Abstract: Osteoarthritis and rheumatoid arthritis are two of the most common chronic inflammatory joint diseases, for which there remains a great clinical need to develop safer and more efficacious pharmacological treatments. The pathology of both osteoarthritis and rheumatoid arthritis involves multiple tissues within the joint, including the synovial joint lining and the bone, as well as the articular cartilage in osteoarthritis. In this review, we discuss the potential for the development of oligonucleotide therapies for these disorders by examining the evidence that oligonucleotides can modulate the key cellular pathways that drive the pathology of the inflammatory diseased joint pathology as well as evidence in preclinical in vivo models that oligonucleotides can modify disease progression.

Keywords: Osteoarthritis; rheumatoid arthritis, synovitis, cartilage, bone, antisense, oligonucleotides, therapeutics.

1. Introduction

1.1 Rheumatoid arthritis

Rheumatoid arthritis (RA) is one of the most common chronic inflammatory conditions, with an estimated prevalence of up to 2% in some ethnic groups [1]. Largely a result of inflammation to the synovial lining (synovitis) of the joint, RA causes joint pain, stiffness and swelling, increased fatigue and results in increased disability and reduced quality of life. Furthermore, around a third of patients are unable to work within 2 years of diagnosis, thus causing a substantial socioeconomic burden [2-4]. There are currently several approved pharmacological drugs for the therapeutic management of RA patients [5]. Corticosteroids and non-steroidal anti-inflammatory drugs such as diclofenac can be administered locally to the painful joint by topical application to reduce joint pain and swelling [6]. However, these drugs do not modify the disease process and are also associated with adverse side effects over the long term when taken chronically. For example glucocorticoids when taken chronically can lead to increased bone resorption [7] and skeletal muscle atrophy [8]. Importantly, the aim of current RA therapies is therefore to target the underlying disease pathology, a “treat-to-target” strategy to influence the disease course, not simply to reduce symptoms [9]. To this end, a number of disease-modifying anti-rheumatic drugs (DMARDs) have been approved for clinical use, such as Methotrexate, Hydroxychloroquine, Sulfasalazine and Leflunomide, which are immunomodulatory drugs [10]. For example, Methotrexate inhibits leukotriene B4 synthesis by neutrophils, and supresses the production of the pro-inflammatory cytokines IL-1, IL-6 and IL-8 [11, 12]. Leflunomide inhibits pyrimidine synthesis, thus reducing lymphocyte proliferation [13], whilst Hydroxychloroquine reduces immune responses [14] by
inhibiting the toll-like receptor signalling [15]. The precise mechanism of action of Sulfasalazine is not fully understood [16], but it is known to inhibit NF-kB activity and thus the production of inflammatory cytokines including tumour necrosis factor alpha (TNF-α) [17]. In recent years improved understanding of the molecular pathology underlying RA disease has led to a revolution in RA treatment [18], with the emergence of a number of biological drugs designed to target specific disease-associated inflammatory cytokines (most notably TNF-α), and drugs targeting the activity of specific immune cell populations. Monoclonal antibodies targeting TNF-α, including Adalimumab (Humira), etanercept and Infliximab have all demonstrated efficacy in reducing disease activity scores (DAS) in patients and in maintaining the disease in remission [19-21], as determined by the number of swollen and painful joints and biomarkers of inflammation. Thus, reducing the risk of irreversible damage to joints. Similar disease-modification has been achieved by biologics targeting other inflammatory immune processes. For example, Tocilizumab, a monoclonal antibody targeting the pro-inflammatory IL6 [22], Rituximab, a monoclonal antibody targeting CD20 on B cells [23], and Abatacept, a fusion protein composed of the Fc region of the immunoglobulin IgG1 fused to the extracellular domain of CTLA-4, which inhibits antigen presenting cells from providing the co-stimulatory signal required for T cell activation [24]. However, despite these successes, all these immunomodulatory medications are associated with adverse side effects and an increase in the risk of developing serious infections, such as pneumonia, due to their action in modulating the immune system [25, 26]. Furthermore, with chronic treatment, efficacy can be greatly diminished due to the patient developing anti-drug neutralising antibodies [27]. Therefore, there is still a great unmet medical need to develop more effective and safer RA therapeutics.

1.2 Osteoarthritis

Osteoarthritis (OA) is the most common degenerative joint disorder in the world, affecting 303 million people globally [28] Historically, OA was seen as a disease solely of the articular cartilage. However, it is now widely accepted that OA is a disease of the whole joint, including not only the loss of articular cartilage mass, but also subchondral bone sclerosis and inflammation to the synovium [29, 30].

Similarly, to RA, OA results in joint pain and increased stiffness, which leads to progressive disability and a reduced quality of life, amounting to a huge socioeconomic burden. Unfortunately, since age is a significant risk factor for OA, the prevalence of OA is set to increase in developed countries with our increasingly ageing society [31].

Unfortunately, current treatment options for patients are limited. Despite a number of clinical trials, including with biologics targeting pro-inflammatory cytokines such as Adalimumab and Tocilzumab [32], there are no pharmacological drugs that have been proven to modify the disease course of OA (DMOADs) [33]. Therefore, patients are advised to take non-steroidal anti-inflammatory drugs such as Ibuprofen, which have limited efficacy and are associated with toxicity over the long term. Patients with knee OA can receive intra-articular corticosteroid injections into the diseased joint to alleviate pain and inflammation [27]. However, the benefit for patients is highly unpredictable, with ~30% of knee OA patients reporting little to no improvement in symptomatic pain [34]. Furthermore, repeated steroid injections into the joint can exacerbate cartilage damage. As a result, OA patients live with painful symptoms for several years before undergoing a joint replacement surgery, a procedure with a high percentage of patient dissatisfaction. A particular challenge in developing a DMOAD has been the effective delivery of drugs into the cartilage, which as an avascular tissue, is not highly amenable for conventional drug delivery. In order to target the chondrocyte cells that mediate
cartilage OA pathology, such drugs need to be able to penetrate the full depth of the cartilage tissue [35]. Furthermore, the focus for many years on identifying candidate targets that directly mediate cartilage degradation such as the matrix metalloproteases (MMPs), neglected the important role of the other tissues in the joint in driving OA disease progression such as the synovium and subchondral bone. To this end, the development of oligonucleotides, that modulate expression of targets at an upstream level, where functional protein products are not made, may offer the potential to target pathological processes across multiple cell types including chondrocytes in the cartilage, osteoblasts in the bone and fibroblasts in the synovium.

In this review, we discuss the potential for the development of oligonucleotide therapies in both RA and OA joint disease by examining the evidence for oligonucleotide therapies to modulate disease pathology and disease-associated cellular pathways within the multiple tissues of the joint (Figure 1; Table 1).

Figure 1. Features of OA and RA pathology and in-vivo oligonucleotide targets. RA is an autoimmune condition driven by inflammation of the synovial lining which degrades cartilage and activates osteoclast bone reabsorption. Whilst OA is a degenerative joint disorder involving the loss of articular cartilage mass, subchondral bone sclerosis and synovial inflammation. Inflammatory synovial fibroblasts produce pro-inflammatory cytokines which stimulate RANKL production in osteoblasts thus promoting osteoclastogenesis and bone resorption. Damaged cartilage exacerbates synovial inflammation driving further cartilage loss. ADAMTS 4, 5; a disintegrin and metalloproteinase with thrombospondin motifs 4, 5, AS-LNA; antisense locked nucleic acid, BMP; bone morphogenic proteins, Col II; collagen type 2, CTX-1; cytotoxin-1, DKK1; Dickkopf-related protein 1, FOXC1; forkhead box C1, FUT4; fucosyltransferase 4, IL-6, 8; interleukin-6, 8, miR-26a, 26b, 145, 449a; microRNA-26a, 26b, 145, 449a, MMK4; mitogen activated protein kinase, MMP-1, 3, 13; matrix metalloproteinase-1, 3, 13, OA; osteoarthritis, OPG; osteoprotegerin, PS-ASO; phosphorothioate antisense oligonucleotide, RA; rheumatoid arthritis, RANKL; receptor activator of nuclear factor kappa-B ligand, siRNA; small interfering RNA, TNF; tumor necrosis factor, Wnt2; Wnt family member 2, YAP; yes-associated protein.

2. Oligonucleotides Targeting Synovial Inflammation

Inflammation of the synovial membrane (synovitis) is a key hallmark of both RA and OA joint disease. Fibroblast-like synoviocytes (FLS), also termed synovial fibroblasts, become activated and hyperplastic in RA [36, 37]. Through the infiltration and subsequent interaction of immune cells in the synovium (including leukocytes and resident macrophages), synovial fibroblasts contribute to a sustained chronic inflammatory state within the joint by releasing pro-inflammatory cytokines into the synovial joint fluid,
such as TNFα and IL-6 [37, 38], which also promotes bone resorption. Synovitis and the associated bone erosion is detected magnetic resonance imagining (MRI) of the RA joint [39]. Similar to RA, synovitis is now widely recognised to play a significant role in OA joint pathology, with synovitis evidence by ultrasound, MRI and histopathology prior to radiographic signs of cartilage damage, with increased infiltration of activated B- and T-cells and synovial proliferation and hypertrophy [32, 40-43]. Synovial fibroblasts from OA patients are more inflammatory compared to non-diseased patients and secrete greater levels of pro-inflammatory cytokine IL-6 and IL-8 [44].

In attempting to develop oligonucleotide therapies to target synovitis, modulation of the activated proliferative inflammatory synovial fibroblast phenotype using antisense oligonucleotides has been documented. For example, Nakazawa et al reported that antisense oligonucleotides targeting Notch-1 protein inhibited both basal and TNFα-induced proliferation of human synovial fibroblasts isolated from either RA or OA patient synovium [45], whilst antisense knockdown of the gene PTPN11, which encodes SHP-2 (a known proto-oncogene), has been reported to inhibit migration and survival of RA synovial fibroblasts [46]. More recently, susceptibility of human OA and RA synovial fibroblasts to fas-mediated apoptosis was increased by antisense oligonucleotides targeting the anti-apoptotic gene FLICE-inhibitory protein (FLIP) [47], and increased apoptosis of human RA synovial fibroblasts was induced upon antisense oligonucleotide targeting of galectin-9 [48]. Furthermore, oligonucleotides have been demonstrated to reduce the inflammatory phenotype of activated OA and RA synovial fibroblasts. For example, the inflammatory fibroblast phenotype mediated by leptin, an adipokine found elevated in the synovial fluid of both OA and RA patients [33, 49], was inhibited by antisense oligonucleotides targeting the leptin receptor (ObR), which reduced leptin-mediated IL-8 secretion [50] and IL-6 expression in OA fibroblasts [51]. Recently, a locked nucleic acid (LNA) oligonucleotide targeting the long non-coding RNA (lncRNA) MALAT1 was found to inhibit both the proliferative and inflammatory phenotype of obese OA synovial fibroblasts [44]. LncRNAs are a relatively novel class of non-coding RNAs, which have been shown to regulate gene expression at both the epigenetic pre-transcriptional and post-transcriptional level through their ability to act as scaffolds for the binding of proteins and other RNAs. Increasing evidence has emerged that lncRNAs, such as MALAT1[52], are central regulators of the inflammatory response [53-57], including the inflammatory response of articular OA chondrocytes [58] and synovial fibroblasts [44]. Therefore, oligonucleotide targeting of lncRNAs that are dysregulated in the tissues of the arthritic joint could provide novel therapeutic strategies to target the epigenetic drivers of joint inflammation [56].

As yet, few studies have reported the effect of oligonucleotides designed to target the synovium in preclinical in vivo models of either RA or OA disease. However, in a surgically induced experimental model of OA, a 21-mer end-capped phosphorothioate antisense directed against Dickkopf-1 (DKK1), the canonical Wnt pathway inhibitor, was intraperitoneally administered at a dose of 20 μg/kg/week for up to 12 weeks in rats and was found to ameliorate synovial vascularity [59]. Similarly, intra-articular injection of FoxC1 siRNA, which is a promoter of TNF-α and IL-8 production in synovial fibroblasts, was found to reduce OA development in a murine model of OA [60].

3. Oligonucleotides Targeting Subchondral Bone Pathology

In bone homeostasis, receptor activator of nuclear factor kappa B (RANK)/RANKL pathway activates NF-kB induced transcription factors that provides the balance between bone resorption and bone formation. However, this homeostasis is lost in the pro-inflammatory microenvironment within the RA joint, where there is the promotion of bone erosion via the pro-inflammatory cytokine induction of RANKL, which binds to the RANK receptor on osteoclasts and activates their bone resorbing activity.
Conversely, in OA the subchondral becomes sclerotic, with pronounced trabecular thickening, areas of subchondral bone that are under-mineralised and the formation of bony spurs (osteophytes), which are notable in x-ray radiographs of the joint [33, 61-64]. An often overlooked pathological feature in OA, there is now evidence that subchondral bone changes in OA precede and drive cartilage damage [65, 66], with OA bone and OA osteoblasts exhibiting an abnormal type I collagen alpha1 homotrimer phenotype [29] with impaired mineralisation [67]. In human primary osteoblasts, ObR antisense oligonucleotides abolished the leptin-mediated production of oncostatin M [68], which, as a member of the IL6 family, has been associated with bone remodelling and cartilage volume loss in OA and RA [69] as well as ObR itself being associated with biomarkers of cartilage loss and bone remodelling over 2 years in knee OA patients [70]. In vitro, antisense oligonucleotides have also been shown to effectively impact on osteogenic differentiation. In mesenchymal stem cells isolated from patients with knee OA, oligonucleotide antisense against miR29a impaired Wnt-mediated osteogenic differentiation via reducing Wnt3 expression [71].

In vivo, in either a surgically induced OA model anterior cruciate ligament (ACL) transection or a collagenase-induced OA model, end-capped DKK1 antisense oligonucleotides delivered intraperitoneally (10-50 μg/kg/week for up to 8 weeks) lowered disease severity, with a reduction in bone mineral density loss, reduced serum levels of bone resorption markers osteocalcin and CTX-1 and suppressed expression of TNF-α, IL-1β, MMP3 and RANKL [72]. Such findings are consistent with the known role of DKK1 in bone homeostasis as an endogenous inhibitor of the Wnt/beta-catenin signalling pathway. DKK1 is implicated in bone development and in the pathological remodelling of bone in both OA and osteoporosis and mediating inflammation-induced bone loss by inhibiting osteoblast differentiation [73, 74]. In osteoporosis patients, serum levels of DKK1 are negatively associated with bone mineral density in the femoral head and lumbar spine [75]. More recently, intra-articular injection of an siRNA oligonucleotide targeting YAP, which promotes osteogenesis and bone remodelling, reduced the aberrant subchondral bone formation in the ACL mouse model of OA [76]. Amelioration of sclerotic subchondral bone formation, as well as an overall reduction in OA severity score, has also been achieved in the mouse DMM model by intra-articular delivery of a 2′OME 5′Chol-modified antisense oligonucleotide (2 nmol) targeting the thyroid hormone receptor (THR) [77].

4. Oligonucleotides Targeting Cartilage Degeneration

Cartilage degradation in OA is a key hallmark of OA incidence and of disease progression [33]. This is driven largely by a pathological switch in the phenotype of chondrocytes. In healthy adult cartilage the chondrocytes are embedded in the extracellular matrix and are in a relatively metabolically inactive state, where they produce type II collagen and aggrecan proteoglycans that hydrate the cartilage and provide the cartilage with its load-absorbing properties. However, in OA the chondrocytes proliferate and become hypertrophic, switching from producing extracellular matrix proteins to producing catabolic MMPs and aggrecanases ADAMTS4 and ADAMTS5, which degrade type II collagen and aggrecan proteoglycan respectively. Induction of MMPs and aggrecanases is promoted by the inflammatory microenvironment of the joint [78], with pro-inflammatory cytokines secreted from synovial fibroblasts and damage-associated molecular patterns (DAMPs) such as fibronectin fragments from degraded cartilage potentiating a vicious cycle of inflammation and cartilage damage via activation of TLRs, the MAPK pathway and the NF-κB pathway [33]. A key component in this is the cellular cross-talk between synovial fibroblasts and chondrocytes, with IL-6 released from cartilage chondrocytes capable of binding to the soluble IL-6 receptor (sIL-6R) in the synovial fluid and this IL-6/sIL-6R complex transactivating the membrane bound gp130 on fibroblasts to promote further IL-6 secretion [30]. This chondrocyte-fibroblast crosstalk is
further exacerbated in obese patients with OA, where the adipokine leptin stimulates greater IL-6 secretion from articular chondrocytes [30].

In vitro, antisense oligonucleotides have been shown to modulate the inflammatory and catabolic phenotype of human OA chondrocytes. Targeted knockdown of the G-Protein Coupled Receptor (GPCR) RDC1 in human knee OA chondrocytes using antisense oligonucleotides modified the OA chondrocyte phenotype, with reduced expression of a panel of MMPs and hypertrophic markers [79]. Similarly, antisense oligonucleotides targeting either p38 MAPK or the downstream MAPKAPK2 (MK2), which regulates TNF stability via TPP regulation, inhibited IL-1β induced production of MMP3, MMP13 and PGE2 [32, 78]. Modulation of MMP13 expression in human chondrocytes was also reported using c-Fos and c-Jun antisense oligonucleotide, which acted to inhibit the potentiating action of SDF-1alpha on MMP-13 promoter activity [80]. In vivo, intra-articular injection of siRNA antisense targeting MMP13 and ADAMTS5 either alone or in combination improved histological scores of OA severity in a murine DMM model, compared to non-targeting control siRNA [81].

In recent years, the profiling of non-coding miRNAs has identified a number of miRNAs that are dysregulated in OA diseased cartilage [82], and/or associated with disease progression [83, 84], and several studies have now demonstrated modulation of the OA chondrocyte phenotype by antisense oligonucleotide targeting of these miRNAs. In vitro, antisense oligonucleotides against miR-320a reduced the IL-1β mediated release of MMP13 in human chondrocytes [85], whilst conversely miRNA oligonucleotide mimics of miR-98 and mir-146 reduced TNF-α and MMP13 production in human OA chondrocytes [82]. In vivo, miR-128 targeting antisense oligonucleotides administered by intra-articular injection were reported to slow articular cartilage degradation, reduce synovitis and slow subchondral bone changes in the ACL experimental model of OA at 8 weeks [86]. In the destabilisation of the medial meniscus (DMM) experimental model of OA, miR-181a-5p LNA antisense oligonucleotides delivered by intra-articular injection (3 μL of 1 μg/μL per knee joint) attenuated cartilage destruction [87]. Similarly, intra-articular injection of antagomir-21-5p significantly attenuated the severity of OA in the DMM model, via modulating expression of FGF18 [88]. Furthermore, intra-articular injection of antisense oligonucleotides targeting miR-34a-5p was chondroprotective in a murine DMM model and in a high-fat diet/DMM model [89], whilst LNA antisense inhibition of miR-449a via intra-articular injection (100 nM injections twice weekly for 8 weeks) promoted cartilage regeneration, expression of type II collagen and aggrecan in a rat acute cartilage defect model after 4 and 8 weeks post-surgery and in a rat DMM model [90].

In addition to miRNA inhibition, miRNA oligonucleotide mimics have also been demonstrated to have potential as arthritis therapeutics in vivo. A miRNA mimic of miR-26a /26b was found to promote chondrocyte proliferation in vitro by targeting of fucosyltransferase 4 (FUT4) and to attenuate development of OA in a rat ACL model of OA when delivered by single intra-articular injection at a dose of 5 nmol, 1 week after surgical induction of OA [91]. Similarly, intra-articular injection of a miR-145 mimic (at a dose of 50 μM twice a week for 7 weeks) reduced cartilage degradation in a rat DMM model via suppression of MKK4 mediated induction of TNF-α [92]. There is therefore increasing evidence that oligonucleotide therapeutics, when delivered by intra-articular injection, are capable of modulating the diseased inflammatory phenotype of arthritis cartilage.

5. Optimisation of Oligonucleotide Delivery into The Joint Tissues

One of the central challenges in the development of drugs to treat inflammatory joint diseases such as osteoarthritis and rheumatoid arthritis is the effective delivery of the therapeutic to the diseased tissues of the joint. In particular, the articular cartilage
represents a formidable challenge since it is avascular, and thus unmodified drug delivery into the chondrocytes occurs slowly and inefficiently. Oligonucleotide therapeutics, at approximately 20 bases, are larger than most small molecule drugs and are also anionic, this making diffusion across a negatively-charged cell membrane challenging.

However, the ability to deliver therapeutics, including oligonucleotide therapeutics, directly into the joint space via intra-articular injection, thus maximising the ability of the oligonucleotides to target the diseased tissues, is an advantage. Indeed, the increasing number of studies demonstrating the efficacy of antisense oligonucleotides and miRNA mimics in reducing disease severity in experimental models of arthritis following intra-articular injection delivery is highly promising. Furthermore, delivery of the therapeutic locally to the joint limits the risk of unwanted side effects at distal sites. Intra-articular delivery is particularly appealing for OA disease. In contrast to RA, OA usually affects only 1 or 2 large joints, commonly the knee or hip joints, with systemic inflammation largely absent.

5.1. Viral delivery systems in inflammatory joint disease

In attempting to optimise both the stability and the delivery of oligonucleotide therapeutics in the joint a number of strategies have been employed. For example, intra-articular injection provides a route for the local delivery of viral vectors (such as lentiviruses, adenoviruses, adeno-associated viruses) capable of carrying oligonucleotide cargo without the risk of systemic side effects [93]. In a murine experimental model of arthritis, lentiviral delivery of an antisense oligonucleotide targeting ATG12, an autophagy regulator, into the cartilage tissue by intra-articular administration was reported by Lian et al. [86]. Similarly, adenovirus delivery of miR-101 antisense oligonucleotides were shown to prevent cartilage degeneration in a chemically induced rat model of OA [94]. However, clinically there is still concern about whether viral-mediated delivery of therapeutics will lead to toxicity. Furthermore, viral mediated delivery is costly. Therefore, non-viral delivery systems may represent a more rewarding therapeutic approach for the delivery of oligonucleotides.

5.2. Biomaterial delivery systems in inflammatory joint disease

One alternative to viral delivery systems is the use of biomaterials, such as hydrogels. Hydrogels have been successfully used to sustain oligonucleotides within the microenvironment of the joint and to facilitate slow release. For example, a hyaluronic acid hydrogel was previously utilised to facilitate a controlled release of a LNA Gapmer oligonucleotide targeting PTGS2 (COX2), the gene which promotes the expression of the inflammatory pain mediator PGE2. Notably, the hydrogel encapsulated COX2 LNA was shown to produce gene silencing in OA chondrocytes over a 14 day period [95]. Using a similar hydrogel approach, efficient knockdown of the aggrecanase ADAMTS5 was achieved up to 14 days in OA chondrocytes [96]. These data provide evidence that hyaluronic acid hydrogel delivery systems have the potential to provide the necessary bioavailability within the joint cavity to support uptake of oligonucleotide therapeutics into the joint tissues, including the avascular cartilage tissue.

5.3. Bioconjugation and cell penetrating peptide delivery

Cell-penetrating peptides (CPPs) such as TAT, penetratin and Antennapedia are short cationic peptide sequences that can translocate across cell membranes [97, 98]. Therefore, a number of studies have demonstrated the utility of CPPs to transport biological cargo into cells in vitro and into tissues in vivo, including oligonucleotide cargo. For example, siRNAs targeting p38 MAPK conjugated to TAT or penetratin CPPs cold deliver siRNA targeted knockdown in a mouse fibroblast cell line. However, in vivo these CPP conjugates provoked the innate immune response. Instead, bioconjugation of the siRNA to cholesterol was found to delivery p38 MAPK knockdown in lung tissues, following intra-tracheal delivery [99]. Bioconjugated cholesterol siRNAs have recently been shown to be efficacious in knocking out the expression of myostatin (a negative regulator of muscle mass) in mice following systemic delivery [100]. An alternative conjugation is the GalNAc (N-acetylgalactosamine) modification [101]. In particular this modification has been shown to facilitate uptake into the liver following systemic administration, in part likely due to high expression of the ASialoGlycoProtein Receptor (ASGPR) in hepatocytes, to which GalNAc has binding affinity for. As a result, GalNAc conjugated antisense oligonucleotides targeting liver disease are currently in development [102]. However, since the GalNAc modification has been shown to confer metabolic stability to oligonucleotide conjugates there are now additional GalNAc antisense oligonucleotide conjugates in development for other conditions, including cardiovascular disease, hepatitis C and type 2 diabetes [103]. As yet, there are no published reports on the anti-inflammatory efficacy of GalNAc modified oligonucleotides in vivo in the joint.

5.4. Nanoparticle delivery systems in inflammatory joint disease

An alternative approach is the use of nanoparticles. Such nanoparticulated drugs (nanodrugs) have recently gained recognition in drug delivery for a number of therapeutic areas [104-106]. Indeed, Geiger et al. showed that nanoparticles carrying IGF-1 successfully penetrated bovine cartilage within 2 days of application [107]. Notably, nanoparticles can exploit the synovial capillary networks within the synovial tissue and previous studies have demonstrated that even systemic delivery of nanodrugs can be detected in the synovial joint in experimental models of RA [108]. In OA, since synovial tissue has fewer blood capillaries, intra-articular delivery of nanoparticle decorated oligonucleotides is likely still to be required in order to achieve sufficient bioavailable delivery to the synovial joint tissues. Importantly, it has been shown that when cationic nanoparticles are administered by intra-articular injection they can efficiently penetrate cartilage tissue [109-112]. To this end, intra-articular injection of polyethylene glycol (PEG) chain-modified single-walled carbon nanotubes (SWCNTs) successfully delivered morpholino antisense oligonucleotides into chondrocytes of both healthy and OA cartilage in mice, with no major adverse effects [113]. Furthermore, it was recently reported that a miR-141/200c aptamer-decorated nanoparticles persisted for 5 weeks in chondrocytes and provided chondroprotection when delivered by intra-articular injection into a DMM murine experimental OA model via inhibition of IL-6/STAT3 pathway [114].

6. Conclusions

Oligonucleotide therapeutics represent an emerging but highly promising class of therapeutic to treat inflammatory joint disease. Data from preclinical experimental models of arthritis provide evidence that the intra-articular delivery of oligonucleotides can modify
OA disease pathology, by reducing synovitis, preventing sclerotic bone formation and protecting from cartilage damage. Importantly, since oligonucleotide therapeutics are based on gene sequences, they are expected to act specifically on the target gene, and thus may be considered less likely to have off-target effects and to elicit adverse side effects. Indeed, the same basic backbone chemistry of oligonucleotides and the safety profile of oligonucleotide therapeutics in the clinic provide confidence that late stage clinical trial failure with this class of drug may be less common than with small molecule or monoclonal antibody entities. Furthermore, they can be rapidly and cheaply synthesised thus greatly reducing drug development timelines. As with conventional drug delivery, approaches to optimise the stability and delivery efficacy of oligonucleotide therapies into the joint tissues remains a major area of current focus and barrier to effective disease modification. To this end, the use of nanocarriers and the GalNAC bioconjugation represent promising approaches but further clinical studies will provide important information on the safety profile of such carriers in the clinical setting for patients with inflammatory joint disease.
