Abstract: Spatially explicit, fine-grained datasets describing historical urban extents are rarely available prior to the era of operational remote sensing. However, such data are necessary to better understand long-term urbanization and land development processes and for the assessment of coupled nature-human systems, e.g., the dynamics of the wildland-urban interface. Herein, we propose a framework that jointly uses remote sensing derived human settlement data (i.e., the Global Human Settlement Layer, GHSL) and scanned, georeferenced historical maps to automatically generate historical urban extents for the early 20th century. By applying unsupervised color segmentation to the historical maps, spatially constrained to the urban extents derived from the GHSL, our approach generates historical settlement extents for seamless integration with the multi-temporal GHSL. We apply our method to study areas in countries across four continents, and evaluate our approach for two U.S. study sites against historical settlement extents derived from the Historical Settlement Data Compilation for the US, HISDAC-US, achieving Area-under-the-Curve values >0.9. Our results are largely in agreement with model-based urban areas from the HYDE database, and demonstrate that the integration of remote sensing derived observations and historical cartographic data sources opens up new, promising avenues for assessing urbanization, and long-term land cover change in countries where historical maps are available.

Keywords: urbanization; long-term settlement patterns; built-up land data; global human settlement layer; historical maps; topographic map processing; data integration.

1. Introduction

By 2050, 68% of the human population is projected to live in urban areas [1]. The increasing urbanization and related processes such as rural-urban migration, socio-economic changes, and land consumption are drivers of issues such as transportation congestion and increasing pollution, posing unprecedented challenges for urban planners and policy makers. In order to make our cities more sustainable, efficient, and resilient to increasingly occurring extreme weather events, natural hazards, as well as climate-change related phenomena, a thorough understanding of the long-term development trajectories of urban areas is indispensable. However, spatially explicit data on the size and structure of urban areas (and their changes over time) are typically derived from remote-sensing based earth observation data and thus, rarely available prior to the 1970s. This shortcoming severely limits our knowledge of historical urban-spatial development, and forces researchers to rely on an observational window of approximately 40 years for retrospective assessments [2-4] and to establish future projections of urban land [5]. Hence, researchers...
studying long-term historical (urban) land development either rely on model-based approaches (e.g., [6,7]), on alternative data sources such as property data [8-11], or on the use of historical maps [12-16] that are mostly constrained to relatively small areas, such as specific cities, regions, or countries, often involving manual digitization work. This research explores the use of historical maps more specifically, as many countries have some form of historical map series and are able to derive knowledge related to urban areas prior to the 1970s. Integrating such spatial knowledge with existing global remote sensing-based settlement layers facilitates building temporally extended depictions of historical urban development for any region in the world for which such map archives have been established. This kind of integration framework is presented herein.

Recent advances in automated georeferencing [17,18], cloud-based data storage technologies and map acquisition methods have catalyzed the availability of large historical topographic map collections to the public, often holding thousands of (georeferenced), digital raster datasets, such as in the US [19,20], the UK [21], Switzerland [22], or international collections [23-26]. Moreover, advances in the automated processing of historical maps have opened new avenues for the efficient acquisition [27] and mining of large volumes of historical maps, and for the detection, recognition, and conversion of historical map content into digital, machine-readable data formats [28-31].

Such recent efforts include the mining of (historical) map collections by their content or associated metadata [32-37], automated georeferencing [18,38-40] and alignment [41,42], text detection and recognition [43-45], or the extraction of thematic map content, often involving (deep) machine learning methods, focusing on specific geographic features such as forest [46], railways [33,47], road network intersections [48,49] and road types [50], archeological content [51] and mining features [52], cadastral parcels boundaries [53,54], wetlands and other hydrographic features [55,56], linear features in general [57], land cover / land use [58], urban street networks and city blocks [34], building footprints [13,59,60] and historical human settlement patterns [61-63]. Other approaches use deep learning based computer vision for generic segmentation of historical maps [64,65], generative machine learning approaches for map style transfer [66,67] or attempt to mimic historical overhead imagery based on historical maps [68].

Many of these approaches have been tested on maps dating back to the late 1800s or even earlier, but are commonly evaluated on relatively small spatial extents only. Thus, it remains unknown how such methods perform for large-scale information extraction from large volumes of historical maps, covering large spatial extents, stretching across different time periods, cartographic designs or map scales. As a consequence, researchers have begun to develop historical map processing frameworks for large-scale data mining and extraction of heterogeneous information in a robust, feasible, and efficient manner [33].

Herein, we propose such a framework, applied to the extraction of historical urban extents. Our approach generalizes the map content by computing low-level image descriptors within spatially aggregated grid cells. A similar grid-based approach has been proposed in [33] and allows for a straightforward integration with other gridded data sources. More specifically, we use urban extents from the Global Human Settlement Layer (GHSL) [69] to narrow down the regions in which urban areas in the historical maps likely occur.

The GHSL (v2018) is the first, high-resolution settlement layer (i.e., on a 30x30m grid) consistently enumerated at a global scale for the time period from 1975 to 2014 [70]. While the GHSL, which is derived from multispectral imagery acquired by the Landsat platforms, has opened up new opportunities to study urbanization and land development on a global scale over almost 40 years (e.g., [2,3,5]), it does not provide information on built-up areas over extended periods of time. The framework presented herein combines historical maps with remote-sensing derived settlement layers in order to extend the GHSL retrospectively and is, to our knowledge, the first study that analytically combines signals obtained from historical maps with remote sensing derived data for urban change analysis.
Our method makes use of a back-casting strategy that spatially constrains extraction results from historical maps to built-up areas derived from the GHSL in 1975. This strategy of constraining earlier urban extents to be within the more recent and presumably more reliable area depictions [70] is commonly used in multi-temporal urban monitoring [71-74]. However, such an approach only evaluates urban growth, not shrinkage. The extraction of historical urban areas is based on 100x100m tiles and makes use of an unsupervised RGB-color clustering approach. We applied our method to six cities in four continents and thus four map products, dated between 1890 and 1960. We used historical built-up property data from the Historical Settlement Data Compilation for the US (HISDAC-US) [8,76] as well as urban areas from the History Database of the Global Environment (HYDE) [6] to evaluate and cross-compare our results.

The extracted historical urban extents are largely in agreement with the evaluation data used, and demonstrate how multi-temporal urban extents from the GHSL can be back-casted efficiently and effectively through the integration with historical maps, an approach applicable to many countries.

2. Materials and Methods
2.1. Data and study areas
2.1.1. Global human settlement layer

We used the GHSL Landsat version 2018 (GHS_BUILT_LDSMT_GLOBE_R2018A) which is derived from Landsat imagery and maps built-up areas in a global grid of 30x30m, on a global grid referenced in a spherical Mercator projection (EPSG:3857), in 1975, 1990, 2000, and 2014 [69,70].

2.1.2. Historical maps

As the GHSL is a globally available product, we chose six study areas in four different countries, where digital historical maps were available. Two study areas are located in the United States (i.e., Boston and Atlanta metropolitan areas) and cover different map scales, time periods, and map designs i.e., 3-color print in Boston (approx. 1900, scale 1:62,500), and 5-color print in Atlanta (approx. 1960, scale 1:24,000). These historical maps were acquired from the United States Geological Survey (USGS) historical topographic map collection (HTMC), which is a digital archive of >190,000 scanned and georeferenced topographic maps created between 1884 and 2006 [19]. The HTMC is available via the Amazon Web Services (AWS) S3 cloud data storage infrastructure. The USGS-HTMC maps used herein consist of a composite of individual map sheets (see Section 2.2.1) (Fig. 1a-d).

We also chose two study areas in the United Kingdom, (i.e., Greater Birmingham and London, see Fig. 2e-g), for which the National Library of Scotland provides georeferenced, seamless composites of historical Ordnance Survey topographic maps [78,79]. These maps are typically 3-color maps and exhibit different map designs than the USGS HTMC maps. For example, they depict urban settlements as blocks (Fig. 1f), whereas USGS-HTMC maps use individual building outlines (Fig. 1d), or red-colored urban areas in maps created after 1950 (Fig. 1c). Like in the US, the Ordnance Survey maps were produced at different scales: the Birmingham maps (approx. 1900) are of scale 1:10,560 (“six-inch to the mile”), whereas the London map (1896) is at a scale of 1:63,360 (“one-inch to the mile”).
Figure 1. Input data for the study areas in the US and in the UK: (a) GHSL-based built up area in 2014 and 1975 in Atlanta metro area (US), and (b) in the Boston metro area (US); (c) 1:24,000 historical map composite for the Atlanta metro area from approximately 1960, and (d) historical map composite for the Boston metro area at scale 1:62,500 from approximately 1900; (e) GHSL-based built up area in 2014 in the greater Birmingham area (UK), (f) historical Ordnance Survey topographic map composite from approximately 1900 (approximate scale: 1:10,000), with an enlargement of a part of the Birmingham downtown area, and (g) historical Ordnance Survey topographic map composite from 1896 for the London area (UK; approximate scale: 1:63,000), overlaid on the GHSL 2014 built-up areas (grey).

Finally, we use a historical topographic map covering the region southeast of the city of Sao Paulo (Brazil), at scale 1:100,000 from 1906 (Fig. 2a,b), and a map covering the Lahore-Amritsar region (Pakistan/India) at scale 1:254,440 from 1943 (Fig. 2c,d). Table 1 summarizes the historical maps used in this study, and Fig. A1 shows the original maps for four out of the six study areas.
Empirical data on historical urban extents are generally sparse, as remotely sensed data are typically not available prior to the 1970s. However, novel data sources such as the industry-generated property database ZTRAX (Zillow Transaction and Assessment Dataset [82]), assembled from heterogeneous county-level assessor data, holds the year-built information for large parts of the US building stock and has recently been leveraged to generate the Historical Settlement Data Compilation for the US (HISDAC-US). HISDAC-US is a fine-grained, historical settlement database for the conterminous US, composed of gridded surfaces consistently enumerated in a grid of 250x250m, measuring e.g., the number of built-up properties per grid cell from 1810 to 2016 [9,76] (Fig. 3a,b).

2.1.4. HYDE database

While the HISDAC-US data are only available for the US, we also used gridded surfaces from the HYDE 3.2 database [6], containing a global model of the fraction of urban area per 5’ grid cell, over very long time periods from 10,000 BC to 2010 (Fig. 3c,d). Due to the model-based nature and the coarse spatial resolution, urban areas derived from HYDE are only of limited spatial compatibility when compared to the urban areas extracted at a resolution of 100x100m, however, they represent the only data source consistently available for all six study areas.
### 2.2. Methods

#### 2.2.1. Preprocessing

Based on metadata for the USGS-HTMC (available from [https://thor-f5.er.usgs.gov/ngtoc/metadata/misc/](https://thor-f5.er.usgs.gov/ngtoc/metadata/misc/)), the geographic footprints of each map sheet contained in the archive can be obtained, allowing for reconstructing the grid (the so-called graticule) in which the USGS-HTMC map sheets are organized. For each quadrangle (i.e., grid cell of the graticule), we identified the earliest available map sheet and its scale within the boundaries of the Boston and Atlanta metropolitan statistical areas in 2010 [83] and automatically downloaded these maps from the AWS S3 archive [77]. By doing so, we obtained 33 maps for the Boston metro area, and 180 maps for the Atlanta metro area. Based on the corner coordinates available for each map sheet, we removed the map collars and generated a seamless mosaic of the maps per study area (see Fig. 1c,d).

For the study areas in the UK, we obtained the historical maps from [78,79] and mosaicced them and, in case of the London study area, georeferenced them. Individual map sheets for the Sao Paulo and Lahore study areas were manually georeferenced. All maps and map composites were then spatially aggregated by computing the RGB averages, separately per channel, within blocks of 100x100m (RGB$_{100}$). This 100x100m grid represents the analytical unit for the subsequent analyses. Such a spatial aggregation allows for the fast processing of large amounts of maps and facilitates the integration with other gridded data. The GHSL built-up land surface as well as the HYDE urban area raster data were both clipped to the historical map extent of each study area, and resampled to create a 100x100m grid that is consistent with the aggregated map data (Fig. 4a). The effect of spatially aggregating RGB information found in the historical maps to create the RGB$_{100}$ layers can be seen in Fig. 4b and c.

#### 2.2.2. Urban area extraction

We applied a simple, unsupervised method to extract the urban areas from the spatially aggregated RGB$_{100}$ surfaces. We performed k-means clustering [84] on these surfaces, for a range of $k \in [2,10]$. For map composites (mosaics of individually scanned map sheets) such as in the Boston and Atlanta study areas (Fig. 1c and d), we conducted a separate clustering analysis for each map sheet (Fig. 4d), in order to account for potential differences in contrast or color tone (see Fig. 4b,c). Moreover, we used the Elbow method [85] to identify the optimum number of clusters per study area.

As a first extraction approach, we used a simple decision rule to determine which of the obtained color clusters represents the urban areas contained in the historical maps. To...
do so, we calculated the area proportion of each detected cluster within the built-up areas reported in the GHSL in 1975, aggregated to 100x100m grid cells. Assuming that the urban areas in the historical map (dated earlier than 1975) are contained within the 1975 built-up areas from the GHSL (BUA$_{1975}$), we identified the cluster of the highest area proportion within the BUA$_{1975}$ as the cluster likely to represent the urban areas in the historical maps. Moreover, we tested whether the average R, G and B values of the RGB$_{100}$ cells within that cluster were less than a given threshold value (e.g., <200). Since urban areas in historical maps are typically depicted in dark or saturated colors (black, grey, red), the use of such a simple brightness-based criterion helps to robustly identify the correct target cluster (i.e., the cluster identified as urban area).

The target cluster may still contain a considerable number of false positives, e.g., dark text elements or major roads (Fig.4e). These artefacts can easily be reduced by excluding grid cells of the target cluster located outside of the BUA$_{1975}$ extents (Fig. 4f), given that this approach only detects urban growth, not urban shrinkage which is consistent with the implemented GHSL modeling strategy [69].

Moreover, we implemented a morphological post-processing strategy, removing further segments of the target cluster that are below a specific area threshold $t \in (10, 50, 100$ pixels). This is based on the assumption that settlements require a minimum size to be mapped at all. Moreover, it is unlikely that the signals of small settlements depicted in the original historical map are still detected correctly after applying the spatial aggregation to RGB$_{100}$. Thus, small segments of the target cluster are likely to be false positives. As can be seen in Fig. 4g, this method removes artefacts and retains the densely built-up urban cores of the settlements depicted in the historical map. Lastly, the grid cells identified as urban in the aggregated map layer are merged with the multi-temporal labels from the GHSL to create a temporally extended set of historical built up land layers (Fig. 4h).

Figure 4. Illustrating the historical urban area extraction method using historical maps and the GHSL. (a) GHSL multi-temporal built-up areas (resampled to 100x100m), (b) original historical map sheets from approximately 1900, (c) generated 100x100m RGB aggregates (averages per channel), (d) color clustering results for k=4, (e) target clusters likely representing urban areas, identified by a rule-based decision mechanism taking into account the GHSL areal proportions per cluster and the cluster brightness, (f) target clusters within GHSL 1975 built-up areas only, (g) post-processed target cluster areas, and (h) extracted historical urban areas integrated with the GHSL multi-temporal built-up areas.

2.2.3. Spatial evaluation
As described previously, a spatially explicit evaluation of the extracted historical urban extents is difficult due to the lack of reference data. The historical built-up property records (BUPR) surfaces from the HISDAC-US provide an estimate of the historical building density distributions across space in urban, but also in rural areas, and are available at a half-decadal temporal resolution. As our urban area extraction approach is assumed to be responsive to densely built-up urban areas only, a direct (i.e., binary) comparison of urban grid cells extracted from the historical map with any built-up reference grid cell (i.e., containing at least one structure) is not suitable, as it would underestimate the accuracy of our approach. Thus, we decided to carry out Receiver-Operator-Characteristic (ROC) analysis [86], to test whether there is a building density threshold in the BUPR surfaces that successfully reproduces the urban/non-urban labels extracted from the historical maps. This threshold may possibly vary between maps and study areas.

We conducted such an analysis for the US study areas where HISDAC-US is available. As these historical map composites consist of individual maps produced in slightly different years (see Table 1) we created a BUPR composite that reflects the BUPR distribution in each map quadrangle in the production year of the underlying historical map. For example, if a map sheet was created in 1898, we used the BUPR estimates in 1900 for the grid cells within the area covered by the map sheet.

2.2.4. Temporal plausibility analysis

While the method described in Section 2.2.3 evaluates our results in the spatial domain, we also assessed how the hind-casted trajectories of urban area (i.e., the urban area reported in GHSL and the urban area extracted from the historical maps) agree with the trajectories extracted from the HYDE urban area dataset.

3. Results

3.1. ROC analysis against historical HISDAC-US building densities

The ROC analysis of extracted historical urban / non-urban labels and the historical building densities from the HISDAC-US BUPR dataset for the US study areas reveals notable effects of spatial constraining and post-processing the areas of the identified target clusters likely to represent urban areas (Fig. 5). When detecting urban areas without spatially constraining them to the GHSL BUA\textsubscript{1975}, Area-under-the-Curve (AUC) values are low (Fig. 5a,d), but increase to up to 0.88 when including the spatial constraints (Fig. 5b,e). The post-processing step (i.e., removing small segments of <50 pixels) further increases the AUC to values >0.9 in both study areas. Generally, the agreement between the extracted urban areas and the BUPR estimates is higher in Boston than in Atlanta, probably due to the higher complexity of the information contained in the Atlanta maps (i.e., smaller map scale, higher number of colors and individual map sheets). The choice of the number of clusters $k$ heavily affects the results in Atlanta, but less so in the Boston study area, where the improvement stagnates when using a $k>5$ (Fig. 5c). This is in line with the results of the elbow analysis, based on the inertia of the detected clusters in RGB\textsubscript{100} space, suggesting that most maps (in spatially aggregated form) consist of approximately 3 to 5 main clusters (Fig. A2). Herein, we use a threshold of 50 pixels for the segment removal during the post-processing step; higher thresholds do not improve the results (Fig. A3).
3.2. Clustering analysis

While the results in the Atlanta study area seem to yield best results for a k=10, we use a k=4 for the subsequently discussed extractions, since most maps are 3-color prints and thus, are expected to perform in a similar way like the Boston study area. Thus, a granularity of k=4 is expected to be sufficient for urban area extraction, which is shown in Fig. 6a-d. However, the “mixed pixel” effects produced by the spatial aggregation of RGB information in the historical maps may cause a higher number of clusters to better characterize the density variations of specific colors (features) in the original map. For example, the clustering results using a k=10 show increasing homogeneity across individual map sheets (in the case of the Boston mosaic, Fig. 6a,e), or even allow to detect subtle scanner- or paper-induced color variations in the historical map (Fig. 6f). Moreover, a higher number of clusters may even be useful to extract mountainous terrain, due to the specific RGB average values produced by densely spaced contour lines (shown in pink color in Fig. 6g, cf. Fig A1b). An integrated illustration of the effects of spatial constraints, number of clusters, and post-processing thresholds can be seen in Fig. A4.

Figure 5. Evaluation of the map-extracted historical urban areas in the US study areas against HIS-DAC-US built-up property densities. (a) Receiver-operator-characteristic (ROC) plots for each clustering scenario (k from 2 to 10) without spatial constraints using GHSL 1975 built-up areas, (b) after applying the spatial constraints, and (c) after post-processing the extracted areas by removing small segments (<50px) in Boston (BOS). Panels (d) – (f) show the ROC plots for the same scenarios in the Atlanta (ATL) study area, respectively.
Figure 6. Raw clustering results illustrating the effect of the number of clusters k on the spatial and semantic output granularity shown for a low k for (a) Boston, (b) Lahore, (c) Sao Paulo, and (d) the London study areas, and for a high k in (e) – (h).

3.3. Historical settlement extents

Finally, we show the extraction results (using a k=4, and a post-processing threshold of 50 pixels) for the six study areas in Fig. 7. The extracted historical urban areas are mostly located in the center of the 1975 urban extents, which seems geographically logical, assuming concentric growth over the long-term given there are no topographic constraints. These results illustrate the robustness of the decision-based identification of the urban cluster, and the effectiveness of constraining the resulting segmentation to the built-up areas from the GHSL. The visualizations in Fig. 7 depict the process of urbanization that occurred prior to the remote sensing era and demonstrate the benefit of integrating remote sensing derived urban footprints from contemporary built-up land data and signals extracted from historical maps.
Figure 7. Extracted historical urban extents for all study areas. (a) Boston metro area, (b) Atlanta metro area, (c) London (dashed rectangle shows the study area extent), (d) Birmingham and surroundings, (e) South-east part of greater Sao Paulo area, and (f) Lahore-Amritsar area with an inset map of Lahore.

3.4. Cross-comparison to HYDE and hind-casted GSHL trajectories

While the extraction results seem to be geographically plausible, how do they compare with the GHSL and HYDE-based trajectories of urban areas over time? Fig. 8 suggests that the extracted urban areas are largely in agreement with the urban area estimated by the HYDE model, especially in the Birmingham and Sao Paulo study areas. We observe higher levels of dispersion of the extracted urban areas in London, where the extracted areas seem to be highly sensitive to the chosen post-processing parameters. Results for Lahore show higher levels of systematic deviation from the HYDE area estimate, in particular for the scenarios involving spatial constraints. This could be attributed to lower levels of quality of the GHSL in 1975, in this area, resulting in higher levels of omission of built-up areas, as compared to HYDE.
Figure 8. Cross-comparison to HYDE urban areas. Box-and-whisker plots illustrating the distribution of built-up areas extracted from the historical maps for all clustering scenarios, per constraint & post-processing scenario, overlaid with the urban area extracted from the HYDE 3.2 database for the respective study areas.

Lastly, we visualized the hind-casted GHSL trajectories of built-up area and overlaid them with the HYDE trajectories extracted for the same areas. Fig. 9 suggests that for most cities, the hind-casted trajectory exhibits high levels of steadiness, except in the London study area. A higher temporal density of historical maps would probably mitigate this effect and produce a smoother curve. Importantly, the uncertainty of these hind-casted trajectories due to the different post-processing parameters is relatively small, and appears to be smallest in the Lahore study area (Fig. 9, yellow bands). As a side note, we observe high levels of discrepancies between the GHSL built-up area and HYDE urban area estimates in some study areas, such as Birmingham. This is likely an effect of different definitions, as the GHSL includes all detected settlements (including rural settlements), whereas the urban areas in HYDE are likely to exclude those areas, but can also be attributed to the general difficulty of global models such as HYDE to estimate historical land use patterns at the regional or local level [87]. In the specific case of the London study area, this discrepancy could also be the result of edge effects due to the small study area in relation to the HYDE grid cells (i.e., 5'), which may exclude partially overlapping grid cells from the study area.

Figure 9. Hind-casted GHSL urban growth trajectories (extracted historical urban areas are GHSL-constraint, k=4, averaged across any post-processing scenario) and their deviation, overlaid with HYDE 3.2 urban area trajectories.
4. Conclusions

The work presented herein is a first attempt to create a framework that combines signals obtained from scanned, georeferenced historical maps with remote sensing data products in an integrated analytical environment. We applied this framework to the extraction and assessment of urban areas over long time periods and demonstrated how such an approach can create spatial-historical data that describe trends of long-term urban-spatial development prior to the era of remote sensing and enhance our understanding of the underlying urbanization processes. The spatial aggregation performed on the historical maps facilitates the seamless integration with other gridded surfaces in general, and effectively reduces the spatial data volume to be processed. Thus, given the availability of georeferenced historical maps in numerous countries, this framework could be applied to back-cast the Global Human Settlement Layer, or other settlement data products, at a country-scale. The presented framework represents an effective way to harvest historical maps and thus, preserve valuable knowledge that can only be found in such archival documents.

From a methodological point of view, we followed the principle of parsimony and implemented a simplistic, rule-based color clustering method to extract the features of interest, and observed satisfactory levels of performance (i.e., high levels of receptiveness with respect to historical building densities - AUC>0.9; and consistency with model-based estimates of historical urban area). Future work will include the use of more advanced extraction methods, taking into account textural characteristics, or more complex rule-based systems, potentially able to distinguish between high-density and low-density urban / built-up areas. The concept of contemporary spatial constraints such as delineating the results to the 1975 GHSL built-up areas, could also be incorporated into an automated training data collection procedure, which could then be used for a supervised, deep-learning approach to extract urban areas and human settlement patterns at finer spatial granularity (cf. [61]).

Ultimately, such efforts create new data and insights that can inform long-term, spatially explicit land use models such as HYDE, and can be used to improve future projections of urban land, and thus, enable more informed urban planning and decision making.
