such effects were not observed with GCs[42]. Meanwhile, some clinicians continue low dose prednisolone in kidney recipients with graft loss more than one year after transplantation who are planned for repeat renal transplantation within 1 year[43].

1.6. Graft versus host disease (GVHD) after SOT

Although rare after SOT, GVHD may still occur. Case series show administration of methylprednisolone for treatment of GVHD in some SOT patients, however, there are GC-treatment refractory patients with high mortality rate of 82%[44, 45].

1.7. Hyperbilirubinemia after liver transplantation

Hyperbilirubinemia after liver transplantation is common and is sometimes due to early allograft dysfunction. A randomized controlled trial assessed the effect of low dose
steroid in combination with ursodeoxycholic acid in liver transplant patients. Control group received only ursodeoxycholic acid. Patients with hyperbilirubinemia due to biliary complications and acute rejection were excluded from the study. Both groups were comparable regarding immunosuppressive regimen, donor and recipient characteristics, and time after transplantation surgery. Steroid group had significantly lower bilirubin concentration 1 day and 15 days after intervention was completed and has shorter hospital stay compared with the control group[46].

1.8. Pregnancy and lactation

GCs crosses the placenta, but near 90% of the dose of prednisolone and methylprednisolone (and to lesser extent dexamethasone and betamethasone) are metabolized by placenta 11β-hydroxysteroid dehydrogenase 2 (11β-HSD2) to inactive metabolite. Although, there were concerns about oral-facial clefts, hypothalamus-pituitary-adrenal (HPA) axis dysfunction, or retard growth in newborns from GC-taking mothers, the risk seems minimal unless there is 11β-HSD2 dysfunction (for example due to preeclampsia in mother). It should be kept in mind that GCs may predispose pregnant women to hypertension and preeclampsia. Taken together, GCs in daily doses equivalent to less than 20mg prednisolone is considered acceptable in pregnant women, and GCs are usually continued in transplanted mothers. GCs are also considered compatible with breast-feeding[47].

1.9. Management of other complications

The number of patients with pulmonary complications after hematopoietic stem cell transplantation (HSCT) is increasing, and some of these patients need lung transplantation to survive. Steroid therapy is the current treatment for pulmonary complications in HSCT patients. A retrospective study that compared 9 patients on low-dose and 13 patients on high-dose GCs for post-HSCT pulmonary complications and before their lung transplantation showed that taking low-dose versus high-dose GCs before lung transplantation in these patients was associated with significantly less complications during first year after lung transplantation and improved long-term survival[48].

1.10. New horizons of GCs use in SOT recipients

Targeted delivery of GCs to goal organ is a favorable method to reduce GC side effects when used for treatment of inflammatory diseases and in SOT patients. After parenteral administration, nanoparticles largely translocate into the liver by passive targeting. Therefore, nanoparticle-mediated drug delivery would be a promising method for treatment of inflammatory liver diseases. In several studies, different nanoparticles have been used for transportation of dexamethasone, such as biodegradable polymers (PLGA, PLLA, PCL, cellulose, cyclodextrin, chitosan, polyglutamic acid, and lipids), inorganic materials, polymer micelles, liposome, and carbon nanotubes. Entrapment of dexamethasone in these nanoparticles resulted in prolonged and sustained release of dexamethasone, but premature release out of the target organ was an undesired matter.
yet. To overcome this issue, dexamethasone in concentrations up to 100mg/ml in olive oil were encapsulated in core-shell silica nanocapsules. During an experimental study, these nanocapsules were internalized by non-parenchymal murine liver cells and resulted in suppression of inflammatory response of liver macrophages and significant decrease in inflammatory cytokines. Pegylation of these nanocapsules led to good stability in plasma and controlled interaction with blood proteins\cite{49}.

With the hope of improving efficacy while decreasing side effects, another animal study compared liposomal encapsulated prednisolone versus conventional prednisolone in a murine model of acute renal allograft rejection. The liposomes were 100-nm phospholipid bilayer vesicles coated with polyethyleneglycol. These liposomes remained in blood for several days after intravenous injection. Liposomes prevent the encapsulated drug to diffuse over blood vessel endothelial cells and spread over the body, while they are small enough to extravasate and accumulate in inflamed sites with increased vascular permeability, where macrophages and other phagocytic cells digest the vesicles and release the entrapped GC. The results of that animal study showed improved renal bioavailability of prednisolone, increased renal perfusion, and decreased cellular infiltrate in allograft by liposomal prednisolone compared with conventional prednisolone. In that study, liposomes were detected in other organs such as liver, stomach, and intestine but in much lower density than the kidney allograft\cite{50}. More animal studies are needed before clinical studies to bring these bench findings to the bedside.

Inducing immune tolerance and eliminating the need for long term immunosuppressive therapy has been an old ideal in SOT. Modulating immunoregulatory cells are a potential target for this purpose. Myeloid derived suppressor cells (MDSCs) are novel immunoregulatory cells and are induced by granulocyte macrophage colony stimulating factor (GM-CSF). In an in vitro study, combination of dexamethasone with GM-CSF was successful for enhanced production of phenotype of MDSCs with enhanced in vitro immunosuppressive activity. Adoptive transfer of these MDSCs significantly enhanced expansion of regulatory T cells and prolonged heart allograft survival in mice model. Mechanistic studies showed that iNOS signaling was required for MDSCs in the control of T-cell response. GR signaling had major role in the recruitment of transferred MDSCs into allograft through upregulating CXCR2 expression on MDSCs. These findings revealed that co-administration of dexamethasone and GM-CSF may be a new and applicable strategy for the induction of immune tolerance in SOT\cite{51}.

2. Transplant donors

Brain death process induces inflammatory response in the donor. Increased intracranial pressure and decreased cerebral blood flow during brain death process activate neurohormonal systems and inflammatory cascade. Increased release of inflammatory cytokines, chemokines, and adhesion molecules leads to infiltration of T-lymphocytes and macrophages into the organs\cite{52}. This inflammatory response causes allografts injury
that in combination with IRI increases the risk of initial allograft poor function\textsuperscript{[53]}. There are two separate stages for IRI. Ischemia leads to cellular metabolic disturbances, glycogen consumption, lack of oxygen supply, and ATP depletion which lead to initial parenchymal cell death. Reperfusion injury results from both metabolic disruptions and intense inflammatory response. IRI triggers inflammatory response mainly through innate immune response. Innate immune activation leads to increased production of cytokines, chemokines, and reactive oxygen species (ROS), and increased expression of adhesion molecules. Moreover, cross-talk between innate and adaptive immunity trigger adaptive immune response that results in tissue infiltration by lymphocytes and monocytes and graft rejection\textsuperscript{[54]}. IRI is an important cause of early allograft dysfunction \textsuperscript{[54]}. Therefore, several investigators administered anti-inflammatory drugs to deceased donors to ameliorate IRI. Although animal\textsuperscript{[55,56]} and small clinical studies\textsuperscript{[57]} showed that administering GCs to brain death donors decreased IRI in kidney, heart, or liver grafts \textsuperscript{[55-57]} and is recommended by organ procurement guidelines\textsuperscript{[58]}, the effect of pretreatment of brain death donors with anti-inflammatory agents on long-term allografts outcomes are not promising\textsuperscript{[59,60]}. A multicenter randomized controlled trial consisting 455 kidney transplant recipients from 306 deceased donors were followed for 5 years after transplantation. These deceased donors were randomized to receive 1g of methylprednisolone or placebo before organ procurement. The incidence of biopsy-confirmed rejection (Banff>1) at 3 months after transplantation and 5-year graft survival and the mean estimated glomerular filtration rates were comparable between steroid and placebo groups\textsuperscript{[59]}. In addition, a meta-analysis on methylprednisolone treatment of brain death liver donors (two studies, 183 participants) showed no effect of the treatment on rates of acute rejection (Table 1)\textsuperscript{[61]}. Interestingly, an animal study showed that pretreatment with methylprednisolone markedly prevented warm liver IRI in normal rats, but aggravated IRI in the steatotic livers of the diabetic Zucker rats with deficiency of the leptin receptor\textsuperscript{[62]}. Leptin resistance is common in diabetes. Thus, more studies are needed to understand how deficiency in the leptin signaling may switch the GC action from protection to aggravation in liver IRI and thus affect GC action in SOT of liver and other organs in humans.

The pro-inflammatory state induced by brain death process also decreases the quality of lungs for donation. To preserve lung quality, methylprednisolone is administered to donors with various doses. To assess the dose-effect association between methylprednisolone and brain-death lung inflammation, an animal study compared low (5mg/kg), intermediate (12.5mg/kg), and high doses (22.5mg/kg) of methylprednisolone. All methylprednisolone doses decreased inflammatory cytokines such as TNF-α, IL-6, and IL-1β. Intermediate and high doses of methylprednisolone also increased protective anti-inflammatory response as established by increased IL-10 expression. Macrophage chemotaxis was attenuated with all doses of methylprednisolone, while neutrophil chemotaxis was more evident with intermediate and high doses of methylprednisolone. Considering dose-related side effects of methylprednisolone, this study suggested the intermediate dose of methylprednisolone to reduce brain death-induced inflammatory responses in donors’ lungs[63]. These findings need human studies before extrapolation to routine clinical use.

3. Organ perfusate solutions

Animal studies have shown decreased generation of pro-inflammatory cytokines, IRI and donated tissues edema by adding (methyl)prednisolone to perfusate STEEN and Perfadex solutions for heart and lung grafts[64, 65]. Recently, normothermic ex vivo heart perfusion using the Transmedics organ care system (OCS) has been used clinically for preservation of hearts donated after circulatory death. Based on Transmedic OCS protocol, methylprednisolone is added to the perfusate solution to reduce IRI and preserve cardiac function[66].

Disadvantages of GCs in SOT

The main drawback of GCs is their diverse adverse effects on various tissues. Side effects are usually related to genomic mechanism of action of these drugs, mainly transactivation ones; therefore, these side effects usually have prolonged onset and are associated with cumulative dose of GC over the duration of its administration[1, 5, 6]. Another aspect that should be considered especially in SOT patients is drug interactions of GCs with other drugs in these patients. These aspects are briefly reviewed below.

1. Side effects

1.1. Infections

Glucocorticoids increase the risk of bacterial, fungal, and viral infections [6]. A multivariate regression analysis on data of 45164 kidney transplant recipients in 2000-2011 from United States Renal Data System (USRDS) showed that steroid-free immunosuppressive regimen was associated with reduced risk of pneumonia (adjusted HR=0.89; P=0.002) and sepsis (adjusted HR=0.80; P<0.001)[67]. A multicenter, case-control study on 988 episodes of Enterobacterale-induced blood stream infection among SOT patients showed that about 40% of these episodes are caused by extended-spectrum β-
lactamase (ESBL) producing organisms. Taking corticosteroid-containing immunosuppressive regimens was identified as a risk factor for ESBL-Enterobacterale induced blood stream infection (adjusted OR= 1.3, 95% CI, 1.03-1.65; P= 0.03)[68]. Nocardiosis is another bacterial infection reported among immunocompromised patients such as SOT recipients. A retrospective study compared 60 adult patients who were hospitalized with nocardiosis to a group of 120 patients which was randomly selected among hospitalized patients with community-acquired pneumonia. Multivariable logistic regression analyses showed that immunosuppressive therapy was positively associated with nocardiosis (matched OR=4.40, 95% CI 2.25-8.62; P < 0.001). Among immunosuppressive therapy, GC therapy was a typical risk factor for nocardiosis (matched OR=4.69, 95% CI 2.45-8.99; P < 0.001), especially for pulmonary nocardiosis (matched OR=5.90, 95% CI 2.75-12.66; P < 0.001). The positive association between solid organ transplantation and nocardiosis was mitigated following adjustment for GC administration in a multivariable model. The association between taking GC and nocardiosis was stronger in patients with chronic pulmonary disease (OR=5.74, 95% CI 2.75-12.66; P < 0.001) than in the pooled analysis of all nocardiosis cases[69]. Another analysis on 112 patients with nocardiosis, among them 67 were immunocompromised patients showed that pulmonary nocardiosis among immunocompromised patients was significantly associated with taking high dose GC. Immunocompromised patients showed more disseminated forms of infection, with the highest rate in SOT recipients, and had significantly higher mortality compared with immunocompetent patients[70]. Taking GCs is a risk factor for fungal infections including mucormycosis[71] and invasive Aspergyllosis[72, 73]. Although American society of transplantation suggests re-initiation of Pneumocystis jirovecii pneumonia (PJP) prophylaxis with intensification of immunosuppression such as treatment of acute rejection with GCs[74], the association between GC bolus for acute rejection and PJP remains controversial[75]. While a French case control study exhibited that GC bolus administration for acute rejection in kidney transplant patients as an independent factor correlated with PJP[76] and a Korean study showed that taking GCs is significantly associated with PJP[77], a meta-analysis found that GCs injections for acute rejection did not increase the risk of PJP[75]. On the other hand, a retrospective case series showed that adding GCs to PJP treatment of non-HIV infected patients (3 of 28 were SOT patients) was associated with lower mortality[78], while an older retrospective study comparing PJP-infected non-HIV patients with or without adjunctive steroid therapy (12 of 59 patients in GC taking group and 14 of 29 patients in no GC group were SOT patients) found that GC use may not improve outcome of moderate to severe PJP in these patients[79].

Regarding viral infections, it has been reported that prednisolone daily doses of 10 mg or higher is associated with higher risk of respiratory viral infection[80]. Community acquired viral respiratory infections (rhinovirus followed by coronavirus and respiratory syncytial virus) has been reported in approximately 25% of lung transplant recipients during the first year after transplantation especially in those receiving nasal glucocorticoids[81]. Corticosteroid use is a risk factor for adenovirus infections including urinary tract infection with this virus (OR = 3.86, 95% CI 1.21-12.24; P = 0.02 for acquiring
urinary tract infections)\[82]\], It has been reported that kidney transplant patients on the maintenance GCs are more likely to be admitted with COVID-19\[83]\]. Some authors reported that one of the major risk factors associated with survival among kidney transplant patients infected with SARS-CoV2 is receiving prednisolone, (OR= 5.98, 95% CI 1.65-21.60); \( P < 0.01 \)\[84]\.

BK (polyoma) virus infection is common during 6 months after renal transplantation and may lead to BK virus associated nephropathy (BKVAN). There are case reports of BKVAN that resulted in native kidney failure in other types of SOT patients. Taking GCs pulse for the treatment of acute allograft rejection has been reported in these patients before BKVAN\[85]\]. Causality assessment needs more studies.

Regarding cytomegalovirus (CMV) infection, a retrospective study evaluated 71 SOT patients during the same time period, among them 49 patients were tested for genotypic resistance CMV variants and 22 were not because of no clinical suspicion for resistance variants. This study compared the patients in 3 groups; group 1 were patients with resistant CMV infections (defined as document of failure to reach at least 1 \( \log_{10} \) decline in CMV DNA load after two weeks of treatment with (val)ganciclovir, foscarnet, cidofovir and at least 1 CMV resistant genotypic mutation), group 2 refractory CMV infection (defined as documented failure to have 1 \( \log_{10} \) or more decline in CMV DNA level after at least two weeks of treatment with (val)ganciclovir), and group 3 (no suspected CMV resistance and not tested for that). Results showed that patients in group 1 and 2 were taking higher mean daily doses of prednisolone compared with patients in group 3 (10 mg a day or higher versus 5 mg daily); however, in the final model, daily GC dose was not a significant risk factor for resistant or refractory CMV infection\[86]\.

An experimental study indicated that GCs activate major immediate-early promoter (MIEP) which drives CMV gene expression. This GC effect is mediated via GR pathway and leads to reactivation of latent CMV from primary monocytes. To investigate the clinical relevance of this experimental finding, the same researchers retrospectively analyzed data of liver transplant patients and found that taking prednisolone as baseline immunosuppression and/or methylprednisolone as augmented immunosuppression can trigger CMV reactivation in intermediate-risk patients (D+/R+) to the levels comparable with high-risk patients (D+/R-)\[87]\.

One-year cumulative doses of 1830 mg or more of GCs has been associated with TB infection in patients with systemic lupus erythematosus (OR= 2.74, 95% CI 1.26-5.98; \( P = 0.011 \))\[88]\] that may be true for SOT patients as well.

Severe Sterngyloides stercolaris infection is associated with high morbidity and mortality among kidney transplant patients and is usually accompanied with gastrointestinal and respiratory symptoms. A multicenter cohort study consisting 46 kidney transplant patients with severe Sterngyloides stercolaris infection and 92 matched control patients found that cumulative GC dose was an independent risk factor for severe Sterngyloides stercolaris infection [median (IQR) of doses of 73.32 (40.93-157.46) mg/kg in the case group versus 65.23 (32.05-155.28) mg/kg in controls] (OR= 1.005, 95% CI: 1.001-1.009; \( P = \))
As seen, the calculated OR is approximately 1, which may not be of clinical importance despite statistical significance.

Although rare, visceral leshmaniasis may occur after solid organ transplantation relating to general prevalence of this parasite in that geographic area. High dose prednisolone within preceding 6 months has been associated with this infection in SOT patients[90].

1.2. Bone disorders

GCs antagonize the effects of vitamin D, decrease intestinal absorption of calcium, inhibit secretion of growth hormone, inhibit bone formation (by inhibiting osteoblasts differentiation and increasing their apoptosis), increase bone resorption (by enhancing osteoclasts formation), and finally lead to osteoporosis and increased risk of fractures especially in trabecular bones[6]. Chronic kidney disease-mineral bone disorder (CKD-MBD) after kidney transplantation is a mix of pre-existing disorders and new alterations. The final results are abnormal mineral metabolism (hypercalcemia and hypophosphatemia) and bone changes (high or more commonly low bone turnover disease) with consequences of decreased bone mineral density and increased risk of bone fractures[91]. Although not completely clarified, several factors play roles in post-transplant bone disorders such as immunosuppressive treatment especially corticosteroids, persistently high levels of PTH, vitamin D deficiency, and hypophosphatemia. Transplant recipients are at four-fold higher risk of fracture compared with general population. One of the most relevant risk factors is high doses or prolonged GC therapy[91, 92]. Kidney transplant recipients with early steroid withdrawal showed higher bone mineral density in lumbar spine and femoral neck and less osteopenia[93]. On the other hand, one study followed 36 renal transplant patients who continued low daily dose of 5mg prednisolone from day 42 after transplantation onward for 1 year. None of these patients received any treatment for bone disorders. In addition to bone mass densitometry, novel bone quality parameters including trabecular bone score and bone material strength index were evaluated for these patients. Findings indicated small decrease in bone mineral density in femoral neck at 3-months and in lumbar spine at 12-months after transplantation, while, no changes in trabecular bone score and bone material strength index were found, showing limited effects of low daily doses of GCs on bone[94]. Osteonecrosis of the hip is another side effects of corticosteroids in SOT patients[95]. Although some studies showed that cumulative dose of methylprednisolone/prednisolone after kidney transplantation has been a risk factor for avascular osteonecrosis[96, 97], a meta-analysis found little correlation between cumulative doses and duration of administration of methylprednisolone/prednisolone and avascular osteonecrosis of femoral head[98].

1.3. Growth in pediatric transplant recipients

By inducing abnormal growth hormone secretion and response, GCs impair stature growth in children and prepubertal adolescence[6]. In contrast, GR in hepatocytes is essential for postnatal body growth by mediating the growth hormone signaling in mice[99]. New animal data also suggests that GCs decrease longitudinal bone growth by
upregulation of fibroblast growth factor-23 (FGF23) and its receptor (FGF23R3) expression\textsuperscript{[100]}. GC-induced growth retardation in pediatric transplant patients encouraged SOT teams to apply steroid minimization protocols in prepubertal kidney transplant patients with better bone health, growth outcome and comparable allograft rejection rates\textsuperscript{[14, 101, 102]}.  

1.4. Metabolic complications and cardiovascular risks

Obesity and metabolic syndrome with three components of hyperglycemia, hyperlipidemia, and hypertension, are common long-term side effects of GCs; these adverse effects increase atherogenesis and the risk of cardiovascular events\textsuperscript{[6]}. Adipocyte GR deficiency promotes adipose tissue expandability and improves the metabolic profile during GC exposure\textsuperscript{[103]}. In contrast, GR in cardiomyocytes is essential in cardio protection; deletion of cardiomyocyte GR increases mortality due to the development of spontaneous cardiac pathology in both male and female mice\textsuperscript{[104]}. The mechanism of GC-induced hyperglycemia is insulin resistance followed by increased hepatic gluconeogenesis\textsuperscript{[1]}. Post-transplant diabetes mellitus (PTDM) is associated with higher risk of mortality and graft loss\textsuperscript{[105]}. PTDM incidence in SOT patients varies from 10\% to 74\% depending on the country and ethnicity of the patients and diagnostic criteria\textsuperscript{[105-107]}. There are several risk factors for PTDM such as viral infections, underlying kidney diseases, and different immunosuppressive drugs that can confound causality assessment between steroid dose and duration and PTDM in SOT patients\textsuperscript{[1]}. A Malaysian study of 168 patients without diabetes before transplantation showed the PTDM incidence of 17\% during one year after renal transplantation. In that study, daily prednisolone dose was not associated with the development of PTDM\textsuperscript{[107]}. Another 4-year follow-up study on 400 kidney transplant patients without history of diabetes before transplantation (96 patients on steroid-free and 304 patients on 5mg/day prednisolone in immunosuppressive regimen) indicated that taking 5mg daily prednisolone was associated with a small but not statistically significant increase in HbA1c and significantly higher risk of prediabetes (RR= 1.789; 95\% CI 1.007-3.040; P= 0.026) but not PTDM compared with steroid withdrawal regimen. Although other components of immunosuppressive regimen such as the type of CNI (tacrolimus versus cyclosporine A) can affect PTDM risk, in the multivariate analysis of Tillmann’s study, independent of the higher risk of tacrolimus compared with cyclosporine in inducing PTDM, higher risk of prediabetes with long-term low dose steroid was shown\textsuperscript{[108]}. On the other hand, a meta-analysis on more than 22 thousand kidney transplant patients showed that early steroid withdrawal during 1 week after transplantation is associated with less PTDM risk (RR=0.91; 95\% CI 0.37-0.97; P= 0.04)\textsuperscript{[10]}. Association between new onset hyperglycemia and GC-containing maintenance immunosuppression among liver transplant recipients is controversial\textsuperscript{[109, 110]}. While a Japanese retrospective analysis on 461 adult liver transplant recipients from living donors did not find any association between taking GC and PTDM\textsuperscript{[109]}, a randomized clinical trial on live donor liver transplant patients reported significantly higher incidences of PTDM among patients taking steroids versus steroid-free group during 3- and 6-months follow-ups\textsuperscript{[110]}. One confounding factor in data
interpretation is using different diagnostic criteria for PTDM in different studies. For example, in Toshima et al study, fasting plasma glucose of 110 mg/dL or higher has been used as a cut-off for PTDM definition[109], while based on standard criteria of American Diabetes Association, plasma glucose level of 126 mg/dL or higher is defined as diabetes[111].

Hyperlipidemia is another known metabolic side effect of GCs. Increased total cholesterol, very low-density lipoprotein (VLDL) cholesterol, and triglyceride levels and decreased HDL-cholesterol concentration have been reported with GCs, depending on the dose and duration of their administration[6]; however, a large US cohort study showed beneficial effect of GCs on increasing HDL cholesterol among population older than 65 years old[112]. Wide ranges of mechanisms have been supposed for GC effects on lipid profile including increased activity of acetyl-Coenzyme A carboxylase and free fatty acids synthetase and enhanced hepatic synthesis of VLDL, inhibition of lipoprotein lipase, alteration in insulin signal pathway, and possible inhibition of the activity of 3-hydroxy-3-methylglutaryl Coenzyme A (HMG-CoA) reductase[6]. The latter mechanism theoretically can have positive effects on lipid profile that may explain some controversies regarding GC-induced lipid changes in the literature. Regarding organ transplant patients, a study on liver transplant recipients showed that taking maintenance GCs was an independent factor associated with hyperlipidemia but not with the two other component of metabolic syndrome (hyperglycemia and hypertension) in this patient population[109]. In contrast, another study that compared steroid-free versus steroid-taking immunosuppressive regimens in living donor liver transplant recipient, found significant higher incidences of all components of metabolic syndrome including new onset hyperglycemia, new-onset hypertension, and hypertriglyceridemia among steroid-taking group[110].

Although the effect of steroid withdrawal on hypertension after transplantation is controversial, a study on pediatric liver transplant patients that followed the patients with ambulatory blood pressure monitoring showed improved blood pressure especially nocturnal hypertension and restoring circadian rhythm of blood pressure after GC discontinuation in these patients[113]. A Saudi study on adult kidney transplant patients showed that steroid-sparing patients had significantly lower weigh gain and a non-statistically significant better blood pressure and lipid control[114]. Different mechanisms have been reported for GC-induced arterial hypertension including salt and water retention by activating renal mineralocorticoid receptor (MR) and regulating vascular activity by activating GR in endothelial and vascular smooth muscle cells. Interestingly, GR in vascular endothelial cells is required for dexamethasone-induced hypertension[115], while loss of endothelial GR increases hemodynamic instability, inflammation, and mortality in sepsis, and GR deficiency in endothelial cells prevents the therapeutic protection by dexamethasone after LPS treatment[116, 117]. Hypertension is more common among patients taking daily doses of more than 20mg prednisolone. Metabolic changes and hypertension increase atherogenesis and risk of cardiovascular events in long-term GC taking patients[6].
1.5. Neuropsychiatric side effects

Most immunosuppressive drugs especially CNIs, glucocorticoids and mTOR inhibitors can induce neurologic side effects. Sometimes the assessment of causality is hard and all drugs work together to manifest the side effect(s). Glucocorticoids easily pass the blood brain barrier and reach all brain cells and result in HPA axis suppression, neuropsychiatric and neurodegenerative side effects. Prolonged exposure to glucocorticoids in SOT patients and high GC doses and concentrations (e.g. during treatment of acute rejection) increase the risk of neuropsychiatric side effects because of structural remodeling in neurons, synaptic loss, and maladaptive alterations in glial function[118]. GCs cause different neurologic side effects such as headache, tremor, seizure, stroke, and pseudotumor cerebri. GC-induced psychiatric adverse effects vary from minor mood changes and confusion, sleep disorders, anxiety to severe psychotic features[6, 118].

1.6. Muscular side effects

GCs has catabolic effects on muscles, leading to muscular atrophy, cramping and progressive symmetrical muscle deficit. They can induce acute or chronic myopathy. Tendon rupture is a rare side effect of GCs[6]. High doses of GCs cause muscular atrophy via activating GR in the muscle[119].

1.7. Adrenal insufficiency

Suppression of the activity of HPA axis and the subsequent adrenal insufficiency are well-known side effects of GCs. Adrenal insufficiency may be potentially life-threatening because of the risk of acute adrenal crisis. A study on renal transplant patients treated with oral prednisolone at daily doses of 5 to 7.5 mg for 6 months or more found insufficient adrenal response to synacthen test in about 43% of the patients which shows high prevalence of adrenal insufficiency due to long-term low dose GCs in these patients[120].

In addition to decrease in endogenous GC production, exogenous GC such as prednisolone may also enhance the activity of 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1), the enzyme that is responsible for regeneration of cortisol from inactive metabolite, cortisone. A cohort study investigated this hypothesis in prednisolone-treated kidney transplant patients compared with healthy controls. The median daily dose of prednisolone in these patients was 10mg (IQR of 7.5-10mg). 24-hour urinary cortisol, cortisone, tetrahydrocortisol (THF), allotetrahydrocortisol (alloTHF), and tetrahydrocortisone (THE) were measured. Twenty-four-hour urinary excretion of cortisol and its metabolites were used as measures of endogenous glucocorticoid production, while (THF + alloTHF)/THE and cortisol/cortisone ratios were used as reflectors of 11β-HSD1 activity. Findings revealed that urinary cortisol and metabolite excretion were significantly lower (indicating reduced endogenous cortisol synthesis), while (THF + alloTHF)/THE and cortisol/cortisone ratios were significantly higher (indicating increased 11β-HSD1 activity) in kidney transplant recipients compared with
healthy controls. Daily doses of prednisolone had significant inverse association with reduced endogenous cortisol synthesis and significant, positive association with markers of 11β-HSD1 activity. Such changes in endogenous GC production and regeneration were associated with increased risk of mortality in kidney transplant patients even after adjustment for confounders such as patients’ age, gender, estimated glomerular filtration rate, C-reactive protein, body surface area, and daily doses of prednisolone[121]. Some researchers found significant associations between HPA suppression and higher prevalence of metabolic syndrome and its individual components (central obesity, dyslipidemia, hypertension, and hyperglycemia) in kidney transplant patients taking prednisolone[122].

1.8. Gastrointestinal side effects

Gastrointestinal side effects of GCs include peptic ulcers, upper gastrointestinal bleeding, pancreatitis, diverticular perforation, and colonic malakoplakia (a chronic granulomatous disease)[123]. Immunosuppressive therapy after solid organ transplantation may change gut microbiota and be associated with increased rates of overall and infection-related mortality, rates of all infections including nosocomial infections, duration of infections, infections complications, rejection rates and graft loss. Some studies tried to differentiate the effect of different types of immunosuppressive drugs that are used in combination in SOT patients. Regarding corticosteroids, a study on liver transplanted mice showed that prednisolone administration reduces the concentration of Bacteroidetes while increases the concentration of Firmicutes in the feces. In that study, prednisolone in combination with mycophenolate and tacrolimus increased E. Coli colonization. Serial testing of fecal samples of kidney transplant recipients revealed that compared to those remaining on maintenance corticosteroid, patients with early GC withdrawal had numerically, but not statistically significant, lower Clostridiales and Erysipelotrichales[124].

1.9. Dermatologic effects

Cushingoid appearance; facial erythrosis; skin thinning; rosacea and acne that may rarely progress to nodulocystic transformation; impaired wound healing; purpura after minor trauma; hirsutism; and striae rubrae are dermatologic side effects of GCs that are usually dose- and treatment duration dependent[6].

1.10. Other complications

GCs increase the risk of thrombosis due to endothelial damage and inducing hypercoaguable state and stasis[6]. Posterior subcapsular cataract and glaucoma are dose-related ophthalmologic side effects of GCs[6]. Hernia occurrence is common after liver transplantation and attributed to several factors, one of them is taking steroid[125].

A retrospective analysis on surgery complications of 382 patients with metabolic and bariatric surgery and prior history of SOT showed that while taking GCs are associated with 2 folds increase in overall morbidity, it was not contributed to morbidities related to bariatric surgery[126].
Pretransplant administration of GCs in patients with idiopathic pulmonary fibrosis may decrease graft survival after lung transplantation compared with GC-free patients\[127\]. Although concerns have been arisen regarding airway anastomotic complications after lung transplantation in patients who were treated with GCs before transplantation, a retrospective study on 66 double lung transplant recipients (40 were steroid user before transplantation) showed that early development of airway complications was not significantly higher in patients who took steroids before lung transplantation. In addition, in preoperative steroid users the dose of steroid was not associated with the rate of posttransplant airway complications\[128\].

2. Drug-drug interactions

GCs are primarily metabolized by CYP450 3A4 isoenzyme and are also substrates for energy-dependent efflux pump, P-glycoprotein\[123, 129\]. GC metabolism may or may not be affected by CYP450 3A4 inhibitors such as macrolide antibiotics, azole antifungal medications, and protease inhibitors. Studies have shown decreased clearance of methylprednisolone but not prednisolone with co-administration of CYP3A4 inhibitors\[130, 131\]. CYP450 3A4 inducers (rifampin, carbamazepine, phenobarbital, phenytoin) can decrease GC’s serum levels\[129\]. GCs can induce CYP450 3A4/5 isoenzymes\[129\] and therefore, increase the metabolism of CNIs (cyclosporine and tacrolimus) as the substrates of CYP3A4/5\[132\]. Clinical studies showed significant increase in dose-adjusted tacrolimus blood levels in patients on GC withdrawal regimens compared with patients taking GC-containing maintenance immunosuppression \[132\]. Interactions between GCs and tacrolimus are more seen in patients carrying CYP3A5*1 allele\[133\]. GCs significantly contributes to inter-individual variability of apparent clearance of oral tacrolimus\[134\]. On the other hand, some studies reported that cyclosporine decreases prednisolone clearance by 25-30% in kidney transplant patients\[135\], while others found no difference in dose-adjusted exposure of prednisolone when co-administered with cyclosporine or tacrolimus\[136\].

Possible need for therapeutic drug monitoring

Prednisolone is a standard component of most immunosuppressive protocols after solid organ transplantation. Therapeutic drug level monitoring is not usually done for GCs. A study evaluated the pharmacokinetic characteristics of prednisolone, prednisone, and also cortisol and cortisone profiles, after treatment with prednisolone in adult kidney transplant recipients in the early 8-week post-transplant period. Blood samples were obtained predose and during a 24-hour dose interval. Findings showed that renal transplant recipients experienced a relatively high prednisolone exposure, in parallel with strong suppression of endogenous cortisol profile as confirmed by a low evening-to-morning ratio of cortisol. A significant negative correlation (r = -0.83) between prednisolone AUC0-24 and morning cortisol concentrations was seen. AUC0-24 of prednisolone and cortisol varied 3-fold and 18-fold, respectively among patients. These results reveal large inter-individual variability in both prednisolone exposure and
suppression of endogenous cortisol that signify a possible need for therapeutic drug monitoring of GCs\[137\].

**Summary and perspective**

GCs have been the mainstay for SOT for decades due to GC’s potent anti-inflammatory and immunosuppressive effects on the innate immunity and the significant tissue protective effects of GR on liver, kidney, and heart. In contrast, many of the side effects of GCs are on the non-target organs/tissues, such as bone, neuromuscular, adipose tissue, GI tract, and skin. Thus, specific delivery of GCs, via nanoparticles or transporter-mediated prodrugs, to the target organs of liver, kidney, and/or heart will enhance the efficacy and decrease the side effects of GCs in SOT. GCs’ side effects are generally associated with long-term use of high doses of GCs. It is noteworthy that most GCs activate both GR and MR. Recent studies indicate that some of the side effects of GCs on the heart, kidney, and adipose tissues may be due to the activation of MR by GCs\[138-141\]. Therefore, GCs with higher selectivity for GR over MR, such as dexamethasone and budesonide, may have less side effects in SOT patients\[23, 142\]. Additionally, GCs’ metabolic actions can be modulated by AMP-activated protein kinase (AMPK), a master regulator of energy metabolism. Activation of AMPK increased the phosphorylation of GR at Serine-211 and reversed GC-induced hepatic steatosis and suppressed GC-mediated stimulation of glucose production in rats\[143\]. Interestingly, impaired AMPK activity was associated with steatotic graft injury in patients with living donor liver transplantation\[144\]. Thus, whether AMPK activators can ameliorate the metabolic side effects of GCs in SOT warrants investigation. In conclusion, approaches that enhance GC’s GR selectivity, increase target-tissue-specific delivery of GCs, and ameliorate the metabolic side effects of GCs will increase the efficacy and decrease the side effects of GCs in SOT.
