Abstract: Macronutrient intake is important in the prevention and management of Metabolic Syndrome (MetS). We characterized energy and macronutrient intake of Koreans diagnosed with MetS at recruitment of the Health Examinee (HEXA) cohort. We included 130,423 participants aged 40-69 years for analysis. Odds ratios (OR) and 95% confidence intervals (CI) were estimated to evaluate the intake of macronutrient. Low energy (OR= 0.94, 95% CI: 0.89-0.98) and fat intake (OR=0.91, 95% CI: 0.86-0.97) was observed among 50-59 year-old men. Only postmenopausal women had lower intake of total energy (OR= 0.95, 95% CI: 0.92-0.97) while low fat intake was observed in all women (OR=0.80 95% CI: 0.77-0.83). For carbohydrate intake, the OR were 1.14 (95% CI: 1.08-1.22) and 1.17 (95% CI: 1.08-1.27) among women in their 50's and 60's respectively. Protein intake was low (OR=0.90, 95% CI: 0.86-0.95) and (OR=0.88, 95% CI: 0.82-0.94) among women in their 50's and 60's respectively. High intake of plant carbohydrates in women (OR=1.16, 95% CI: 1.12-1.20) and plant protein in both genders (OR=1.09, 95% CI: 1.05-1.13) were observed, but low intake of total energy, fat and animal-source carbohydrates in both genders. Fat intake was low regardless of food source. In conclusion, high consumption of plant-source and low consumption of animal-source macronutrients was observed in Korean adult diagnosed MetS.

Keywords: Macronutrient intake; Metabolic syndrome; the Korean Health Examinee (HEXA) stud

1.Introduction

Interconnected risk factors of metabolic syndrome (MetS) such as abdominal obesity, atherogenic dyslipidemia, raised blood pressure and insulin resistance increase the risk of coronary heart disease, other cardiovascular diseases (CVD) and type 2 diabetes mellitus (T2DM)[1–3]. CVD and T2DM are global health issues with a high prevalence and increasing burden of economics in public health [4,5] . MetS has a high prevalence in many countries [6,7] and it has as well gradually increased in Korea over the last 10 years [8,9]. Although the etiology of MetS is unclear, various factors such as genetics, metabolism and the environment including diet may contribute to its development [10]. A recent review highlighted

a possible interconnection between gut microbial dysfunction, Non-alcoholic fatty liver disease (NAFLD) and colonic diverticulosis as possible underlying risk factors of MetS [11].

Diet is an important factor in the prevention and management of MetS [12]. Previous studies reported conflicting results on the association between macronutrient intake and risk of MetS according to gender, geographical location and food sources [13–15]. In 55-80 years old men and women with MetS, intake of total fat above the Acceptable Macronutrient Distribution range (AMDR) and lower intake of energy and carbohydrates were reported [13]. Plant protein, especially soy protein and wheat gluten compared to animal proteins were linked to reduced risk of MetS components [14]. In a meta-analysis of observational studies, high carbohydrate intake was associated with increased odds of developing MetS [15]. The observational study using national survey data from the United States and Korea showed not only different percentages of energy intake from carbohydrate, protein and fat between the two countries, but also increased risk of MetS with high carbohydrate intake only in Korean men and women [16]. This finding was attributed to a high percentage of energy from carbohydrates in Korean compared to the US.

Differential association between protein intake were also observed in Korean adults, a positive association between animal protein and MetS components (abdominal obesity, low HDL-C and hyperglycemia) and a protective effect of plant protein on blood pressure in men, while null findings were observed in women [17]. The percentage of energy from carbohydrates in men and particularly refined grains, including white rice in women were associated with MetS [18].

The patterns of macronutrient intake in the Korean population with MetS have been rarely reported. Therefore, this study aimed to identify the characteristics of total energy, carbohydrate, protein, and fat intake in participants diagnosed with MetS at recruitment of the Health Examinees (HEXA) cohort, considering the plant and animal sources of each macronutrient. We also examined whether macronutrient intake differs by diagnosis of each metabolic syndrome component.

2. Materials and Methods

2.1. Study population

The Health Examinees (HEXA) Study is a community-based, large genomic cohort that was conducted in Korea from 2004 to 2013. Detailed information about the study design have been described in previous studies [19,20]. For the homogeneity and comparability of participants, previous HEXA study was updated to Health Examinees-Gem (HEXA-G) [21]. A total of 139,345 participants aged 40-69 years remained in the HEXA-G data after excluding withdrawers ($n = 11$) and participants from invalid institutions ($n = 31,375$). In addition, 8922 participants were excluded among the HEXA-G. These included participants with missing baseline information on hypertension, diabetes mellitus or hyperlipidemia history ($n = 600$); missing data on blood pressure, fasting glucose, triglycerides, high density lipoprotein (HDL)-cholesterol, and waist circumference (WC) ($n = 4540$); and those with energy intake <800 or ≥ 4000 kcal/day in men and <500 or ≥ 3500 kcal/day in women ($n = 3782$). Finally, 130,423 participants of whom 43,850 were men and 86,573 were

women remained in the final sample (Figure 1). All participants gave informed written consent prior to participating in the study. The Institutional Review Board of the Seoul National University Hospital approved this study for statistical analysis (IRB No. E-1503-103-657).

2.2. Dietary Assessment

Dietary information was collected using a validated semi-quantitative food frequency questionnaire (FFQ) developed for the Korean Genome and Epidemiology study (KoGES) [22]. Trained interviewers assessed the intake 106 food items consumed by participants over the past year. Food consumption frequencies were classified into nine levels (from “never” to “three times or more a day”), and portion size into three levels (one-half, one, one and a half servings). Energy, carbohydrate, protein, and fat intake were calculated using a food composition table developed by the Korean Health and Industry of Development Institute [23]. Plant and animal-based carbohydrate, protein, and fat intake were determined after classification according to food source. Classification of macronutrients according to plant or animal sources was based on the guidelines of KoGES database (<https://www.kdca.go.kr/contents.es?mid=a40504100200>). Based on the guideline, the weighted amount of constituent foods based on the representative recipe of each food item constituting the mixed dishes are given. These amounts were used to evaluate mixed dishes and calculate plant or animal source macronutrients. The percentage of energy from each macronutrient was calculated using the standard conversion factors: carbohydrate 4 kcal/g, protein 4 kcal/g, fat 9 kcal/g.

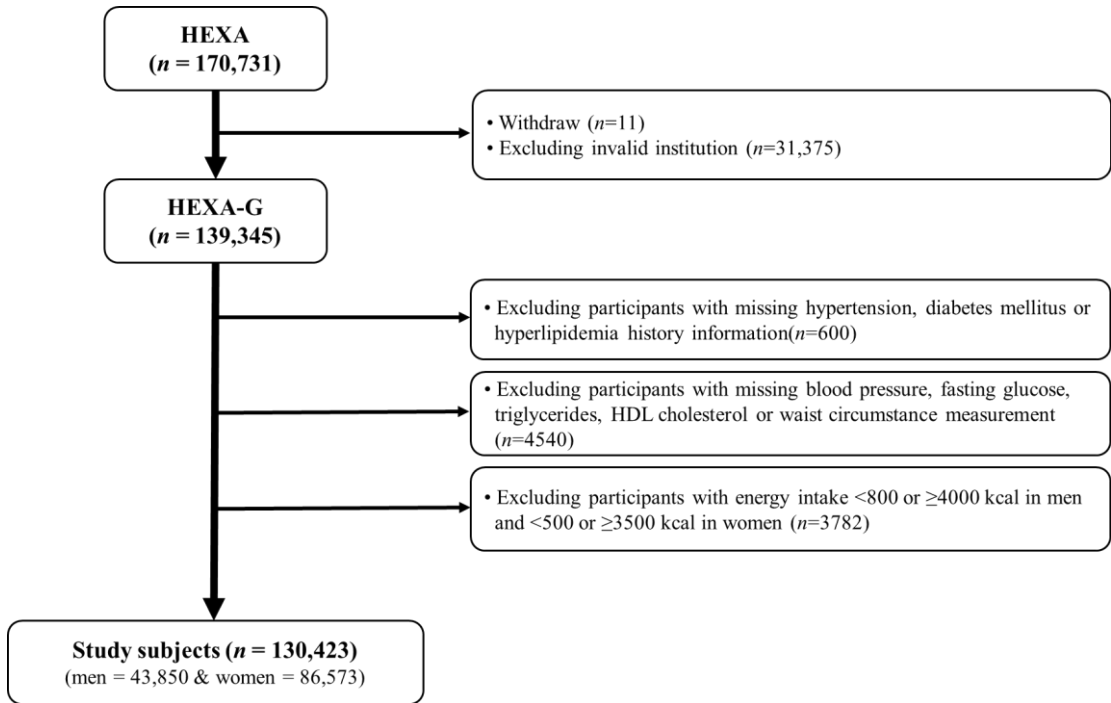

Figure 1. Flow diagram of analytical sample in this study using the Health Examinees (HEXA) cohort.

2.3. Definition of Metabolic syndrome

MetS was defined using the National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III) [24], modified for the

Asian guideline for WC [25]. Participants who met three or more of the following criteria were classified as having MetS: (1) WC ≥ 90 for men and ≥ 80 cm for women; (2) triglycerides (TG) ≥ 150 mg/dL or drug treatment for elevated triglycerides; (3) HDL-cholesterol ≤ 40 for men and ≤ 50 mg/dL for women; (4) systolic blood pressure (SBP) ≥ 130 mmHg, diastolic blood pressure (DBP) ≥ 85 mmHg or drug treatment for elevated blood pressure; and (5) fasting blood glucose ≥ 100 mg/dL or drug treatment for elevated fasting blood glucose.

2.4. Covariates

Demographic and lifestyle factors such as age, marital status, education, family income, occupation, body mass index (BMI), health-related behaviors, and macronutrient intake were included. Age was categorized into three groups: 40–49, 50–59, and 60–69 years old. Marital status, education, family income, and occupation were categorized into two groups each. Marital status: yes (married, cohabit), no (single, separated, divorced, widowed, others). Education: 12 years, 12 years or more. Family income: below \$3000, \$3000 and above per month. Occupation: occupied (11 types of occupation including senior officials and managers and professionals *etc*), unoccupied (unoccupied, housewife, and others). BMI was calculated as weight in kilograms divided by the square of height in meters (kg/m^2). Non-smokers were defined as those who had smoked less than 400 cigarettes during their lifetime. Former smokers were defined as those who had smoked more than 400 cigarettes during their lifetime but did not smoke at the baseline. Participants who had smoked more than 400 cigarettes during their lifetime and still smoked at the baseline classified as current smokers. Non-current drinkers were defined as those who had never consumed any alcoholic drink during their lifetime or those who did not consume alcohol at baseline. Current drinkers were defined as those who still consumed alcohol. Regular exercise was classified into two groups (yes: regular exercise that caused body sweating; and no: otherwise). Menopausal status was classified as either pre-menopausal women who currently experience monthly menstrual cycle or post-menopausal women who have gone a year without menstrual flow.

2.5. Statistical Analysis

The Mantel-Haenszel chi-square test for categorical variables and general linear model (GLM) for continuous variables were used to analyze the demographic and lifestyle factors of participants according to quartiles of total energy intake. Categorical variables such as marital status, education, family income, occupation, smoking, drinking and regular exercise were presented as percentage (%). Continuous variables including age, BMI, energy and macronutrient (carbohydrate, protein, fat) intake were presented as median and interquartile range (IQR). Multivariable logistic regression models were used to examine the characteristics of energy and macronutrient intake in participants with MetS diagnosis at recruitment after adjusting for age, BMI, education, family income, occupation, smoking, drinking, regular exercise, and energy intake. Results are presented as odds ratio (OR) and 95% confidence interval (CI). P-value < 0.05 (2-tailed test) was considered statistically significant. All data were analysed using SAS (version 9.4; SAS Institute Inc., Cary, NC, USA).

3. Results

Demographic and lifestyle factors of participants according to metS are presented in Table 1. Both men and women diagnosed with MetS were significantly older (men: OR=1.03, 95% CI: 1.03-1.04; women: OR=1.07, 95% CI: 1.06-1.07) and had higher BMI (men: OR=1.51, 95% CI: 1.49-1.53; women: OR=1.40, 95% CI: 1.39-1.42) compared to controls. In addition, both men and women with MetS were more likely to be current smokers (men: OR=1.37, 95% CI: 1.30-1.45; women: OR=1.34, 95% CI: 1.18-1.53), had occupation (men: OR=1.20, 95% CI: 1.12-1.28; women: OR=1.12, 95% CI: 1.08-1.17), were less educated (men: OR=0.89, 95% CI: 0.85-0.94; women: 0.75, 95% CI: 0.71-0.79) and less likely to exercise regularly (men: OR=0.85, 95% CI: 0.81-0.89; women: OR=0.90, 95% CI: 0.86-0.94) compared to controls. Current drinking was more frequent among men with MetS (OR=1.09, 95% CI: 1.03-1.16). Women with MetS were less likely to be current drinkers (OR=0.80, 95% CI: 0.76-0.84), and were less likely to earn $\geq 30,000$ USD a month (OR=0.87, 95% CI: 0.83-0.91) compared to controls (table 1). Socio-demographic and lifestyle factors of participants according to quartiles of total energy intake are presented in supplementary table 1.

Table 2 shows energy and macronutrient intake of participants according to MetS and MetS components. Total energy intake was lower in men and women with MetS (men: OR= 0.95; women: (OR= 0.97). Low fat intake was observed in men (OR= 0.93), but high carbohydrate intake, low protein and fat intake was observed in women (carbohydrate; OR=1.14, protein; OR= 0.90, fat; OR= 0.80). When MetS components were characterized according to macronutrient intake by gender, men and women with abdominal obesity consumed more total energy (men: OR=1.08; women: OR=1.04). Conversely, low energy intake was observed in participants with low HDL-cholesterol (men: OR=0.94; women: OR=0.97), high blood pressure (men: OR=0.94; women: OR= 0.97) and hyperglycemia (men: OR=0.95; women: OR= 0.96). High carbohydrate intake was reported in men and women with high triglycerides (OR=1.05 and 1.11 in men and women respectively) and low HDL-cholesterol (OR=1.14 and 1.17 in men and women, respectively), but only in women with high blood pressure (OR=1.08). In contrast, low carbohydrate intake was observed among those with hyperglycemia (men: OR=0.91; women: OR= 0.) and in men with high blood pressure (OR=0.93). Participants with hyperglycemia reported high intake of proteins (OR=1.07 in men and 1.04 in women). Regarding fat, low intake was linked to high triglycerides (men: OR=0.94; women: OR= 0.84), low HDL-cholesterol (men: OR=0.81; women: OR= 0.79) and high blood pressure (men: OR=0.94; women: OR= 0.93).

The intake of macronutrients according to baseline MetS diagnosis stratified by gender and age group are presented in table 3. Low energy (OR=0.94) and fat intake (OR=0.91) was only predominant among 50–59-year-old men. Among women in their 50's and 60's, a high carbohydrate intake (OR=1.14 and 1.17 respectively), and a low protein intake (OR=0.90 and 0.88 respectively) were observed. Moreover, low fat intake was observed in women in their 40, 50 and 60's (OR=0.87, 0.81, and 0.78 respectively). The median intake of energy and macronutrient intake for each MetS component stratified by age group is presented in supplementary

table 1 while the corresponding odds ratios are presented in supplementary figure 1.

The characteristics of each macronutrient intake from plant and animal food sources are presented in Figure 2. Women diagnosed with MetS consumed more carbohydrate from plant (OR= 1.16), but less from animal sources (OR= 0.91). Low intake of animal carbohydrate was also observed in men (OR= 0.92). In both gender, low intake of animal proteins was observed (OR=0.97 and 0.91 for men and women, respectively) while high intake of plant protein was reported (men: OR=1.05, women: OR=1.09. All participants diagnosed with MetS had low intake of plant fat (men: OR:0.97; women: OR= 0.89) and animal fat (men: OR=0.95; women: OR:0.87). Characteristics of macronutrient intake according to MetS components also varied according to the source of macronutrients. Men with high triglycerides had a high intake of plant carbohydrates and proteins (OR= 1.08 and 1.09 respectively), but low intake of animal carbohydrates, protein and fat (OR=0.92, 0.96, and 0.94 in order). Similarly, men with low HDL-cholesterol reported high intake of plant carbohydrates (OR=1.15) and low intake of animal protein and fat (OR=0.89 and 0.85 respectively). Men with high blood pressure had a high intake of plant protein (OR=1.05) and a low intake of animal carbohydrate and fat (OR=0.93 and 0.96 respectively). High intake of plant protein (OR=1.05) and animal fat (OR=1.05), but low intake of plant fat (OR=0.94) was observed in men with hyperglycemia. On the other hand, women with high triglycerides had a high intake of plant carbohydrates and protein (OR= 1.13 and 1.06 respectively), but low intake of animal carbohydrates (OR=0.95). Moreover, women with low HDL-cholesterol had high intake of plant carbohydrates and proteins (OR=1.21 and 1.06 respectively), but low intake of animal protein (OR=0.91). High blood pressure among women was characterized by high intake of plant carbohydrate and protein (OR=1.08 and 1.10 respectively) but low intake of animal protein and fat (OR=0.96 and 0.93, respectively). Women who had hyperglycemia reported low intake of animal carbohydrate (OR=0.95).

4. Discussion

This study was designed to evaluate macronutrient intake of participants diagnosed with MetS at recruitment of the HEXA cohort. Total energy and fat intake were low in both men and women diagnosed with MetS. Carbohydrate intake was high, but protein intake was low only in women. A high intake of total energy and fat were observed among 50-59-year old men with MetS. A high carbohydrate and low protein intake was shown in women aged 50 and above. However, low intake of fat was reported regardless of age group. Participants diagnosed with MetS had low intake of carbohydrate and protein from animal foods, but high intake of carbohydrate and protein from plant foods. On the other hand, fat intake was low in both men and women regardless of source. Moreover, macronutrient intake varied across diagnosis of MetS components and this variation also depended on the source of macronutrient.

Consistent with our findings, MetS participants consumed lower total energy compared to non-MetS participants [26,27]. In a 2005-2007 survey, Koreans 40 years and above with MetS consumed less energy than those without MetS [28]. In contrast, high energy intake was observed among MetS participants [29,30] while no differences in energy intake were observed between MetS and non-MetS participants [31]. In our study, total energy intake might have been restricted by participants prior to MetS diagnosis, because of changes in food intake even when at least one of the five MetS components are diagnosed.

Reports have indicated excessive intake of carbohydrates at the expense of other macronutrients in elderly Koreans [32] and a positive association between high carbohydrate intake and risk of MetS in women [32–37]. A typical Korean diet is rich in refined grains especially white rice and noodles. Studies from Asian countries have reported a positive association between frequent consumption of refined grains and MetS [38,39]. Excessive intake of carbohydrates in form of refined grains increases the glycemic load and leads to postprandial hyperglycemia, hyperinsulinemia and insulin resistance, which plays a key role in MetS, dyslipidemia, obesity, and T2DM [40]. Women with MetS reported high carbohydrate intake unlike men. The gender difference is consistent with higher intake carbohydrates in Korean women than men. Thus, carbohydrate substitution or improving the quality of carbohydrates will likely benefit Korean women. Similar to our findings regarding plant carbohydrates, women but not men with MetS consumed more energy from refined grains and white rice [41]. These results suggest that gender is an important factor in the choice of carbohydrate sources among Koreans suffering from MetS; women consuming more carbohydrates from plant sources. A Korean-style diet mainly characterized by grains and vegetables, may be associated with elevated risk of MetS [42]. In contrast, low intake of animal carbohydrate among subjects with MetS might reflect overall low consumption of milk in the Korean diet [43] since animal carbohydrate mainly come from milk and dairy products. Several studies have reported low intake of milk and other dairy products among MetS cases [44–47].

Women with MetS consumed less absolute protein than those without MetS and absolute protein intake decreased with age suggesting that Koreans restrict protein intake as they age. Korean young and middle aged adults consume 71.0g/d of proteins, way above the RDA of 50g/d [48] while inadequate protein intake is only evident among the elderly [49]. The association of protein intake with MetS are inconclusive, with some studies reporting positive [50–53] while others reporting negative findings among women [54]. A Korean study reported increased odds of abdominal obesity, hypertriglyceridemia and high fasting glucose especially in middle-aged women with low protein intake [55]. Since our study was a cross-sectional study, it is possible that Korean women under-reported their protein intake or restricted protein intake after diagnosis of one of the metS such as

high blood pressure, low HDL-cholesterol and high triglycerides as reported in the current study. Absolute amount of protein intake from plant source in this population might be correlated with intake of refined carbohydrate, predominantly from white rice [49]. This might explain high intake of plant proteins among women diagnosed with MetS and some of its components in our study. Evidently, plant sources supplied more proteins than animal sources in this population. Korean studies have reported more intake of proteins from plants, predominantly grains with only 1/3 of proteins from animal [56]. Elderly people tend to eat more plant proteins since they are easy to chew, have less appetite for animal foods and might restrict animal protein due to metabolic concerns [57]. Results on protein intake according to dietary sources, and MetS are inconsistent. Both cross-sectional and longitudinal studies have reported a positive association between animal protein and MetS risk factors [52], and a negative or null association between plant proteins and MetS components [53,58].

Fat consumption has gradually increased in Korea but still within the Acceptable Macronutrient Distribution range (AMDR) and lower than that of the US [59,60]. Lower consumption of animal source foods such as processed red meat in middle-aged Koreans has been reported [61]. Moreover, total unprocessed meat, particularly poultry consumption was inversely related with CVD risk among middle aged Koreans [61]. A semi-Western diet characterized by relatively high intakes of animal foods, was associated with a low risk of low HDL cholesterol [62]. Energy from total fat was associated with lower prevalence of MetS in both men and women. Similarly, participants with MetS were more likely to consume low percent of energy from fats [42]. Among individuals in the unbalanced Korean dietary pattern, individuals in the extreme consumption of this pattern had a lower percent of energy from fat and increased odds of MetS [36]. Percent of energy from fat was significantly lower in MetS participants compared to normal participants [63]. In contrast, dietary total fat positively influenced metabolic syndrome in Tehranian adults but the mean percent of calories from fat was 30% [64] which is higher than our study. Longitudinal studies did not find any association between total fat and MetS but found inverse associations with vegetable fats but not animal fats [65]. Inconsistencies in findings might be due to different amounts of fats consumed in other countries vs Korea or the study designs employed. Some longitudinal studies and systematic reviews have reported no association between MUFAs, PUFAs and SFAs with MetS or CVD risk factors [65–67] suggesting that dietary sources of fatty acids rather than individual fatty acids and total fat intake should be considered in the interpretation of our findings. Culturally, meat dishes are usually consumed with vegetables, and it is notable that meat intake in Korea differs from Western style [68] which could underlie differences in the characteristics of fat intake among MetS subjects in Western countries and Korea.

Results of our study should be cautiously interpreted because of several limitations. First, because we used a cross-sectional study design, we could not examine any causal link between macronutrient intake and the risk of MetS. To be diagnosed with MetS, at least 3 or more of high blood pressure, diabetes mellitus, hypertriglyceride, low HDL-cholesterol, and abdominal obesity must be present. Therefore, it is possible that participants changed their lifestyle prior to MetS diagnosis at recruitment. Second, we used a food frequency questionnaire to assess dietary intake. Since the food frequency method relies on participant memory, dietary intake could have been over or underestimated by participants. Third, current food and nutrient intake might differ from the intake assessed at recruitment of this study. Therefore, our findings might not reflect current intake and changes in dietary intake over time. Lastly, we could not evaluate the amount of alcohol consumed by participants because alcohol intake was not quantified in the HEXA study. However, several strengths could be noted. First, our results can be generalized to the entire Korean population aged 40–69 years since we analyzed a large sample of participants. Second, we used a FFQ that was previously validated for this population[22]. Hence it is possible that we reduced the measurement error in dietary measurement.

Third, we stratified our analysis by dietary source of macronutrients to capture differential characteristics of macronutrients and MetS according to macronutrient source. Fourth, we adjusted for known confounders of dietary intake and MetS. Nevertheless, residual confounding cannot be completely excluded. Finally, we excluded participants who were undergoing treatment for any of MetS components, since these participants could have altered their nutrient intake after diagnosis.

5. Conclusion

We found low intake of total energy and fat in both men and women diagnosed with MetS, and high intake of carbohydrate and low intake of protein was only observed in women. Although people diagnosed with MetS have high carbohydrate, and low protein and fat intake, this characteristic varied according to the source of macronutrients. The intake of plant carbohydrates and protein was high, while the intake of animal carbohydrate and protein was low. On the other hand, fat consumption was low regardless of its source. Moreover, the intake of plant and animal-based macronutrients differed according to metabolic syndrome components. Longitudinal cohort studies with long follow-up duration and repeated dietary intake assessment are necessary to confirm these findings.

Author Contributions: The authors’ responsibilities were as follows: S.-A.L. —designed and conducted the research, and had primary responsibility for the final content of the manuscript; H.P. and Y.K. —analyzed the data and performed the statistical analyses; H.P. and A.K. —wrote the manuscript. All authors read and approved the final manuscript.
