Abstract: As shown previously, a relation between the superconducting transition temperature and some characteristic distance in the crystal lattice holds, which enables the calculation of the superconducting transition temperature, T_c , based only on the knowledge of the electronic configuration and of some details of the crystallographic structure. This relation was found to apply for a large number of superconductors, including the high-temperature superconductors, the iron-based materials, alkali fullerides, metallic alloys, and element superconductors. When applying this scheme called Roeser-Huber formula to Moiré-type superconductivity, i.e., magic-angle twisted bi-layer graphene (tBLG) and bi-layer WSe₂, we find that the calculated transition temperatures for tBLG are always higher than the available experimental data, e.g., for the magic angle 1.1°, we find $T_c \approx 4.2\text{--}6.7$ K. Now, the question arises why the calculation produces larger T_c 's. Two possible scenarios may answer this question: (1) The given problem for experimentalists is the fact that for electric measurements always substrates/caps are required to arrange the electric contacts. When now discussing superconductivity in atomically thin objects, also these layers may play a role forming the Moiré patterns. The consequence of such substrate-induced super-Moiré patterns is that the resulting Moiré pattern always will show a larger cell size, and thus, a lower T_c of the final structure will result. (2) A correction factor to the Roeser-Huber formalism may be required to account for the low charge carrier density of the tBLG. Here, we test both scenarios and find that the introduction of a correction factor η enables a proper calculation of T_c , reproducing the experimental data. We find that η depends exponentially on the value of T_c .

Keywords: Moiré Superconductors; twisted bilayer graphene, WSe₂, superconducting transition temperature, Roeser-Huber formula

1. Introduction

Moiré superconductivity, which was first demonstrated experimentally in 2018, involves creating large, periodic superstructures in 2D materials as compared to the atomic scale. The first sample belonging to this new family of superconductors was found when stacking two graphene layers together with a small misalignment angle, $\Theta \sim 1.1^\circ$, called also the first magic angle. This graphene stack is called twisted bilayer graphene or abbreviated tBLG [1,2]. The misalignment between the two graphene layers creates a Moiré pattern which has a spatial period, a_M , being a factor $1/\Theta$ larger than the unit cell on the atomic level. Very remarkably, the observed superconducting transition temperatures, T_c , can be several degrees K high, and the transition temperatures are highly sensitive to the misalignment angle Θ .

Since these first experimental reports, superconductivity in tBLG has been observed in ambient conditions [3–7] and under pressure [2] by other authors in the literature as well, including various angles around the magic angle, different charge carrier densities, and different thicknesses of the hexagonal boron nitride (abbreviated h-BN) layers on top and bottom of the tBLG [7]. The superconducting properties, including the critical fields and the superconducting parameters κ , λ_L and ξ of these samples, are well documented including a classification by Talantsev [8]. Furthermore, the superconductivity of a trilayer stack of graphene with a misalignment of $\pm 1.1^\circ$ was reported [9]. Arora et al.

have combined the tBLG with a monolayer of WSe₂ additional to the h-BN layers [10], and also a report of superconductivity in misaligned ($\Theta = 1^\circ, 4^\circ$) double layers of WSe₂ [11] can be found in the literature, but the data provided concerning superconductivity are less convincing as mentioned also in a recent review [12]. As superconducting domes appear in the phase diagram at different charge carrier concentrations and are separated by insulators and ferromagnets, this topic is intensively investigated by band structure calculations [13–16].

It is important to note here that Moiré patterns can be formed also in cases when different types of 2D-layered materials are stacked together, with or without angular misalignment, or between a 2D layer and a substrate [17,18]. As result, the resulting Moiré lattice parameter, a_M , may be considerably larger than the original atomic unit cells of any ingredient. Several details of the mathematics of Moiré patterns were already presented in Refs. [19–22]. Thus, the stacking of various 2D-layered materials offers a versatile new way to control superconductivity in layered 2D-systems (“Moiré-superconductors”), the full potential of which has been barely explored yet [23]. Thus, to further investigate this field and unleash more possibilities to find new materials with higher T_c 's, a simple calculation procedure which can be included in machine-learning approaches, see, e.g., Refs. [24–28], is extremely useful.

As the lattice constant of the Moiré pattern is playing an important role for the observation of superconductivity, it is straightforward to follow this relation between superconductivity and the characteristic sample dimension in more detail. For high-temperature superconductors (HTSc), and later also for iron-based superconductors (IBS), fullerenes, elemental superconductors and metallic alloys, the Roeser-Huber formula was developed to calculate the superconducting transition temperature, T_c , which only requires to find a characteristic length of the sample crystallography, x , and some knowledge about the electronic configuration [29–36]. All this information may be found in existing databases. Using the Roeser-Huber formula, the T_c of several superconducting materials could be calculated with only a small error margin, and recently, the approach was employed to predict T_c of metallic hydrogen with different crystal lattices [37]. In case of double-doped HTSc materials (e.g., the Cu-O-plane of Bi₂Sr₂CaCu₂O_{8+δ} (Bi-2212) doped by oxygen and by additional metal ions like Y or La), two characteristic doping patterns result, and the final T_c of the materials is calculated as a Moiré-pattern of the two patterns [31]. Thus, it is only straightforward to apply this calculation scheme to the real Moiré superconductors, where a clear crystallographic relation is defined by the orientation of the tBLG and by the unit cell of the tBLG itself.

In the present contribution, we present the application of the Roeser-Huber equation to Moiré superconductivity using the existing literature data for comparison.

2. Materials and Methods

2.1. Roeser-Huber model

The basic idea behind this approach is the view of the resistive transition to the superconducting state as a resonance effect between the superconducting charge carrier wave, λ_{cc} , and a characteristic length, $x = \lambda_{cc}/2$, in the sample. The details of this were already discussed in Refs. [29,30,35]. The Roeser-Huber-equation, originally obtained for high- T_c superconductors, is written as

$$\left[(2x)^2 2M_L\right] n_0^{-2/3} \pi k_B T_c = h^2, \quad (1)$$

where h is the Planck constant, k_B the Boltzmann constant, x the characteristic atomic distance, T_c the superconducting transition temperature, M_L the mass of the charge carriers, and n_0 is a correction factor describing the number of Cu-O-planes in the HTSc unit cell. For YBa₂Cu₃O_{7-δ} with one Cu-O-plane per unit cell, we have $n_0 = 1$, and the compound Bi₂Sr₂CaCu₂O_{8+δ} (Bi-2212) with 2 Cu-O-planes per unit cell has $n_0 = 2$. Thus, n for tBLG is taken to be $n = 1$ as the two graphene layers at the magic angle give

together one superconducting unit. A system corresponding to $n_0 = 2$ would be then a stack of two 2D layers like h-BN-tBLG-h-BN-tBLG-h-BN, where the two tBLG layers are separated by a h-BN layer. As charge carrier mass, we assume in a first approximation $M_L = 2m_e$, corresponding to a Cooper pair.

An energy, $\Delta_{(0)}$, can be introduced via

$$\Delta_{(0)} = \pi k_B T_c \quad , \quad (2)$$

which may correspond to the pairing energy of the superconductor. So we can write

$$(2x)^2 \cdot 2M_L n_0^{-2/3} \cdot \Delta_{(0)} = \hbar^2 \quad . \quad (3)$$

Using eq. (2) and regrouping of the terms leads finally to

$$\Delta_{(0)} = \frac{\hbar^2}{2} \cdot \frac{1}{M_L} n_0^{2/3} \cdot \frac{1}{(2x)^2} = \pi k_B T_c \quad . \quad (4)$$

Now, the formalism described above requires only minor adaptations to the case of tBLG and its derivatives: $n_0 = 1$ was already mentioned. The Moiré lattice constant, a_M , plays the key role to describe a Moiré superconductor, so the characteristic length corresponds to $x = a_M$.

For a proper comparison of the calculated data to the experiments, T_c in the Roeser-Huber formalism is to be taken from resistance measurements as the maximum of the derivative, dR/dT , corresponding to the mean field transition temperature T_c^{MF} , which also plays an important role for the fluctuation conductivity analysis as described in Refs. [38–40]. In the literature, T_c is often derived often from 50% of the normal-state resistance, which is not necessarily the same as T_c^{MF} , especially not in the case of a two-step transition. Both these definitions of T_c are distinct from the T_c used in the Uemura plot [1,8,41,42], where the completed transition when reaching $R = 0 \, \Omega$ is considered. Other authors also have used $T_{(\text{BKT})}$, the Berezinskii–Kosterlitz–Thouless (BKT) temperature, which is well suited for describing the superconducting transition in 2D systems like the ones investigated here. Most of the approaches mentioned here have, however, problems to give a proper value of T_c when the superconducting transition is very broad, shows a secondary step, does not reach $R = 0 \, \Omega$ or when the deviation from the normal-state resistivity is difficult to be defined.

Thus, in the present work all the published resistance data were digitalized and the derivative, dR/dT , was plotted graphically to obtain values for T_c according to the demands of the Roeser-Huber formalism.

2.2. Materials

Figure 1a presents a Moiré superlattice of two graphene layers (blue, red) tilted by an angle of 5° for clarity. The resulting lattice parameter, a_M , is indicated by a black line. In Ref. [9], also a tri-layer structure was presented with the top and bottom layers tilted by $\pm 5^\circ$ with respect to the center layer. This situation is depicted in Fig. 1b.

The lattice parameter of graphene is $a_0^G = 0.246 \, \text{nm}$, and the one of WSe_2 is $a_0^{\text{WSe}_2} = 0.353 \, \text{nm}$ [43]. Then, the possible Moiré patterns of two identical layers at an angle Θ have a periodicity according to

$$a_M = a_0 / 2 \sin(\Theta/2) \quad , \quad (5)$$

with a_M denoting the lattice constant of the Moiré superlattice (MSL). Figure 1c depicts the dependence of the Moiré lattice constant, a_M , as a function of Θ for graphene as well as for WSe_2 . The first magic angle, 1.1° , is indicated by a dashed green line.

To measure the superconducting properties of tBLG by means of resistance measurements, a structure called device is fabricated using the tear-and-stack or cut-and-stack method encapsulating the tBLG between h-BN layers. This arrangement is then pat-

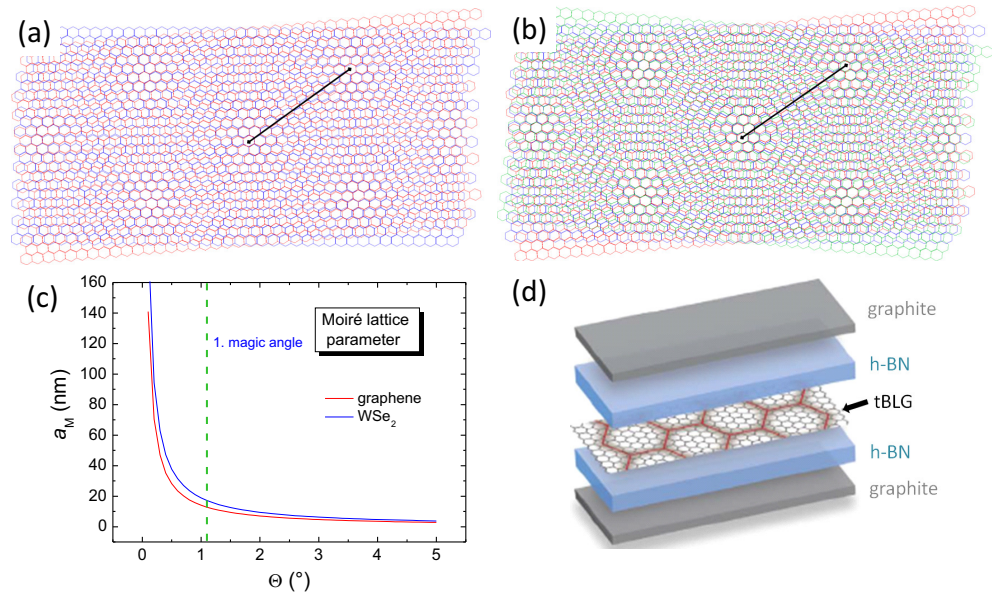

Figure 1. (a) Moiré pattern of two graphene layers (red, blue) tilted by 5° . This value was chosen for clarity. The black line indicates the resulting Moiré lattice parameter, a_M . (b) Moiré pattern of a tri-layer graphene system (red, blue, green) with the top and bottom layer tilted by $\pm 5^\circ$ with respect to the center layer. (c) Moiré lattice parameter, a_M , of graphene as function of the tilt angle, Θ . The first magic angle, 1.1° , is marked by a dashed green line (---). (d) Schematic view of the various layers in a device for resistance measurement. Figure adapted from Ref. [2].

turned into a Hall bar geometry with multiple leads using electron beam lithography and reactive ion-etching. The final device is placed on Si/SiO₂ substrate with an intermediate thick graphite layer serving as back gate. Another graphite layer on top serves for protection. This construction is required to prepare proper electric contacts to the sample. A schematic drawing of the arrangement of the various layers is given in Fig. 1d.

The accuracy achieved to determine the tilt angle of the graphene layers is typically $\sim 0.03^\circ$ [7]; Stepanov et al. describe the twist homogeneity within a device as good as 0.01° per $10 \mu\text{m}$ [6].

3. Results and Discussion

New results with much higher values of T_c were presented recently by Saito et al. [7], who also used the h-BN as top and bottom cover, but varied the tilt angle between 1.02° and 1.20° and the thickness of the h-BN layer between 6.7 nm and 68 nm. These experiments demonstrated that the device (device 5) with a tilt angle of $\Theta = 1.10\text{--}1.15^\circ$ and a h-BN thickness of 45 nm showed the highest T_c ever reported for the tBLG systems. Stepanov et al. [6] also fabricated devices with varying the h-BN thickness between 7 and 12.5 nm. Codecido et al. [4] showed superconductivity in tBLG at a much smaller angle $\Theta = 0.93^\circ$, so superconductivity does exist in a wide range around the magic angle. Lu et al. [3] have shown a complete phase diagram of their tBLG sample with four domes of superconductivity at positive and negative charge carrier densities by plotting the measured longitudinal resistance versus temperature and charge carrier density, demonstrating the experimental advances since the first reports of superconductivity in tBLG.

These results provided the base to compare the Roeser-Huber calculations with a wider experimental dataset. For comparison, we employed the data of Saito et al. (their Fig. 3c), and those of Refs. [1–6,10]. The $T_{c,\text{opt}}$ determined by Saito et al. corresponds directly to T_c^{MF} required by us, so the data can be directly compared to each other as done in Table 1 below. Table 1 presents the T_c -values of several tBLG devices of various

Figure 2. Experimental data for the superconducting transition temperature, T_c , with the respective error bars. Data taken from Saito et al. (Ref. [7]), together with data of Cao et al. [1], Yankowitz et al. [2], Lu et al. [3], Liu et al. [5], Codecido et al. [4], Stepanov et al. [6] and Arora et al. [10].

authors [1–7] together with data of a graphene tri-layer [9], the data of WSe₂-stabilized tBLG [10] and the data obtained on twisted WSe₂ bi-layers [11]. Listed are the tilt angle α , the experimentally determined value of $T_c(\text{exp})$ corresponding to our definition of T_c^{MF} , the characteristic length, x , corresponding to the Moiré lattice constant a_M , the energy $\Delta_{(0)}$ calculated using $n_0 = 1$, $M_L = 2m_e$ and the calculated values of $T_c(\text{calc})$. When doing the calculations, the calculated values $T_c(\text{calc})$ turned out to be much larger as the experimentally observed values for T_c . The first two rows give the data for tBLG at the magic angle, $\Theta = 1.1^\circ$, yielding 4.23 K with $n_0 = 1$. Using $n_0 = 2$ would lead to a T_c of 6.714 K, which is even higher and unrealistic. Table 1 shows further that the experimental variation of the tilt angle between 0.93° (the smallest tilt angle reported for superconductivity in tBLG) and 1.18° leads to T_c -values of pure tBLG ranging between 3.024 K and 4.867 K. Thus, all calculated data are clearly higher than the experimental ones. What could be the reason for this?

There are two possible scenarios to explain this outcome.

(1) The effective Moiré lattice parameter is much larger as determined by eq. (5).

This is possible when considering the fact that Moiré superlattices can be formed by all layers involved forming the device, not only the graphene bilayer as intended. The fully encapsulated graphene has necessarily two interfaces with the h-BN layers on the top and bottom, where an extra tilt can occur. Looking at Fig. 1c and eq. (5), the effect is largest at very small angles. Thus, attempting to align the top and bottom h-BN layer to the graphene may generate much larger Moiré superlattice parameters. Such a situation was discussed by Wang et al. [18].

In case of a stack of h-BN with graphene, there is a misfit between the two lattices, so the resulting superlattice can be described as [2,20]

$$a_{\text{MSL}} = \frac{(1 + \delta)a_0}{\sqrt{2(1 + \delta)(1 - \cos \Phi) + \delta^2}} \quad , \quad (6)$$

where δ denotes the lattice mismatch between h-BN and graphene (1.8 %) and Φ is the twist angle of h-BN with respect to graphene. A result of this is that the largest possible Moiré lattice constant is ~ 14 nm, which occurs when the one graphene layer is fully

Table 1. Table giving the experimental data of T_c , the angles and the resulting characteristic length, x , the calculated energy $\Delta_{(0)}$ and $T_c(\text{calc})$ using the Roeser-Huber equation (eq. 1 with $n = 1$ and $M_L = 2m_e$. The energy $\Delta_{(0)}^*$ and the transition temperature $T_c^*(\text{calc})$ are calculated using the correction factor η . Furthermore, the sample names of the original publication and the references are given. The T_c marked by † is the value claimed by the authors from a two-step transition. Our T_c determined from their data is $T_c = 0.32$ K. ‡ This value gives the zero resistance. Stars (*) mark the WSe₂ T_c -data from the experiments of An et al. [11], where the T_c values given are determined by us. (⊗) as given by the authors for $R = 0 \Omega$. (**) indicates T_c determined via a 50% normal-state resistance criterion.

aligned to the h-BN layer. Wang et al. showed that they can increase the MSL lattice parameter to 29.6 nm by aligning both h-BN layers to the graphene. Calculating T_c with this MSL parameter would yield a value of ~ 0.8 K, which would be much closer to the experimental data.

However, the high pressure experiment of Yankowitz et al. [2] and the data of Saito et al. [7] demonstrated that this explanation cannot be the solution of the present problem. The optical images of the devices presented by Cao et al. [1], Yankowitz et al. [2] and Saito et al. [7] showed all arrangements made before putting the top h-BN layer in place. Thus, the misfit would be created when placing this layer. While this scenario might have applied to the first reports of superconducting tBLG, all authors of the more recent contributions have explicitly checked for such effects and even provided a dedicated discussion in their Supplementary Data (see, e.g., Fig. S2 of Ref. [3]), so this effect can be ruled out. Furthermore, the high-pressure experiment could increase T_c from 0.6 K to 3 K with the same configuration, and the data of Saito et al. [7] showed that their experimental values of T_c are approaching the calculated ones.

(2) A new correction factor must be introduced to the Roeser-Huber equation.

The band structure calculations have shown that the charge carrier density of the tBLG at

Figure 3. The correction factor η as function of temperature. Included here are the tBLG data of Refs. [1–7], the trilayer graphene (TLG) of Hao et al. (♦, [9]), the tBLG/WSe₂ of Arora et al. (★, [10]) and the 2° WSe₂ data of An et al. (■, [11]). The violet line (—) is a fit to all data using eq. (8).

the magic angle is very small, and it is shown by Lu et al. [3] that several superconducting domes can be found when plotting the linear resistance versus carrier density and temperature, which equals a phase diagram of tBLG. Thus, this fact must be accounted for in our calculations. Cao et al. [1] showed that the effective mass of the charge carriers is only $0.2 m_e$, and in the Uemura plot (their Fig. 6), they demonstrated that the tBLG samples are located at low Fermi temperatures $T_F \approx 20$ K and $n_{2D} = 1.5 \times 10^{11} \text{ cm}^{-2}$, being clearly distinct from the HTSc.

Thus, we introduce a correction factor, η , to the charge carrier mass M_L in eq. (1) by writing:

$$M_L = \eta m_e \quad (7)$$

The situation $\eta = 2$ will then correspond to our initial value of 2. Now, we come back to Table 1. The energy $\Delta_{(0)}^*$ and the corresponding $T_c^*(\text{calc})$ were obtained by introducing the correction factor η to the Roeser-Huber equation, which is listed as well. The parameter η was obtained by adapting the calculation procedure manually to the experimentally obtained values of T_c . The result of this procedure is that we can now fully reproduce all the experimentally observed values for T_c . The slight deviations in $T_c(\text{calc})$ account for the difficulties when extracting the T_c -values. The data for the h-BN–WSe₂–tBLG–h-BN stacks of Arora et al. [10] show that the WSe₂-layer stabilizes superconductivity at angles much smaller than the magic angle, and also smaller (0.79°) as the smallest angle reported for pure tBLG. We also see that such a monolayer of WSe₂ is not superconducting on its own; Arora et al. describe the WSe₂-layer as insulating. The trilayer graphene (TLG, Hao et al. [9]) would have a quite high T_c of 8.5 K when calculating with $M_L = 2$ due to the small value of a_M . Thus, the required η is quite large and also off the fit in Fig. 3.

Figure 3 plots the resulting values for η as function of temperature. The dashed green line indicates the bottom value of $\eta = 2$, which corresponds to the case of HTSc materials. The lower the measured transition temperature, the larger the parameter η . Fitting the data with an exponential decay of the type

$$y = 2A_1 \cdot \exp((x - x_0)/t_1) \quad (8)$$

Figure 4. Roeser-Huber plot including the data of the various tBLG samples (●) and WSe₂ (●) and the previously calculated data for several HTSc and metals/alloys (■). The straight red-dotted line follows the equation for a particle in a box [44] and the blue dashed line gives the linear fit to the data (see text).

we obtain a quite good correlation with the parameters $A_1 = 14.17$, $x_0 = 0.6$ and $t_1 = 0.766$ as shown in Fig. 3. The tBLG/WSe₂-data fall below this fit line, and the TLG and WSe₂ are located above it. Furthermore, the values for η are only in a small range between 2 and 22, which is equal to the narrow window for the tBLG samples in the Uemura plot (T_c as a function of the Fermi temperature, $T_F = E_F/k_B$ with E_F denoting the Fermi energy) in a line below the HTSc samples [1,8]. As T_F is directly linked to the Fermi velocity, v_F , via

$$T_F = \frac{m^* v_F^2}{2k_B} \quad (9)$$

and

$$v_F = \frac{h}{2\pi m_e} (2\pi^2 n)^{1/3}, \quad (10)$$

there is the effective mass, m^* , and the density of the charge carriers, n , directly involved. We also must note here that η depends not only on the calculated value of T_c at a given misorientation angle Θ , but also on the charge carrier density. Thus, the parameter η determined here should contain all this information, which will then also enable to judge via the value of m^* ($m^* < 0.1m_e$) [8], if a material can be a superconductor or not. The newer experimental reports also present superconductivity measured at different superconducting domes in the phase diagram, which can be accessed at various positive and negative charge carrier densities. A dedicated analysis of all the data available (tBLG samples as well as the extreme elemental superconductors like Bi or Li) will allow to further clarify the properties of η .

The case of bi-layer WSe₂ [11] is more complicated to be solved. The first problem in the case of WSe₂ is the value for n_0 to be taken in the calculations. If a monolayer WSe₂ is superconducting itself, n_0 must be taken as 2. If only the product from two misaligned WSe₂ layers is superconducting, we would have $n_0 = 1$ like for tBLG. A first glance on Table 1 gives the idea that $n_0 = 2$ could be correct, but as seen from the combined WSe₂-tBLG-data from Arora et al. [10], we can consider $n_0 = 1$ to be the more realistic case. Thus, we have listed both cases in Table 1 to give some predictions of T_c for the WSe₂ system. As seen from Fig. 1c, the larger lattice parameter of WSe₂ will lead to

slightly larger a_M for a given angle Θ , and thus, the resulting values for T_c are higher as compared to tBLG, which is also observed experimentally [11]. The main problem is now that the experiments of Ref. [11] do not convincingly demonstrate superconductivity in this system as compared to the tBLG data, where much more detailed information is available. So it is difficult to extract properly defined values for T_c from the data presented (WSe₂ bilayers with 1°, 2° and 4° misalignment). For the 1° sample (E7), T_c could be around 3.5–4 K, for the 2° sample (F²) ~4 K (-6.65 V) or ~6 K (-6.92 V) and for the 4° sample (D11, marked by a star in Table 1), one may get T_c somewhere between 4 K and 12 K, if at all. The calculation of the Moiré pattern parameter for the 4° sample gives $a_M = 4.72$ nm, which would yield a T_c of 49.9 K (with $n_0 = 2$) or 31.13 K with $n_0 = 1$. These values for $\Delta_{(0)}$ and T_c are considerably too high and unrealistic. As the authors show in their paper higher order Laue reflexes from electron diffraction patterns for the 1° sample, which would indicate a lattice constant of the order of 20–25 nm (instead of the calculated 18.9° using eq. (5)), we have used 20 nm for x in Table 1 for the 1° sample and left the 4° sample out of further consideration. If we calculate T_c using $n_0 = 2$, the calculated values come quite close to the experimental data assuming $T_c \sim 3$ K. In all cases, the superconductivity is best documented for sample F² (their Figs. 5a and S11), yielding a T_c of 4.53 K (-6.65 V) and 6.1 (-6.92 V) at two different gate voltages. These T_c -values are clearly higher than those of tBLG, but also smaller than the calculated value of 7.78 K ($n_0 = 1$). Determining the correction factors η for this sample yields $\eta = 3.44$ and 2.55 at the two gate voltages, which are only small corrections. To summarize this part, the published data of WSe₂ are not suitable for a good comparison, but when extracting T_c via the first derivative from the published data (best for sample F²), we only require small correction factors to reproduce the experimental T_c . This would indicate that the WSe₂ bilayers have properties being more similar to that of HTSc compounds.

Finally, Fig. 4 presents the Roeser-Huber plot, now extended towards lower temperatures to include the various tBLG samples reported in the literature. The black squares (■) correspond to the data published in Ref. [35], the red data points (●) are for the various tBLG samples investigated here, and the blue bullet (●) shows the 2° WSe₂ data. The straight red-dotted line follows the equation for a particle in a box [44] with the slope $h^2/(2\pi k_B) = 5.061 \times 10^{-45} \text{ m}^2 \text{ kg K}$. The linear fit (dashed-blue line) is almost perfect with only a small error margin, which manifests the basic idea of the Roeser-Huber formalism.

Harshman and Fiory [45] presented another way of calculating the transition temperature of tBLG from experimental data. Also this approach was originally developed for HTSc samples, and the parameters involved are quite similar to those of the Roeser-Huber approach. However, there is no relation between the T_c and the crystal lattice parameters, except a distance between the superconducting layers, which in turn is not contained in the Roeser-Huber formalism. In all cases, it will be interesting to compare the various parameters of the models with each other.

So, we can say here that an extension of the Roeser-Huber formula is required to account for the low charge carrier densities and the resulting low charge carrier mass using the new parameter η . When doing so, we can directly reproduce the experimental data of the various tBLG measurements published in the literature. We also note that the calculation using $\eta = 2$, that is, a charge carrier mass of $2m_e$, gives an upper limit for T_c , to which the experiments come now close by applying pressure or using thicker h-BN layers. This observation is a very positive output for use of the Roeser-Huber equation to predict the transition temperatures of still unknown materials.

4. Conclusion

To conclude, we have shown the calculation of T_c of Moiré superconductors based on the Moiré lattice parameter. The Roeser-Huber formula in the standard form with $M_L = 2 m_e$ gives an upper limit of T_c for tBLG, which is close to the experimental

observations. Introducing a correction factor η to the Roeser-Huber formalism enables to account for the small charge carrier density and charge carrier mass, so that the experimentally obtained data can successfully be reproduced. Further work is required to find a theoretical foundation for η . For WSe_2 , the currently available experimental data are not sufficient to extract proper values for T_c to enable a proper comparison with calculated data.
