**Abstract:** Research on the pathogenesis of tuberculosis in recent years has focused largely on the granulomatous stage of primary tuberculosis. However, post-primary tuberculosis that accounts for 80% of clinical disease is seldom studied because of the paucity of animal models and human tissues. The early lesion of post-primary tuberculosis is a subclinical obstructive lobular pneumonia that develops asymptotically for months accumulating secreted mycobacterial antigens in alveolar macrophages and highly sensitized T cells before onset of clinical disease. Here we demonstrate antigen of *M. tuberculosis* in the cytoplasm of ciliated bronchiolar epithelium and alveolar pneumocytes in association with elements of the programmed death ligand 1 (PD-L1), cyclo-oxygenase (COX)-2, and fatty acid synthase (FAS) pathways in the early lesion. This suggests a new synthesis of the pathogenesis of post-primary tuberculosis in which *M. tuberculosis* use its secreted antigens and cord factor to direct prolonged subclinical development of the early lesions in preparation for a sudden necrotizing reaction sufficient to produce a cavity and/or granulomas. Available evidence indicates that most successful human and animal vaccines and host directed therapies of post-primary tuberculosis target the early lesion, not granulomas. Recognition of this will facilitate design and evaluation of improved vaccines and therapies for tuberculosis.

**Keywords:** tuberculosis, secretory antigens, bronchiolar epithelium, alveolar pneumocytes, M2 polarization, COX-2, FAS. Pathogenesis, early lesion

## 1. Introduction

Pathologists in the pre antibiotic era were familiar with a series of tuberculous lesions that are seldom seen to-day [1]. They recognized that the onset of clinical post-primary tuberculosis (PPTB) is preceded by 1-2 years asymptomatic subclinical development of the early lesion in the lung before appearance of caseous pneumonia and granulomas [2-4]. Today, since there is no medical reason to biopsy such lesions and autopsies are infrequent, most investigators are unaware of their existence even though they remain familiar to radiologists as the 'tree-in-bud' sign characteristic of developing PPTB [5].

The early lesions of PPTB do not begin until after establishment of sufficient immunity to prevent disease in all extra pulmonary and most pulmonary sites [1]. PPTB begins as an alveolitis and spreads for months via bronchi as an obstructive lobular pneumonia that is recognizable on high resolution CT scans as the 'tree-in-bud' sign [5]. Foamy alveolar macrophages accumulate behind obstructed bronchi in close association with highly sensitized T cells. Many lesions spontaneously regress, but some undergo necrosis to produce caseous pneumonia that is either coughed out to form cavities or is retained to become the focus of post-primary granulomas and fibrocaseous disease [6]. Post-primary granulomas are easily identified because they contain ghosts of alveoli rather than the homogeneous caseum of primary granulomas [1]. Primary and post-primary granulomas are seldom found together in the same lung. We reported sequestration of secreted mycobacterial antigens in foamy alveolar macrophages in the

developing lesions of post-primary TB and that they are released with the onset of caseation necrosis in a fashion suggestive of the Koch phenomenon [6].

Here we report finding *M. tuberculosis* (MTB) antigens, but not acid fast bacilli (AFB), in alveolar lining cells (pneumocytes) and ciliated bronchial cells in addition to foamy alveolar macrophages in developing lesions of PPTB. This suggested that MTB use secreted antigens and cord factor to orchestrate an extended sequence of subclinical lesions that prepare for a sudden massive necrotizing reaction sufficient to produce cavities from which the organisms can escape to new hosts. Post-primary granulomas arise to surround foci of caseous pneumonia that are not coughed out to form cavities. They persist to become fibrocaseous disease. Available evidence suggests that several components of the early lesion of PPTB are attractive targets for vaccines and/or host-directed therapies. Most nascent lesions regress spontaneously leaving apical scars. If we understood why they regress, it might be possible to make them all regress and thereby drive MTB to extinction.

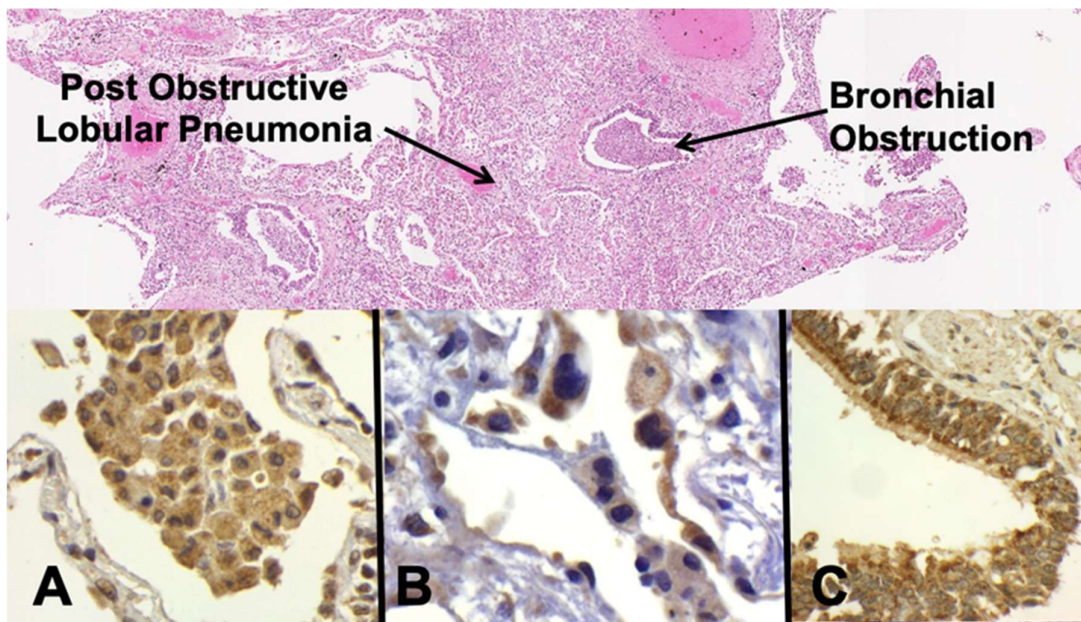

## 2. Material and Methods

Formalin-fixed and paraffin-embedded tissue blocks of over 100 cases of human tuberculous lung samples were obtained during regular autopsy practice and after the completion of all medical, legal and ethical re-quirements and were de-identified. Furthermore, this study was conducted according to the principles expressed in the Declaration of Helsinki. Hematoxylin and eosin (H&E) staining was used to identify cases that of the early lesion of post-primary TB [1].

Immunohistochemistry was performed on five micrometer sections that were de-paraffinized and stained with monoclonal antibodies for: MTB antigen (ab905, Abcam, Cambridge, MA); cyclo-oxygenase (COX)-2 (SP21rabbit, Biocare Medical, Pacheco, CA); Programmed Death-Ligand 1 (PD-L1: Spring Bioscience, Pleasanton, CA); Programmed Death-1 (PD-1, Biocare Medical); and fatty acid synthase (FAS:C20G5, Cell Signaling Technology). Positive and negative controls were run concurrently. The immunohistochemical reactions/ expressions were graded in accordance with the brown chromogenic signal intensity of the 3,3'-diaminobenzidine (DAB).

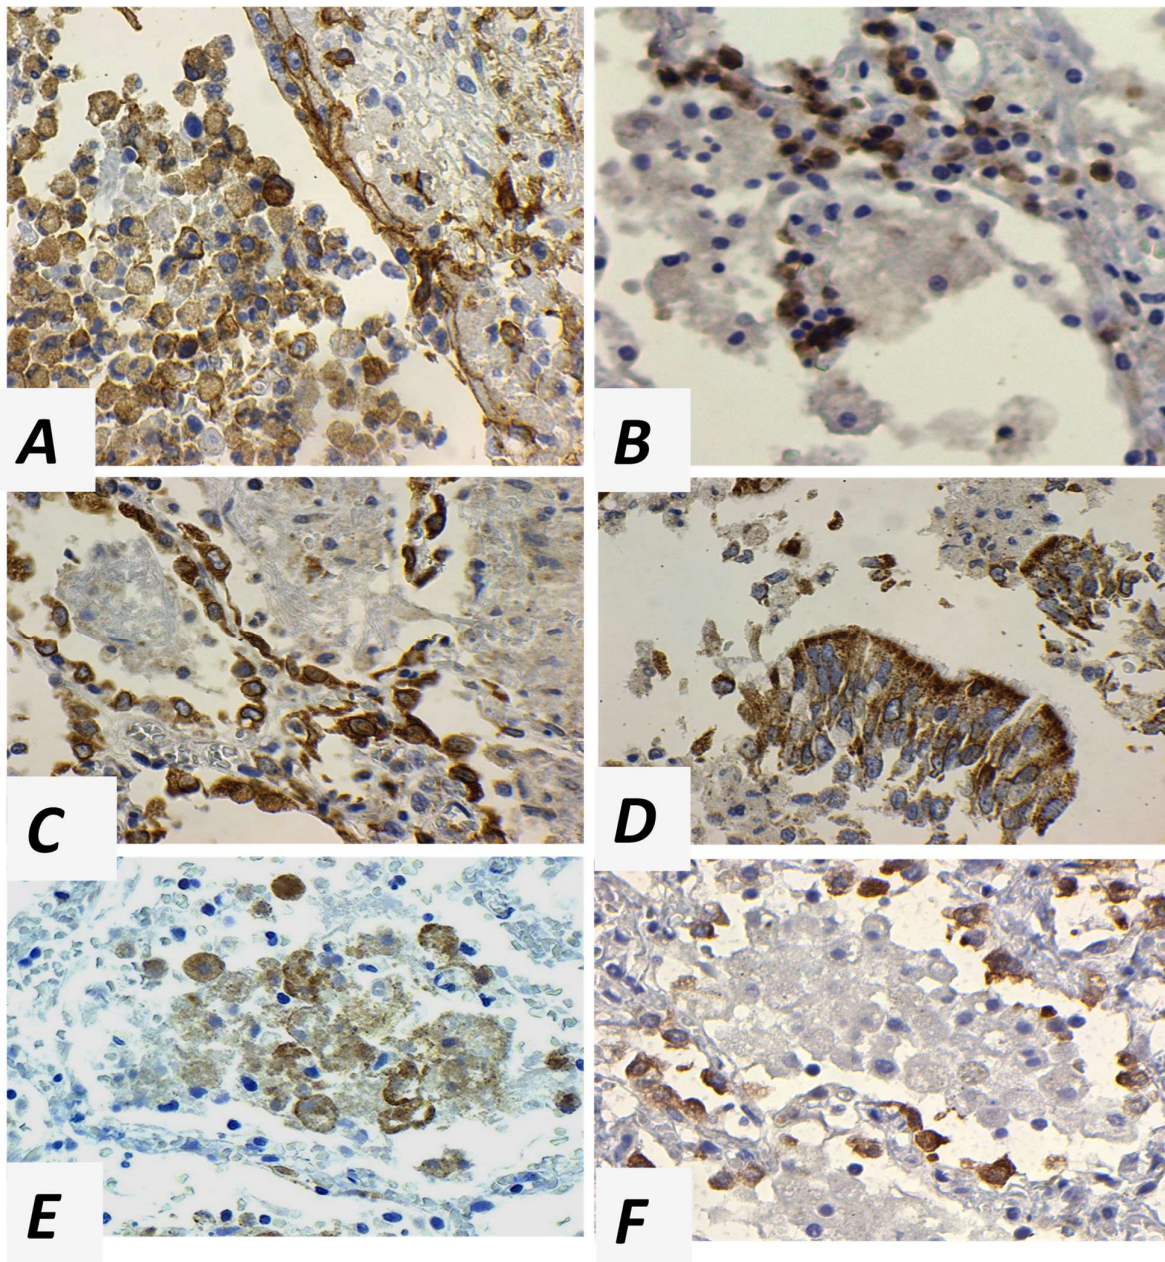

## 3. Results

The early lesion of post-primary tuberculosis is a post obstructive lobular pneumonia that spreads via bronchi for months prior to caseation [1] (Figure 1). MTB antigen in the early post-primary phase was detected by immunohistochemistry as a brown chromogenic signal within alveolar macrophages (Figure 1A), alveolar pneumocytes (Figure 1B), and ciliated bronchiolar epithelial cells (Figure 1C). Alveolar monocytes and macrophages are not necessarily foamy in the early post-primary phase and show mild expression of MTB antigen compared with the later phases. The mycobacterial antigens were diffusely present throughout the cytoplasm of the cells as is characteristic of secreted antigens rather than the discrete spots characteristic of intact organisms [7]. PD-L1 expression was present on alveolar pneumocytes, sloughed bronchiolar epithelial cells, and alveolar monocytes and macrophages (Figure 2A). PD-1 staining was present on lymphocytes primarily in the interstitium (Figure 2B). COX-2 expression was evident by immunohistochemistry within reactive alveolar pneumocytes (Figure 2C) and bronchiolar epithelial cells (Figure 2D) in the early post-primary phase of human tuberculous pneumonitis. Alveolar macrophages in the early lesion of post-primary tuberculosis stain with CD163, a marker for M2 polarized macrophages (Figure 2E). Finally, fatty acid synthase (FAS) expression was present in the cytoplasmic compartment of reactive alveolar pneumocytes surrounding increasingly foamy alveolar macrophages (Figure 2F).

**Figure 1.** MTB Antigen in the Early Lesion of Post-primary Tuberculosis. Post-primary tuberculosis begins as an alveolitis that spreads subclinically as an obstructive lobular pneumonia for 1-2 years before undergoing necrosis as caseous pneumonia to initiate clinical post-primary TB. Evidence suggests that MTB uses its secreted antigens to direct these lesions towards cavitation that can transmit infection to new hosts (H&E stain 20x).

**A.** Mycobacterial antigens in alveolar macrophages (Immuno stain 600x). **B.** Mycobacterial antigens alveolar lining cells types 1 and 2 (Immuno stain 600x). **C.** Mycobacterial antigens in ciliated bronchial cells (Immuno stain 400x).

**Figure 2.** Characterization of the Early Lesion of Post-primary Tuberculosis. Immunostains for PD-L1, PD-1, COX-2, CD163 and FAS provide evidence that MTB through its secreted antigens manipulates the host's responses in the early lesion to develop conditions for a necrotizing reaction sufficient to form a cavity from which it can escape to infect new hosts.

**A.** PD-L1 expression on alveolar pneumocytes and on alveolar macrophages (600x). **B.** PD-1 expression on lymphocytes in adjacent alveolar walls (600x). **C.** COX-2 in reactive alveolar pneumocytes (600x). **D.** COX-2 in bronchiolar epithelium (600x). **E.** CD163 staining of alveolar macrophages marking them as M2 cells (400x). **Figure 400. x).**

#### 4. Discussion

The finding of secreted mycobacterial antigens in multiple cell types of the early lesion of PPTB suggests a new synthesis of the pathogenesis of post-primary TB driven by secreted antigens and cord factor (trehalose 6,6' dimycolate). Since MTB is an obligate human parasite, everything that it does has been selected to insure survival and

transmission among people. MTB secretes at least 257 proteins into surrounding media that are not necessary for its survival in culture, but are required for virulence in humans [8]. The functions of some secreted proteins such as ESAT-6 and Ag85 have been studied, but most remain unknown [8, 9]. Similarly, virulent MTB secrete large amounts of trehalose 6,6' dimycolate (TDM or cord factor) an insoluble lipid that remains on the surface of the organisms [10]. It is also required for virulence, but not for growth in vitro. It remains on the surface of the organisms and is responsible for the formation of serpentine cords and protects MTB from killing by macrophages [11].

The early lesion of PPTB is an asymptomatic obstructive lobular pneumonia that develops for 1-2 years before onset of symptoms [12]. It is a prolonged asymptomatic accumulation of mycobacterial antigens and host lipids in alveolar macrophages with little or no inflammation even though there may be intense tuberculous inflammation elsewhere in the same lung [7]. The process slowly spreads via bronchi in a process known as bronchogenic TB and may be observed as the 'tree-in-bud' sign on CT scans [5, 13]. The finding of MTB antigens in multiple cells of the early lesion suggests that MTB use these antigens to manipulate diverse components of the host response to asymptotically produce the components necessary for a sudden and massive necrotizing reaction sufficient to form a cavity large enough to support transmission of infection.

To accomplish this, MTB must evade diverse inflammatory responses while it secretes antigens that manipulate its host. MTB has a remarkable ability to do this. While some tubercle bacilli produce massive tissue damage, especially in the lung, others simultaneously persist in many tissues with no gross evidence of infection [14]. Available evidence suggests that this is mediated by TDM that forms cylindrical micelles and an intercalated bilayer with surfaces composed entirely of trehalose [15, 16]. We reported evidence that these trehalose surfaces bind and immobilize water to produce an "invisibility cloak" that facilitates the persistence of MTB in multiple cell types without producing inflammation, even in highly immune individuals [17].

The invisibility cloak of MTB makes it invisible to receptors. Instead of seeing a multitude of pathogen-associated molecular patterns (PAMPs) and epitopes, receptors in cells containing such MTB would see only water that will not move out of the way. Such a mechanism could contribute to the ability of MTB to infect many types of cells and to persist in grossly normal tissues in people with otherwise strong immune responses and severe inflammation and granulomas in other parts of the body. In particular, we propose that this mechanism is an important part of developing post-primary TB that is characterized by asymptomatic accumulation of mycobacterial antigens and host lipids in lungs of highly sensitized people. An invisibility cloak would provide MTB with ability to manipulate its environment in at least two ways. First, MTB would not have to develop means of neutralizing or evading all of the defenses of many types of cells. Second, MTB could release signaling molecules of its choosing to manipulate the functions of the host for its benefit.

The early lesion of post-primary TB involves asymptomatic coordination of multiple types of cells in the lung for a period of months prior to undergoing necrosis to produce caseation pneumonia that is coughed out to form a cavity or retained to become the focus of post-primary granulomas and fibrocaseous disease. The components of the early lesion include:

- 1) Alveolar macrophages that have the M2 phenotype (CD163 Staining)
- 2) Bronchial obstruction traps alveolar macrophages to produce a post-obstructive lipid pneumonia [18].
- 3) Increase production of lipids by alveolar lining cells (FAS) that are taken up by macrophages that become increasingly foamy.
- 4) Accumulation of secreted mycobacterial antigens in the foamy alveolar macrophages.
- 5) Stimulation of highly sensitized tissue resident T cells (TRM) in adjacent alveolar walls.

#### 6) Suppression of T cell activity with PD-L1.

These lesions spread via bronchi as an obstructive lobular pneumonia, recognized by CT scans as the 'tree-in-bud' sign, until they either regress or undergo necrosis to become caseous pneumonia that gives rise to cavities and post-primary granulomas.

Our new findings include demonstration of mycobacterial antigen within both the alveolar pneumocytes and detached bronchiolar lining cells with mild expression in associated alveolar monocytes/ macrophages; marked COX-2 expression in reactive alveolar pneumocytes and detached bronchiolar epithelium, the latter potentially leading to obstruction and contributing to lipid pneumonia; expression of fatty acid synthase (FAS) that could contribute fatty acids to the alveolar macrophages; expression of programmed death ligand (PD-L)1 on the alveolar monocytes/macrophages and on the pneumocytes and bronchiolar epithelial cells; and CD163 expression on the non-foamy monocytes/macrophages in the alveolar interstitium and alveoli.

In previous studies we have reported that the early lesion of post-primary tuberculosis contains foamy alveolar macrophages with the M2 phenotype that marked with CD163, PD-L1, phosphorylated mTOR, insulin-like growth factor-1 receptor (IGF-1R), and human cyclooxygenase 2 (COX-2) [19]. Relatively few CD4<sup>+</sup> cells were present, but abundant CD8<sup>+</sup>, PD-L1 cells were in the alveolar walls, Foamy macrophages stained strongly with CD68 and frequently also with the dendritic cell marker DEC-205. T-regulatory cells were also observed in the early lesion [20, 21]. These findings indicate that MTB creates a protective microenvironment that accumulates high concentrations of MTB antigens and sensitized T cells that when released lead to necrosis, cavitation, post-primary granulomas and fibrocaseous disease [21].

Several lines of evidence suggests that the early lesion is an attractive target for vaccines to prevent post-primary tuberculosis. First, many nascent lesions regressed spontaneously. If we knew why it might be possible to induced all to regress. Second, slowly progressive pulmonary tuberculosis in the mouse is a model of the early lesion of post-primary tuberculosis [22]. Several experimental vaccines have been shown to prevent development of these lesions [23-25]. Finally, the ASO/M721E vaccine that was successful in a human clinical trial was designed to induce a strong Th1 macrophage response without an M2 response [26, 27]. Since a strong Th1/M1 response occurs in people with severe disease, we propose that the protection was provided by suppressing the M2 response and thereby preventing development of the early lesion of post-primary tuberculosis.

There is also evidence that the early lesion of post-primary TB is an attractive target for host directed therapies [19, 28]. Multiple studies of vitamin D3, metformin, and isoniazid on human specimens in vitro suggest efficacy against the early lesion of PPTB. Mice, guinea pigs and rabbits all develop infections that at certain points appear to be models of human post-primary TB [25]. In multiple studies, effective vaccines and host directed therapies were associated with lessening of the PPTB like pathology in these models [23, 24, 28-32]. For example, slowly progressive pulmonary TB in immunocompetent mice is characterized by an alveolitis with infected foamy macrophages that have multiple characteristics of the human disease [22]. We demonstrated that inclusion of lactoferrin, with a BCG vaccine in this model induced a sustained reduction in lung pathology, but not numbers of organisms in tissue [23].

Evidence for a mechanism of host directed therapy is provided by studies of fatty acid synthase (FAS). The presence of FAS in alveolar lining cells of the early lesion of PPTB indicates increased synthesis of lipids that is a critical component of these lesions. We demonstrated that inclusion an FAS inhibitor, lactoferrin, with a BCG vaccine in mice induced a sustained reduction in lung pathology, but not numbers of organisms in tissue [23]. Metformin and orlistat are also inhibitors of fatty acid synthase [33-35] and have shown efficacy against TB in preclinical studies of TB [23, 34]. In two separate human trials, metformin treatment was associated with improved control of infection and decreased disease severity [29, 36]. Vitamin D3 has also been shown to reduce accumulation

of lipids by macrophages and to produce beneficial effects in patients in a controlled trial of pulmonary tuberculosis [37, 38].

## 5. Conclusion

The finding of secreted mycobacterial antigens in multiple cells of the early lesions together with markers of multiple immune regulatory pathways suggest that these sub-clinical asymptomatic lesions are actually the major drivers of clinical post-primary tuberculosis. They serve both to control and direct development of the early lesion and to accumulate antigen targets for necrotizing hypersensitivity reactions. Study of these lesions will remain challenging because of the paucity of informative human tissues that can be used both to study the disease and to validate animal models. Fortunately, new multiplex technologies can measure proteins and nucleic acids on slides with a depth and precision undreamed of a decade ago. Such technologies are needed to finally study these critical lesions of tuberculosis and to develop more effective interventions.

**Authors' Contribution:** Both authors contributed equally to the writing of the manuscript, and to the review and editing of the final manuscript.
