## Abstract:

(1) Teeth, represent in humans the most resilient tissues. However, exposure to concentrated acids might lead to their obliteration, thus making human identification difficult. Teeth often contain dental restorations from materials that are even more resilient to acid impact. This paper introduces novel method of 3D reconstruction of dental patterns as a crucial step for digital identification with dental records.; (2) With combination of modern methods of Micro-Computer Tomography, Cone Beam Computer Tomography, Attenuated Total Reflection in conjunction with Fourier-Transform Infrared Spectroscopy and Artificial Intelligence Convolutional Neural Network algorithms, the paper presents the way of 3D dental pattern reconstruction and human remains identification. Research studies morphology of teeth, bone, and dental materials (Amalgam, Composite, Glass-ionomer cement) under different periods of exposure to 75% sulfuric acid; (3) Results reveal significant volume loss in bone, enamel, dentine, and as well glass-ionomer cement. Results also reveal significant resistance of composite and amalgam dental materials to sulfuric acid impact, thus serving as strong parts in the dental pattern mosaic. Paper also introduces probably first successful artificial intelligence application in automated forensic CBCT segmentation.; (4) Interdisciplinary cooperation utilizing mentioned technologies can solve problem of human remains identification with 3D reconstruction of dental patterns and their 2D projections over existing ante-mortem records.

## 1. Introduction

### *Human identification from dental patterns*

Human remains are relatively easy to destroy. However, some tissues, such as bones and teeth, are more durable than others. Teeth are still not as durable as some dental materials, which can withstand not only mechanical forces but also the heat of fire, decomposition, or other means of destruction, including impact of acids. Acid destruction is often the preferred method to prevent body identification. It can dissolve DNA, metals, the whole body and liquefy even bones and teeth. Sulfuric, hydrochloric, nitric acids and their combinations are among the most frequently used acids for this purpose [1–6].

In history, there have been several acid-related crime cases. One of the first "Acid Bath Murderers" was the British killer John George Haigh, who dissolved at least six of his victims in sulfuric acid-filled barrels in the 1940s. He said the victims had completely dissolved in about two days and that he had to leave the room because the fumes were unbearable. During the police arrest, John George Haigh said, "Mrs. Durand-Deacon no longer exists, I destroyed her with acid. You can't prove murder without a body." He was arrested after the last of the murders. He has rented a workshop in Sussex, which did not have a floor drain. He therefore disposed the remains by pouring the container onto a pile of rubble at the back of the garden. The special plastic containers are used to store these aggressive substances, and a conventional bathtub, as is often visualized in films, is not a reliable container as it is itself subject to corrosion [7]. Examination of the area by pathologist revealed 12.7 kg of human, part of the human foot, gallstones, and plastic part of the denture, which was later identified during the trial as Ms. Durand-Deacon. He later confessed to another eight murders, in which he destroyed the body in a sulfuric acid bath. Haigh, whose motive was money, was finally hanged for his crimes in 1949 [8].

Total destruction is usually avoided by very few materials of a specific composition, most often plastics-composites. These can be dental materials such as root or composite fillings, plastic nails, or other composite materials. The materials that would remain would be identified with the help of 3D scanning and 3D reconstruction. Three-dimensional (3D) digital reconstruction of the most resistant parts of human remains – teeth, with their extremely specific modifications based on medical records provide the possibility of reconstruction of the so-called dental patterns. Dental patterns show considerable variability not only between age groups within the same year of birth, but also between different years for the same age group, thus offering the key distinctiveness and power of discrimination needed to forensically identify people [1–3]. Furthermore, the data obtained from dental patterns can considerably narrow the search range of an individual and thus help in the process of identifying the victim after mass disasters or criminal liquidation of a body [1,9].

After extensive destruction, as in acid, the reconstruction and identification of human remains is extremely difficult and even the most modern technologies still do not offer a textbook method for virtual reassociation for fragmented human remains [2,9–14]. The solution of the problem may lie in a multidisciplinary combination of the most modern digital methodologies linking the fields of forensic anthropology, forensic dentistry, forensic radiology, forensic chemistry and possibly with the implementation of artificial intelligence. Forensic dentistry and forensic anthropology require interdisciplinary knowledge, as information obtained from the remains can make a significantly contribution to the identification of the individual or provide the information needed in a legal process [15].

The identification of human remains, or cadavers is the central activity of forensic odontologists and anthropologists [16]. There is a considerable number of cadavers or human remains arriving at the morgues with no identity. Forensic dentistry (odontology) is a specialized field of forensic sciences, which deals with the identification of teeth and surrounding oral structures in a legal context. It brings knowledge about orofacial

structures, their variations, and consequences of dental treatment into the identification process [1,17]. Various forensic odontological techniques help to identify human remains in incidents such as traffic accidents, terrorist attacks, fires, mass murders, natural disasters, and many others [2,9]. The most often encounter the problem of comparing one victim between post-mortem findings and ante-mortem dental records. Forensic dentistry is more than 2,000 years old, having developed into a scientific discipline requiring advanced training. Since the fourth century, technological advances and modern imaging techniques and methods, including dental diagnostics and care, have advanced the profession to modern era [18,19]. Advances offer a forensic expert useful equipment that allows even archived cases to be revisited. The forensic dentistry and anthropology disciplines have expanded beyond dental identifications to include recognition and reporting of child and elder abuse, age assessment [20–25], bitemark analysis [26,27] and many more [1,2,28,29].

Identifying an unidentified body is seldom a straightforward path, and forensic dentistry has long been a reliable discipline in the process of human identification [1]. Research and identification are often based on a multidisciplinary principle and an integrated, multi-institutional coordinated approach. The combination of all available dental characteristics leads to a definition of a unique dental pattern that offers individualizing and differentiating potential regarding the process of identification [2]. The implementation of modern digital technologies offers a simplification of the reconstruction of these patterns. Digital 3D reconstruction supports effective compliance with pre-mortem dental records. In this logic, human identification through comparative dental evidence does not inevitably have to meet a minimum number of resemblances (e.g., concordant points or matching evidence), but rather a considerable number or quality of points of concordance between ante-mortem and post-mortem records (with no unexplainable differences) [30–38]. Furthermore, the process of human skeletal identification must provide conclusions about the degree of certainty or probability of identification. At this point, the new forensic identification methods based on the quantification of evidentiary value for forensic radiologic comparisons of dental patterns, are excellent. In cases of missing dental therapeutical alterations on the preserved teeth and bones, further studies, and documentation of population frequencies for skeletal and dental traits/characteristics are desired. Additional research in this area will contribute significantly to Forensic Dentistry, Forensic Anthropology and Forensic Radiology by facilitating the use of anatomical diversity for identification and can be based on advanced artificial intelligence algorithms in a near future [7,15,16].

Utilization of dental patterns for human remains computerized identification is a common and undisputed method in forensic dentistry [2,11,12,14,25,32]. Forensic experts worldwide continue to stay divided about the need for a definition of a minimum number of concordant points to confirm dental identification [30]. There rather appears to be no basis for defining this minimum and numerous studies reinforce the view that each case has its own individuality and should be treated as such [30,33–35,38,43,44].

Emerging technologies and their interdisciplinary arrangements allow more complex reconstructions of fragmented information from dental patterns preserved and reconstructed remnants of dental materials after significant acid impact. In this paper, we communicate the benefits of an interdisciplinary combination of digital photography [10,31,37], cone-beam computed tomography (CBCT) [45–47], micro computed tomography (micro-CT) [48,49], advanced Artificial Intelligence (AI) algorithms like 3D Convolutional Neural Network (CNN) algorithms [40,42,50] and Attenuated Total Reflection (ATR) in conjunction with Fourier-Transform Infrared Spectroscopy (FTIR) [51,52].

#### *Tissue destruction in acids*

Teeth are the most durable structures of a body resisting various means of destruction even more than skeletal tissue. Above-described concept of dental patterns takes

advantage of the fact, that therapeutical alterations of teeth and surrounding tissues (tooth fillings, crowns, bridges, implants and other) can be even more resilient [15]. Commercially available acids can be used to obliterate the human remains in effort to make its identification impossible. Criminals may use Sulfuric acid,  $\text{HNO}_3$ , or  $\text{HCl}$  to hinder the person identification; still, the individuals can be identified using resilient dental patterns. These frequently persist even after exposure to the concentrated acids [19,53].

Teeth can serve as a reliable tool in identification even after exposure to concentrated sulfuric acid ( $\text{H}_2\text{SO}_4$ ). In absence of matchable dental records, they frequently serve for age estimation or sex determination of the victim [54].

In a “mafia” - type crime cases, forensic experts frequently face situations where criminals were trying to destroy a cadaver by immersing it in acids. In these situations, dental patterns are represented as residues possible for identification. This paper approximates processes morphologically and chemically happening to bone and dental structures when exposed to 75% sulfuric acid. Experience of other scientists shows that teeth are completely dissolved after 14 hours of immersion in 37% solution of hydrochloric acid, while at 90 hours in 96% sulfuric acid. Even after 90 hours in 96% sulfuric acid, the destruction of the samples was still incomplete. In nitric acid the teeth undergo a complete dissolution in 12 hours, and in 17 hours in aqua regia (chloroazotic acid – hydrochloric/nitric acid 1:3). Despite exposure to acids the Mazza et al. 2005 were able to recognize the characteristic morphological features of dental tissues and structures up until the advanced stages of degradation [55].

Dental materials frequently resist decomposition and high temperatures and are among the last ones to disintegrate after death. The principles of the dental identification lie in the fact that no two oral cavities are alike, and the teeth and their therapeutical modifications (dental patterns) are unique to an individual. The dental evidence of the deceased recovered from the scene of crime/occurrence is compared with the ante-mortem records for identification. Resistance of teeth to acid exposure is remarkable among all body tissues. Dental characteristics such as morphology of the tooth, differences in size and shape, number of cusps, colour, restorations, pathologies, hypodontia, wear patterns, malocclusions and position of the tooth, and other distinctive dental anomalies give every individual a unique identity – dental pattern [56].

#### *The technology of cone-beam computed tomography*

In this paper, it is described a combination of three technologies with additional presentation of artificial intelligence algorithm for automated cone-beam computed tomography (CBCT) segmentation and digital photo matching. This novel approach for reconstruction and matching of dental patterns depends on CBCT, micro-CT and chemometric methods. These can be widened for chemometric and micro-CT evaluation of other dental materials in the future. CT scanner is a valuable tool for postmortem forensic examinations and is more than a decade a forensic routine application [57]. Post-mortem computed tomography is now routinely applied in forensic medicine due to its diagnostic accuracy not only as a diagnostic instrument that can provide support even for determination of body weight assessment prior to autopsy [58,59]. It is now an established documentation tool in forensic science.

When the problem is described as morphological destruction of tissues and experts face necessity to match it to the dental records a CBCT is the most typical available computed tomography available. It is used primarily in maxillofacial applications. CBCT may also be particularly useful in some forensic contexts, offering numerous advantages for post-mortem forensic imaging including a good resolution for skeletal forensic radiology, relatively low cost, and simplicity. CBCT may be a beneficial and accessible alternative in many cases [15,60].

Identification of unknown remains by means of dental comparison is well established in the dental forensics. Most frequently a two-dimensional (2D) intraoral photo or 2D x-

ray image from dental records are used for matching. In different levels of morphological destruction of skeletal human remains due to various reasons including acids, a reconstruction of dental patterns is a turntable approach.

If many individuals need to be identified in a short time, the dental identification can be a time and resource consuming procedure [61]. Using a CBCT unit, protocols have been developed to reproducibly and reliably reformat CBCT volumes. The reformatted images can be compared directly with conventional digital images from the same anatomic area. Images derived from CBCT volumes are similar enough to conventional dental radiographs and allow 2D dental forensic comparison and identification. CBCT offers a superior option over multi-slice CT scanners for this purpose [61,62].

As the 2D reconstruction was appropriate for matching two 2D radiographic images, it was facing a struggle to find the appropriate projection. As the dental records are typically in 2D format, it is sufficient; albeit it is not necessary to give up of the advantage of 3D reconstructed matching to the 2D image. The reconstruction of skeletal remains using conventional CBCT provide accurate three-dimensional reconstructions, which demonstrate its reliable use as a forensic tool [63].

Post-mortem dental examinations play a key role in the individual identification. In forensic dentistry, in the first step of individual identification is based on a traditional visual comparison of the ante-mortem dental record and dental radiographs with those obtained by post-mortem examinations [62]. Digitization in forensic odontology started more than 30 years ago. It enabled a new era of digital processing, nowadays leading to smart AI algorithms performing trillions of matching sequences per second, albeit yet to be established as an accurate and reliable methodologies by scientific research. Digital forensic methods are today *modus operandi* in contrast to the past, when were considered as expensive, requiring pricey special equipment [64]. Further research is currently being conducted and progress is made every day in the field of forensic odontology along with the progression of general digital technology nowadays powered by sophisticated AI algorithms [64].

Regarding the current dental records, these are changing too. Together with progress in digital diagnostics, we witness more frequent availability of 3D digital records (CBCT from dental diagnostics in orthodontics or CT and nuclear magnetic resonance images from other medical examinations). For a long time has been forensic dentistry a fundamental discipline in the post-mortem identification of human remains. Majority of forensic dental identification is established upon the comparison of two sets of records from different time. Apart from dental casts, documented dental records, and digital intraoral scans and photographs; radiographs are one of the key sources of evidence. These are being compared with concurrent images taken of the forensic subject. In the process of reconstruction of dental patterns, these examinations are performed on the remains [65].

CBCT was found to be more accurate compared to orthopantomography (OPG) in dental anatomy evaluation. This is natural as CBCT is 3D data and OPG is 2D data. For example, even a small field of view of CBCT centred on the mandibular angle of a teenager is an accurate method for dental age estimation [66].

Medical imaging technologies that are utilized to assist forensic experts define a specific subfield of forensic radiology. CBCT is frequent in forensic odontology for image analysis examinations. Forensic odontology has been developed extensively through various CBCT radiology applications. The everyday role of forensic witnesses' in analyses of bite marks, examination of trauma cases, and determination of age, sex and race are often multidisciplinary approach implementing skillsets of forensic anthropologist, radiologists, and dentists. CBCT digital radiographs help significantly in forensic identification, especially in skeletal and odontology cases [45].

### *The technology of micro computed tomography*

Present limited availability of the micro computed tomography (micro-CT) within forensic practice is the reason it remains an emerging technology. This paper puts micro-CT in the context, within the presented complex analysis, in effort to reconstruct dental patterns, facing the problem of morphological destruction of tissues. Its main value is the considerably higher level of detail when compared to CBCT. Micro-CT provides information to forensic practitioners about characteristic details accompanying the process of destruction as well as the potential details of dental procedures performed. For example, about technique of the dentist in cavity preparation or other micro details not identifiable on CBCT.

The micro-CT has in the forensic expertise a practical role to provide more details in comparison to other x-ray examinations. Its implementation in the 3D dental pattern reconstruction is to enhance forensic investigation [48].

Digital imaging techniques are used in many areas of forensic dentistry. We shall understand that these dental records were originally created on a living tissue and thus with limited radiation dose and limited accuracy. On the contrary the post-mortem records have no relevant limitations of this kind and can provide an unprecedented 3D information in significantly higher detail. Among all digital imaging modalities in dentistry, digital periapical radiography is the most frequently used; albeit with limited area covered and limited information value [15]. However, new contemporary imaging techniques like micro-computed tomography (Micro-CT) can be used in post-mortem analysis of the remains. The accuracy and reliability of enamel and dentin thickness measurement with Micro-CT was researched. Comparison was made between periapical radiographs and Micro-CT methods and there were differences evaluated between measurements by periapical radiography and Micro-CT methods. Micro-CT showed the highest accuracy. Measurements of dentin and enamel by Micro-CT is highly accurate and dependable as in the conventional methods. Micro-CT evaluations are suggested for implementation in the future anthropological studies [67].

Age estimation is a notable aspect of forensic science. Accurate age estimation methods are required for an increasing number of situations such as unidentified body remains, refugees and asylum seekers without proof of identification or other people with question of a threshold age that has arisen for legal reasons. It is a known fact that the volume of a pulp chamber of maxillary second molars has the largest correlation coefficient with age. Also, a micro-CT can be implemented for this task to provide accurate information about the volume proportion of the pulp chamber [15,68].

Micro-CT can be forensically utilized for analysis of detailed marks like saw marks created on human bones [69].

### *The technology of advanced artificial intelligence*

The advanced Artificial Intelligence (AI) algorithms proved as useful tools in processing digital data and soon will subdue the area of automatized assessment of age, sex, ethnicity, microfractures, or dental pattern identification and comparison. This is inevitable and will provide forensic expertise with unprecedented efficient analytic tools [42].

AI can be understood as a branch of computer science that describes the research and development of simulated human intelligent behaviour in machines. This involves researching methods that enable a computer to develop behaviour similar to human thinking and work independently on problems. The introduction of cone beam computed tomography (CBCT) to dental-maxillofacial radiology in the late 1990s has changed the means the profession investigates the maxillofacial complex. Dental providers, who were previously limited to 2D images of truly 3D anatomical structures, suddenly gained the ability to visualize the hard tissues of the head and neck region in all desired planes as well as in 3D reconstructions. CBCT scans may reveal a concealed pathology and produce incidental findings of forensic significance located in structures outside of conventional

area of focus. Incidental findings on CBCT were reported with the frequency of 3.2 findings per CBCT scan. The most frequent incidental findings recognised by CBCT were malignancy, maxillary sinus pathology and ameloblastoma [40].

This paper introduces first practical forensic implementation of AI algorithm used for auto-segmentation of the mandible, mandibular teeth, and their sockets as well as the canal of mandibular nerve .

The AI algorithms will bring unprecedented analytical tools; however, they need to be trained first. For this a vast amount of data is necessary. In the forensic radiology discipline, a specific algorithm can be created to further help with identification of distinct microscopic characteristics forming an array of specific topographies in 3D. Such a 3D array would represent a new form of AI – identified dental pattern, hardly comprehensible with a human brain. AI is advancing in the field of dental radiology and will bring a change in thinking within the next decade [40,42,70–81].

Dental records play a key role as well for AI in modern forensic identification. Post-mortem dental patterns reconstructed possibly with AI algorithms will be compared to considerable amounts of digital records of variable quality, covered anatomical region, time of origin or type of diagnostic technology. Technologies used today providing data that can contribute to final completion of mosaic are 3D intraoral optical scan, 3D CBCT scan of the skull, 3D nuclear magnetic resonance scan of the head, 3D lidar face scan, 3D ultrasonographic scan of submandibular region, 2D dental local x-ray scans or orthopantomography scan and many more. Most of them are dismissed today as they are too difficult to implement and research has not proved them to be accurate for the final matching, yet. This wide variety of possibly hundreds medical and dental records are as well randomly distributed in time from childhood until the final days. Ability of AI to simulate aging, based on big data trained networks, this can help adapt these records in time and incorporate them valuably into the final mosaic of the reconstructed dental pattern [42].

With narrowed focus, currently, dental findings and teeth conditions are recorded in a dental chart and compared with those of ante-mortem records. However, this is a physically and mentally laborious task, when managed by human force, especially in large scale disasters. AI can be utilized to automate and enhance this process. Contrasting the conventional approaches, AI methods are useful in gaining extraordinary classification correctness without the necessity for extremely precise tooth segmentation. The AI tooth automated classification method can be useful in automatic filing of dental charts for forensic identification [82].

Currently the quantity of studies describing the utilization of AI in the forensic aspects is rather low. Nevertheless, AI developments in prosthodontics are demonstrating its feasible application for automated diagnostics, and as an effective classification or identification tool. In the future, AI technologies will likely be used for collecting, processing, and organizing patient-related datasets to provide patient-centred, individualized dental treatment [83]. A wide range of “enablers” for AI clinical implementation in the dental diagnostics are already known. Opinion leaders in the field will consider these aspects to foster further implementation of AI in dentistry [84].

A novel AI system based on deep learning methods, which was used for the mandible auto-segmentation presented in this paper, was scientifically evaluated in the past (Ezhov et al. 2021). This research assessed real-time AI performance on CBCT identification of anatomical landmarks, pathologies and general clinical effectiveness when used by dentists in a clinical setting [42]. The study of Ezhov et al. showed that the proposed AI system significantly improved the diagnostic capabilities of participating dentists [50].

The success of the artificial intelligence (AI) system in dental implant planning using three-dimensional cone-beam computed tomography (CBCT) images has been published recently. Further development of AI systems and their utilization in implant planning will facilitate the work of dentists with a support system for the future implantology practice [85].

AI has proven efficient as well in detecting impacted third molars on cone-beam computed tomography scans. Diagnostic performance of AI application evaluating the impacted third molar teeth in CBCT images was clinically evaluated. The AI application indicated high accuracy values in the recognition of impacted third molar teeth and their relationship to surrounding anatomical structures [86]. The effectivity of AI in the identification of periapical pathosis on CBCT scans is impressive as well. Diagnostic performance of an AI system based on the deep convolutional neural network method to detect periapical pathosis on CBCT images has been evaluated in the past. Research of Orhan et al. 2020 of the deep convolutional neural network system showed the system was successful in detecting teeth and numbering specific teeth. Only a single tooth was not correctly identified [86]. The AI system was able to detect 142 of total 153 periapical lesions. The reliability of correctly detecting a periapical lesion was 92.8%. The deep Convolutional Neural Network (CNN) volumetric measurements of the lesions were comparable to those with manual segmentation. AI systems based on deep learning methods can be useful for detecting periapical pathosis on CBCT images for clinical application [87].

AI technology is still currently underestimated in the clinical implementations in forensic anthropology, dentistry, radiology, and chemistry. It will undoubtedly shift the paradigm in this area [42,70,73,80,88–94].

#### *The technology of Infrared spectroscopy for chemometric forensic evaluation*

Application of chemistry and its subfield, forensic toxicology, in a legal setting defines the Forensic chemistry. The identification of unknown materials found at a crime scene can be processed with a forensic chemist. In the focus of this article the bone and tooth tissues including dental fillings undergo particular chemical changes when exposed to 75% sulfuric acid. Specialists in this field use a wide array of methods and instruments to help identify chemical composition of unknown substances. One these technologies implemented in this article them is Attenuated Total Reflection (ATR) in conjunction with Fourier-Transform Infrared Spectroscopy (FTIR). This is the final pillar of a novel hybrid and complex forensic approach for reconstruction of dental patterns, introduced with the assessed model in this paper.

Chemical analysis of mineralized tissues is extensively supported with the FTIR during the past few decades. FTIR is a perfect method to analyse chemical structural properties of unknown materials since the frequencies of various vibrational modes of organic and inorganic molecules are active in the infrared spectre. FTIR methodology, in conjunction with the attenuated total reflection (ATR) sampling mode, is suitable particularly for characterization of enamel, dentin and bone tissues. These are composed of a mineral and an organic phase. The mineral phase is differentiated as nonstoichiometric substituted apatite, being the carbonate and phosphate spectral peaks the main representative of these phase. Organic matrix of the post-eruptive enamel is small (~1% weight). The dentin and bone organic phases are mainly composed of type I collagen that appears as spectral bands of amide I, amide II, amide III bands [95].

With a shortfall of dependable and precise techniques, determination of the post-mortem interval of human skeletal remains is one of the most challenging tasks in forensic medicine. Numerous studies of the changes to bone chemistry were using FTIR spectroscopy in conjunction with other chemometrics methods. For example, research published with Wang et al. 2017 evaluated paired bone samples collected from fifty-six human corpses that were buried (in soil) and unburied (exposed to the air) for intervals between seventy-six and 552 days. This paper demonstrates the viability of FTIR utilization and chemometrics as an appealing option for post-mortem interval estimation of human remains and the noteworthy potential of these methods in real forensic cases [96].

Another remarkable utilization of ATR-FTIR was published with Chopi et al. in 2020. Human lips are often covered with lipsticks layer. Due to its prevalence, it can be frequently encountered at the crime scene as evidence. ATR-FTIR analyses of such

exhibits can deliver evidence to link the suspect with the victim or with the crime scene or support the victim identification. In this study, thirty-eight different red shade lipsticks of twenty different manufacturers were analysed using ATR-FT-IR (attenuated total reflectance-Fourier transform-infrared) spectroscopy. Chemometric procedures: linear discriminant analysis and principal component analysis, utilized to provide unbiased interpretation of results resulted in 100% discriminating power and 81.48% correct classification respectively [97]. However, this application indicates the path of enhancing the dental pattern reconstruction protocol with dental material chemical changes as a vital part.

Numerous dental materials may possibly contain gelatine which is a protein obtained either from piggish, bovine, or other animal sources. ATR-FTIR can be utilized as a reliable tool to discover gelatine in dental materials and other pharmaceuticals [98]. ATR-FTIR can be utilized to as a simple, sensitive, and non-destructive technique for characterizing dental enamel erosion. In forensic aspects, a simple, non-destructive method with sufficient sensitivity and accuracy is required, albeit several either destructive or complicated techniques are available [99].

Dental materials exposed to chemically or otherwise destructive force undergo dynamic process that might stop on a particular level. Even aging of the dental material might render chemical changes. For example, in methacrylate peak determination, ATR-FTIR can be utilized to investigate polymerization of dental methacrylate mixtures. Numerous dental studies investigate polymerization kinetics with ATR-FTIR utilization, however, peak selection techniques to determine monomer-polymer transformation can differ, subsequently altering results. ATR-FTIR can reliably evaluate polymerization of methacrylate and is therefore suitable for forensic analysis as well [100].

ATR-FTIR mapping can be applied to screening in situ bone and teeth preservation in several modern and archaeological samples. It allows multi-scale and multi-technique approaches with the potential to identify the better-preserved areas in fossils. Bones and teeth are highly hierarchically structured and heterogeneous materials, and post-mortem processes can reinforce this heterogeneity. In the research of Lebon et al. from 2014, ATR-FTIR mapping technique was applied to some archaeological samples. ATR-FTIR mapping delivered spatially resolved information on alteration state of mineral and organic matter. FTIR-ATR is a powerful tool that allows identification and characterization of local heterogeneities in bone preservation. This method begins new possibilities to reconstruct the taphonomical history of ancient samples [51]. ATR-FTIR is also suitable for assessment of surface alteration of human tooth enamel exposed to acidic and neutral 30% hydrogen peroxide in terms of chemical structure, mechanical property, surface morphology and tooth colour. The research of Sun et al. 2011, proposed that neutral 30% hydrogen peroxide had the same efficiency in tooth bleaching, and it caused less deleterious effects on enamel than acidic 30% hydrogen peroxide [101].

ATR-FTIR analysis was also used in evaluation of possible differences in the chemical structure of orthodontic aligner materials [102].

A forensic investigation of single human hair fibres using FTIR-ATR spectroscopy and chemometric evaluation was performed and published by Barton in 2011. Human hair strands are ubiquitous in nature and are found frequently at crime scenes regularly because of exchange between the offender, victim and/or the environments. Therefore, hair fibre evidence can provide valuable information for crime investigation. For human hair evidence, the modern forensic techniques of analysis depend on comparisons of either hair morphology by microscopic examination or nuclear and mitochondrial DNA analyses. Unfortunately, in some cases the application of microscopy and DNA analyses are often not possible. Barton has presented a protocol as a systematic method to rapidly investigate unknown or questioned single human hair using FTIR-ATR spectra from different genders and racial origin, including fibres of different cosmetic treatments. Unknown or questioned spectra were first separated based on chemical treatment i.e., untreated, mildly treated or chemically treated, genders, and racial origin i.e., Asian, Caucasian, and African type. The approach has accompanied the current forensic analysis

methods of fibre evidence (i.e., Microscopy and DNA), offering information on the morphological, genetic, and structural levels [103].

Human and non-human identification of unknown remains is important in forensic and anthropologic contexts. However, the traditional morphological methods for bone species identification are subjective or time-consuming. With utilization of FTIR spectroscopy and chemometric methods forensic experts can determinate the spectral variances between human and non-human (i.e., pig, goat, and cow) bones. FTIR spectroscopy is a reliable tool to assist in bone species determination and has exciting potential in real forensic cases [104].

Utilization of ATR-FTIR spectroscopy in separating forensic, WWII, and archaeological human skeletal remains is also common. As ATR-FTIR spectroscopy is recognized as a quick and available, minimally, or non-destructive method which provides information on physiochemical characteristics of analysed materials. In forensic and archaeological sciences, it is commonly used for answering numerous questions, including the archaeological or forensic context of the human skeletal remains. Results of research published by Leskovar et al. 2019, showed that employing whole spectral domains works best for the separation of archaeological, WWII, and forensic samples, even with samples of highly variable origin [105].

#### *Aim, highlights, and principal conclusion*

Aim of this article is to introduce a novel multidisciplinary approach for forensic human identification from acid-obliterated remains based on dental pattern reconstruction.

Highlights of the article are:

- Human mandible with post-mortem treated teeth was degraded in 75% sulfuric acid and accompanying morphological and chemical changes were documented.
- CBCT and Micro-CT technologies were used for 3D reconstruction of dental patterns
- ATR-FTIR spectroscopy was utilized to investigate the of human skeletal remains.
- Advanced AI – CNN algorithm was utilized for automated mandible segmentation.
- This research provides unprecedented 3D morphological set of four stages of degradation of human mandibular bone and teeth presented on five different regions/samples.

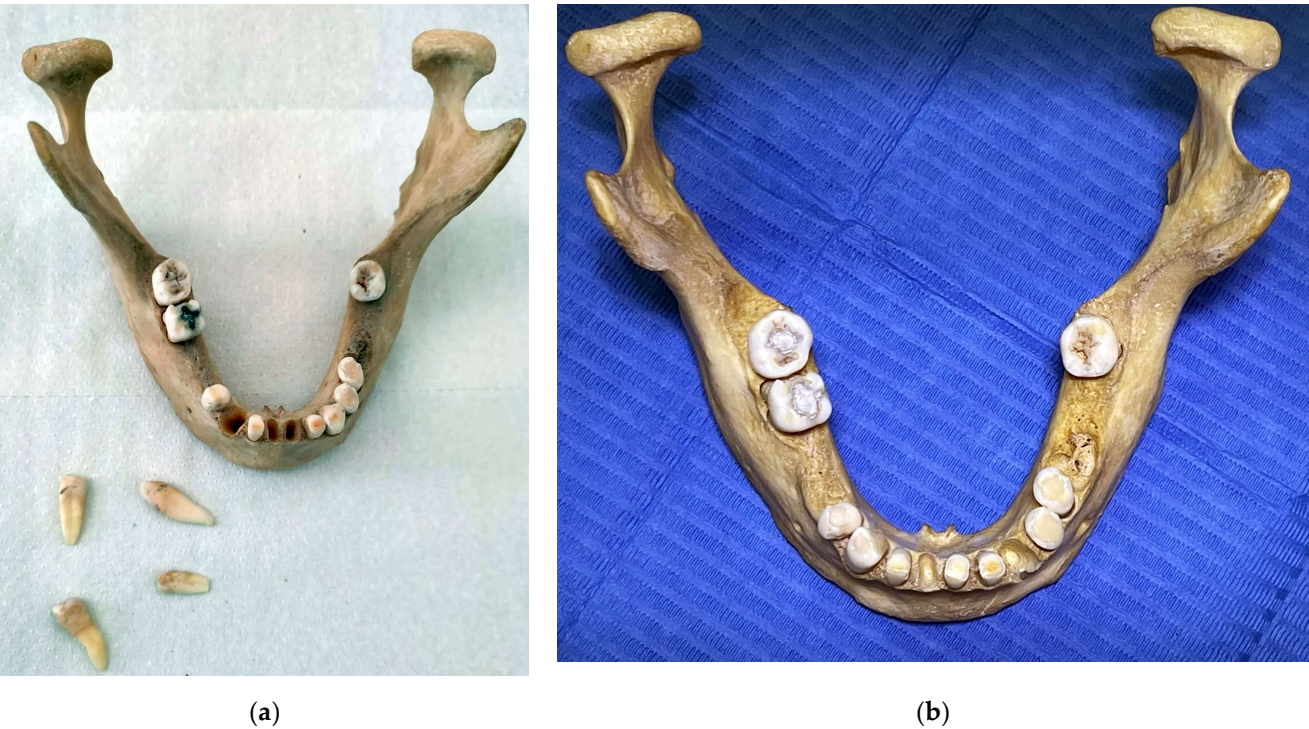

The principal conclusion of the article is that combined multidisciplinary effort of experts from forensic dentistry, forensic anthropology, forensic radiology, and forensic chemistry can reconstruct dental pattern from even acid-obliterated human remains and use it for successful identification.

## **2. Materials and Methods**

The primary working hypothesis for this research was that dental restorations can resist the degradation effect of 75% sulfuric acid more than dental tissues.

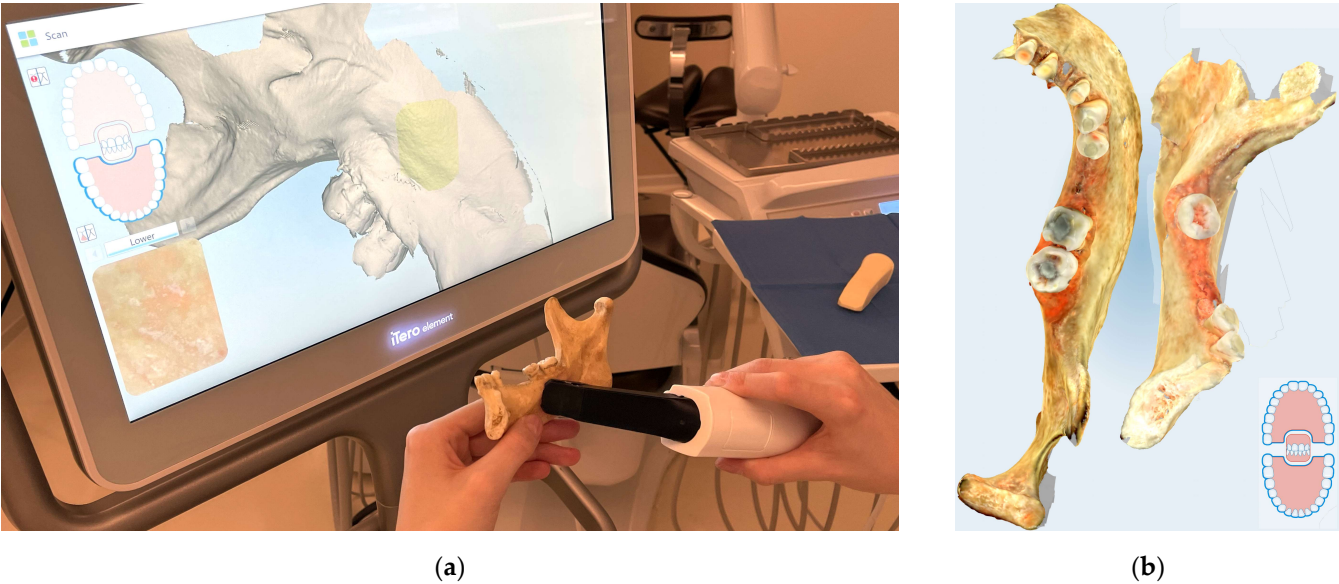

The secondary hypothesis was premising that 3D reconstructed dental patterns can be utilized for matching with 2D dental records represented with intraoral digital photo and OPG scan.

The bone of human mandible with teeth (**Figure 1 a, b**), described in this article, was donated from Institute of Forensic Medical Expertise – Forensic.sk. It originated as a random anonymous finding during excavation of a cancelled cemetery and was intended for disposal. It was found without a remaining skeleton and collected by forensic experts for scientific research more than 20 years ago.

**Figure 1.** The human mandible with teeth: (a) Before creating dental preparations; (b) After preparations and CBCT scan.

Digital optical scanning of the original mandible was performed with iTero Element intraoral scanner and exported to STL (Figure 2 a, b). Models from this output were compared to segmented models from CBCT to prove this optional step as a valid procedure. Only one initial scan was created and was sufficiently accurate in comparison to segmented CBCT mandibular surface (Figure 2 b).

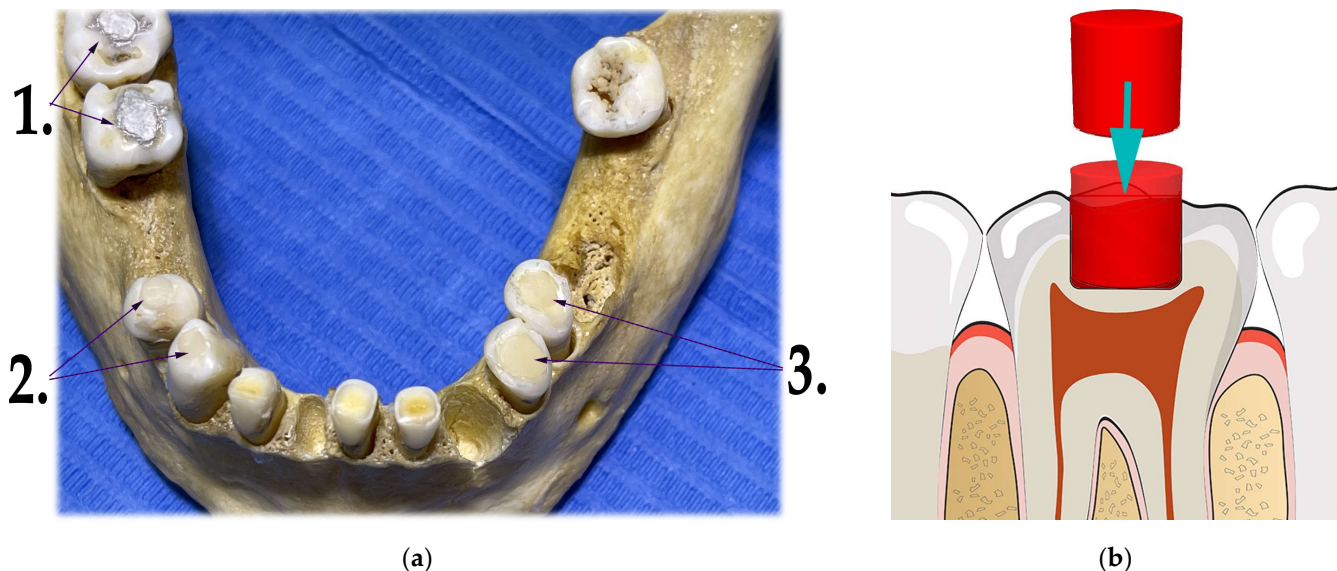

**Figure 2.** Optical scanning of the mandible: (a) iTero Element intraoral scanner and other scanners are commonly available; (b) PLY/STL export for comparison to the CBCT segmented models. This approach confirmed sufficient accuracy of the surface scan, albeit remains optional, as the surface scan has no morphological information about the inner structure.

In three pairs of teeth, dental fillings of a special shape were created with three different dental materials (**Figure 3 a**). Older dental filling was removed. The objective was to create a plane surface that would be extending the surrounding enamel surface to allow contact with the FTIR sensor (**Figure 3 b**). Later the objective of FTIR examination of dental fillings has been abandoned due to possible breakage of the whole tooth in later stages of the degradation process. Three pairs of tooth fillings were created from the following dental materials:

1. Dental amalgam - Ana 2000 Capsules Non-Gamma Two, Extra High Copper (Contains: 43% Silver, 26.1% Copper, 30.8% Tin)
2. Glass ionomer - GC FUJI IX GP wear-resistant multipurpose (Contains: Powder: 95% Fluoro alumino silicate glass, 5% Polyacrylic acid powder; Liquid: 40% Polyacrylic acid and tartaric acid, 50% Distilled water, 10% Polybasic carboxylic acid)
3. Dental composite - Neo Spectra ST (Contains: Methacrylate modified polysiloxane, Dimethacrylate resins, fluorescent pigment, UV stabilizer, Camphorquinone, Ethyl-4 (dimethylamino)benzoate, Bis (4-methyl-phenyl) iodonium hexafluorophosphate, Barium-aluminium-borosilicate glass, Ytterbium fluoride, Iron oxide pigments and titanium oxide pigments according to shade). Prime & Bond Universal were used as adhesive system in preparation with composite.

**Figure 3.** Dental fillings made on the teeth post-mortem: (a) Three dental materials were used in dental restorations: (1) Amalgam Extra High Copper Non-Gamma Two - Ana 2000 Capsules, (2) Glass ionomer - GC FUJI IX GP wear-resistant, (3) Photo-composite methacrylate resin - Neo Spectra ST (Methacrylate modified polysiloxane); (b) The filling was created with occlusal part above the enamel surface with horizontal plane with intention to support the contact with the FTIR sensor. This objective has been abandoned due to high probability of tooth destruction in later stages of the acid-degradation process.

CBCT used for scanning (**Figure 4 a, b**) was performed with Planmeca ProMax 3D Mid CBCT with the following parameters:

- Panoramic exposure with following settings and values: 2D Panoramic, Standard, Patient size M = Medium-sized adult, 67kV, 11mA, 15s
- 3D exposure was performed with following settings: CBCT Volume Ø100x100 in High Definition (HD) mode, voxel size 150µm
- Two pairs of OPG and CBCT were created. First scan before teeth preparative treatment and final scan after preparation.

**Figure 4.** CBCT scanning with Planmeca ProMax 3D Mid CBCT: (a) Positioning of the mandible consisting of two fragments and stabilization of teeth in the sockets; (b) OPG and CBCT scans were created before and after dental restorations were made.

The final CBCT scan with custom post-mortem dental preparation was subjected to manual and as well a novel advanced AI CNN algorithm for segmentation of teeth and jaw.

For manual segmentation was used full version of software Invivo dental 6.5 (Anatomage, Inc., Santa Clara, CA, USA). For AI automated segmentation the mandibular segment, teeth, dental sockets, and canal for mandibular nerve were segmented with Diagnocat on-line program (LLC "DIAGNOCAT" Moscow, Russia) (**Figure 5**). This solution processed the CBCT scan of the mandible within five minutes and created STL segments of described anatomical structures with the use of convolutional neural network [50,85–87]. The STL segments were downloaded from this program and stored on computer.

**Figure 5.** AI automated segmentation of the mandible with on-line tool Diagnocat: (a) Separate segments of teeth, bone, and nerve canal can be visualized with distinct colours, opacity and exported as separate STLs; (b) Scan of teeth without preparations shows unfinished recognition of the right mandibular canal and cut of distal parts of wisdom teeth.

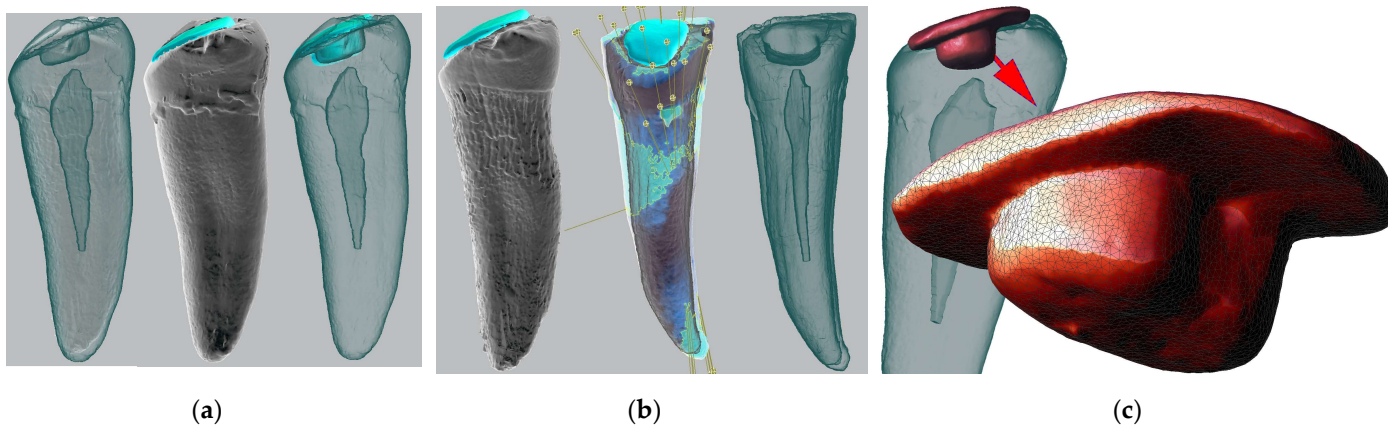

After CBCT scanning the mandible has been cut into five segments (**Figure 6**) and scanned initially with X-ray micro-CT.

**Figure 6.** The mandible was cut into five segments labelled (47, 43, 38, 32 and 33) to allow repeated sequences of sulfuric acid bath, triple washing, drying, photographing and Micro-CT scanning.

Micro-CT scans were created using microtomography system Nanotom180 (GE Phoenix). The X-ray tube was equipped with a tungsten target and micro-focusing mode M0 was applied. For standard micro-CT scan of a tooth the following settings were used: accelerating voltage  $U=150$  kV, beam current  $I=80$   $\mu$ A, detector sampling time  $t=750$  ms. Voxel size was twenty  $\mu$ m and totally 1,800 X-ray projections were recorded during one CT scan. For filtering of outgoing X-ray beam a 0.2 mm Cu plate was used.

For micro-CT scans of a tooth with amalgam filling different settings were used: accelerating voltage  $U=170$  kV, beam current  $I=90$   $\mu$ A, detector sampling time  $t=500$  ms and pixel binning 2x2 was applied. For filtering of outgoing X-ray beam a 0.5 mm Sn plate was used. The 3D volume reconstruction was done using Phoenix datos|x CT software using Feldkamp filtered back-projection algorithm. The 3D data sets were rendered and segmented using VGStudio MAX 2.1 software. For the segmentation of volume data, the region growing method was mostly used along with the opening/closing and erosion/dilation image processing techniques (**Figure 7 a, b, c**). The segmented 3D model of the preserved dental filling is a crucial part of dental pattern and will be used in matching to different 2D projections from pre-mortem dental records (**Figure 7 c**).

**Figure 7.** Outputs from micro-CT segmentation: (a) Original segment of tooth 34 before acid bath; (b) segments of tooth and dental filling after 96 hours in acid bath; (c) 3D reconstructed dental filling for future projections over various 2D (typically) diagnostic pre-mortem dental record (x-rays, digital intraoral photography).

The five segments of the mandibular bone with treated and untreated teeth were exposed to 75% sulfuric acid in sequential exposition after 2, 6 and 24 hours. After each exposition, the specimens were washed and dried and a Micro-CT scan was performed on every sample. There were 4 Micro-CT scans for each sample and each scan was segmented into bone part and tooth part as a separate STL (**Figure 8**). Set of output STLs were made publicly available on-line. Visualizations of micro-CT segmentation outputs of all five samples are summarized in detail in **Appendix** section of this article as well as digital photo documentation.

Samples of bones and teeth were submerged in the 75% sulfuric acid. This concentration was chosen after consideration together with expert chemists in the scientific team and upon the field experience of forensic experts in the team regarding their recommendations and other aspects that shall not be publicly disclosed. There is known a substantial difference of  $\text{H}_2\text{SO}_4$  dynamics in the process of bone degradation dependent on its concentration. More aggressive degradation take place with less concentrated  $\text{H}_2\text{SO}_4$ .

**Figure 8.** There were four micro-CT scans made for each sample and each scan was segmented into three parts: bone, tooth, and in case of treated tooth, also with dental material part. On this picture is preparation with photo-composite resin on tooth 34 from the segment labelled “33” after exposure to 75% sulfuric acid after various times of exposure. It is obvious the composite filling is not losing the volume in the acid bath in contrast to remaining tooth structures.

After timed exposure, all five samples were taken out from the acid bath and were washed three times in deionized water and then dried in a multifunctional oven APT Line Series FED with the regulation R 3.1 by Fisher Scientific at the temperature of 40 °C for 60 minutes. At this time of intermission, micro-CT scan was performed after 2, 6, 24 and 96 hours. As well the ATR-FTIR spectra were measured, however, only after 2, 6 and 24 hours. The ATR-FTIR was not measurable after 96 hours of acid exposure as the samples were too fragile and ATR-FTIR measurement would represent a significant risk of the sample mechanical destruction.

Subsequently, after the measurements the samples were re-immersed in fresh / new sulfuric acid (75% H<sub>2</sub>SO<sub>4</sub>) and the whole procedure was repeated.

Method of ATR FTIR spectroscopy was performed with the following setting. Attenuated Total Reflectance (ATR) mode FTIR spectra of bone and teeth samples were acquired using FTIR spectrophotometer Varian Excalibur Digilab FTS 3000MX, (Palo Alto, CA, USA), equipped with the ATR adapter with diamond crystal. The measurement range was from 4000 to 600 cm<sup>-1</sup>; resolution 4 cm<sup>-1</sup>, sensitivity 8; 30 scans. The background was air. Three different spectra in various places were measured, averaged, and evaluated using Origin (version 8.5, MicroCal) software.

### 3. Results

#### 3.1. Descriptive morphological evaluation based on micro-CT analysis

Significant volume loss was observed on segments of bone, teeth, and glass-ionomer cement. Insignificant volume loss was detected on amalgam (<0.1%). No volume loss was detected on photo-composite dental material. Volumetric changes after 6, 24 and 96 hours are visualized in the (Figure 9) and detailed in Table 1.

**Figure 9.** Graph representing volume loss over time in tooth, bone, composite, glass ionomer cement, and amalgam. The representation of photo-composite resin is hidden behind amalgam.

**Table 1.** Volume loss of dental materials and bone after exposure to 75% sulfuric acid.

time (h)	0	6	24	96
	volume <sub>0 h</sub> (mm <sup>3</sup> )	volume <sub>6 h</sub> (mm <sup>3</sup> )	volume <sub>24 h</sub> (mm <sup>3</sup> )	volume <sub>96 h</sub> (mm <sup>3</sup> )
sample 32

<sup>1</sup> No values for glass ionomer are a result of drop-out of the tooth filling during washing or drying process and skipping a round of Micro-CT scanning. However later to be found in the plastic sieves used in the process of washing.

### 3.2. Digital matching and AI implementation in CBCT segmentation

Digital matching of 3D reconstructed dental fillings, segmented from micro-CT, which survived acid bath, was successfully performed on all four localizations (2x amalgam, 2x composite). Restorations with glass ionomer cement dissolved and was not reproducible. One of the exemplary matchings over digital OPG is visualized on (Figure 10).

**Figure 10.** Reconstructed dental pattern of restoration from tooth 43 matched to 2D representing volume loss over time in tooth, bone, composite, glass ionomer cement, and amalgam. The representation of photo-composite resin is hidden behind amalgam.

Optional objective to compare manual (software) and AI segmentation methods of CBCT was fulfilled. This is possibly first implementation of advanced Artificial Intelligence algorithm utilization in clinical forensic research. The result of successful AI automatic segmentation took less than 5 minutes and provided comparable results to manual segmentation which took more than 2 hours to a human operator. Small errors were observed in nerve canal segmentation and distal part of terminal molar contours (**Figure 5b**).

### 3.3. ATR FTIR spectroscopy

ATR FTIR spectroscopy was used to evaluate the chemical changes of the bone due to its degradation by 75% sulfuric acid. The spectrum of the original sample in (**Figure 11a**) contains characteristic bands of both organic and inorganic bone components. Amide I band at  $1635\text{ cm}^{-1}$  and amide II band at  $1540\text{ cm}^{-1}$ , as well as weak bands at  $3080\text{ cm}^{-1}$  (Amide B) and  $1240\text{ cm}^{-1}$  are characteristic of the collagen, which is a major organic component of bones [106]. The absorption band at  $1020\text{ cm}^{-1}$  belongs to the phosphate group of hydroxyapatites (bioapatite,  $\text{Ca}_5(\text{PO}_4)_3\text{OH}$ ), the main inorganic component of bone, the bands at  $1460$ ,  $1418$  and  $874\text{ cm}^{-1}$  belong to the carbonate group in  $\text{CaCO}_3$  [107].

After immersion of the bone in 75% sulfuric acid, the bands drop already after two hours, mainly in the amide region, which indicates a preferential removal of collagen from the bone surface. Significant bands are formed at  $1100$  and  $1150\text{ cm}^{-1}$  (typical of the sulphate group in the calcium sulphate), which indicates the formation of a layer of calcium sulphate on the surface of the samples. Since the beam penetration depth at our ATR FTIR setting is  $1 - 4\text{ mm}$  ( $1\text{ mm}$  at  $4000\text{ cm}^{-1}$  and  $4\text{ mm}$  at  $600\text{ cm}^{-1}$ ), we measure only a thin surface layer, and the dominant bands belong to calcium sulphate forming on the surface after a brief time. This complicates the process of evaluating changes in the material and limits us to measuring surfaces. Measurement of ATR FTIR after more than 24 hours failed to perform due to mechanical disruption of degraded bones due to pressure. The accumulation of calcium compounds on the bone surface was also confirmed by X-ray fluorescence (XRF) measurements, where after a brief time there was an increase in the calcium content compared to phosphorus. XRF is a non-destructive analytical method used to define the elemental composition of materials. XRF analysers decide the chemistry of a sample by calculating the fluorescent (or secondary) X-ray emitted from a sample when it is excited by a primary X-ray source.

**Figure 11.** ATR FTIR spectra of bone (a) and tooth (b) immersed in 75% sulfuric acid for 2 h (blue line), 6 h (red line), 24 h (green line) and original sample (black line).

With the same measurements on the model tooth (**Figure 11 b**), teeth showed as more stable and were naturally expected to last longer than bone [52]. The main absorption bands of the tooth are in the same areas as the bone. The band at  $1020\text{ cm}^{-1}$  was retained after six and partly after 24 hours in sulfuric acid, while the absorption bands belonging to collagen ( $1641$  and  $1540\text{ cm}^{-1}$ ) decreased significantly, thus leading to a faster loss of organic components. In the spectra measured at different times of acid action, there is not only a simple decrease in bands, but the differences are larger (e.g., between two and six hours of exposure to 75% sulfuric acid), which is related to the fact that the tooth is a multilayer material and after dissolving the enamel we can observe dentin (the spectrum after 6 h of sulfuric acid treatment corresponds to the spectrum of dentin, where bands between  $1410$  and  $1650\text{ cm}^{-1}$  are typical for carbonate overlapped with collagen) [95]. As in the case of bone,  $\text{CaSO}_4$  formation was observed also on the tooth surface in all the samples.

**Figure 12.** FTIR spectrophotometer Varian Excalibur Digilab FTS 3000MX, (Palo Alto, CA, USA), equipped with the ATR adapter with diamond crystal (a) sample placed in the spectrophotometer; (b) example of fragile sample 33 after 96h of acid bath exposure – not suitable for sensor pressure.

#### 4. Discussion

Results showed outstanding resistance of high copper non-gamma two amalgam and photo-composite resin to impact of 75% sulfuric acid. Even after 96 hours in the 75% sulfuric acid bath the volumetric loss was less approximately 0.1% in amalgam and none in photo-composite (**Table 1** and **Figure 9**). These findings correlate to complex research presented in the master thesis of Trapp 2018 from School of Medicine Boston University [108,109] that provides comprehensive research of the effects of household corrosive substances on teeth restorations. Particularly the author provides an evaluation of effect of solution of 93.2% sulfuric acid on silver amalgam (Figure 4.3, page 62 [108]). The silver amalgam tooth filling had minimal changes and was as well resistant to sulfuric acid even after 264 hour-exposure. To approximate these findings, it is important to understand difference between high silver and high copper amalgam (**Table 2**). In general, the high copper amalgam is stronger, and it might be expected even more resilient to sulfuric acid solutions than high silver amalgam.

**Table 2.** Comparison of high silver and high copper amalgam

<b>high silver amalgam</b> ANA 70   Nordiska Dental	<b>high copper amalgam</b> ANA2000   Nordiska Dental
Silver shining	Long-lasting, resistant, and strong
Dimensional change: 24 h +0,1%	Dimensional change: 24 h +0,02%
<b>PHYSICAL PROPERTIES</b>	<b>PHYSICAL PROPERTIES</b>
Compressive strength: 1h - 110 MPa 24h - 420 MPa	Compressive strength: 1h - 140 MPa 24h - 450 MPa
<b>ALLOY COMPOSITION</b>	<b>ALLOY COMPOSITION</b>
Ag 69,9%	Ag 43,1%
Sn 18,8%	Sn 30,8%
Cu 10,2%	Cu 26,1%
Zn 1,1%	

However, this resistance to sulfuric acid was not shared with the third used dental material - glass-ionomer cement. The glass-ionomer preparation dissolved completely after 96 hours. Results suggest that the dental restorations from typical dental restorations as high copper non-gamma two amalgam and photo-composite methacrylate resins, have minimal volume loss and deformation under 75% sulfuric acid exposure. And might serve for dental pattern reconstruction during the process of identification.

The acid concentrations are especially important for the final morphological and chemical impact. This is confirmed with research of Raj et al. in 2013 [54]. It evaluated the resistance of teeth to acids (37% conc. HCl), 65% conc. HNO<sub>3</sub>) and 96% conc. H<sub>2</sub>SO<sub>4</sub>). The research confirms that teeth will completely dissolve in HCl and HNO<sub>3</sub>, however in 8 hours, they still retain morphology in H<sub>2</sub>SO<sub>4</sub>. Concentration of the acid is one important aspect, the time of exposure another. Other studies [55] conducted earlier by Dr. Mazza and published in the Journal of Forensic Sciences were initiated by judges in so called "mafia" crimes to examine whether the body could be destroyed by immersion in acids and whether any remains could be identified at all. The aim of this study was to observe the behaviour of teeth exposed to four types of acidic solutions. The teeth were placed in plastic jars with 25 ml of acid and observed. Experience has shown that the teeth are completely dissolved after 14 hours of immersion in a 37% hydrochloric acid solution, while after 90 hours in 96% sulfuric acid the destruction of the samples is still incomplete. In nitric acid, the teeth completely dissolved in 12 hours and in 17 hours in solution of hydrochloric acid / nitric acid 1: 3, it was possible to recognize the characteristic morphological features of dental tissues and structures up to advanced stages of degradation.

Regarding significant differences of acid impact depending on its concentration, a group of forensic scientists decided to engage in research to dispel myths and test whether the body, after soaking in acid, actually does or does not disintegrate within a few minutes. Massimo Grillo of the University of Palermo and his collaborators presented their findings at a conference of the American Academy of Forensic Sciences. When the researchers placed pieces of pig carcasses in sulfuric acid, it took several days for the meat to dissolve. When water was added to the mixture, they were able to reduce the dissolution time to 12 hours for muscle and cartilage and two days for bone. This is a valuable observation. It is known that acid should be poured into water and not the other way around, in the case of sulfuric acid it is a strong exothermic reaction producing a lot of heat and fumes of explosive gases. Dutch research [110] confirms the experience of

forensic experts that, in addition to macroscopic findings such as bone residues and artificial teeth, in both cases clear microscopic bone residues were found: (partially) digested bone, thin-walled structures and recrystallized calcium phosphate. Although some believe that the body can be completely dissolved in acid, at least some of these microscopic residues are always found. These microscopic residues might be future path for implementation of artificial intelligence algorithms in modern reconstruction of dental patterns.

As a limitation of this study might be considered that research has been performed on old - dried out skeleton. This is not representative in considerations for reproduction of processes accompanying complete human tissues exposed to acids. Another limitation is on the contrary the fact that dental restorations were only a week old before exposure to acid bath and were never exposed to native environment of the oral cavity. Both aspects might not be relevant for presented results, however, shall be taken into consideration before approximation of these results to different environments and situations.

## 5. Conclusions

The primary working hypothesis was confirmed and proved that typical dental restorations from high copper non-gamma two amalgam and photo-composite nano hybrid methacrylate modified polysiloxane (organically modified ceramic) Dimethacrylate resins, have minimal volume loss and deformation under 75% sulfuric acid exposure.

The secondary hypothesis was also confirmed premising that 3D reconstructed dental patterns can be utilized for matching with 2D dental records represented with intraoral digital photo and OPG scan.

CBCT, Micro-CT and ATR-FTIR spectroscopy represent a suitable combination of technologies for successful morphological and chemometric reconstruction of dental patterns.

Advanced artificial intelligence algorithm was successfully implemented to perform automatic segmentation of the CBCT scan with separate STL outputs of mandibular bone, teeth, and nerve canal.

**Supplementary Materials:** The following supporting information can be downloaded at: Data supporting reported results are freely available at: <https://drive.google.com/drive/folders/1UqhTbdDWZwxHamUMh6xxgqx3UDC1wimF> The online location provides full digital photo set and STL segmentations of every from 4-stages of degradation for bone and separately for teeth in that particular segment. Also, digital iTero scan of the mandible and CT segmented with AI is provided in this location.

**Funding:** This research was funded by the KEGA grant agency of the Ministry of Education, Science, Research, and Sport of the Slovak Republic (Grant No. 081UK-4/2021) as well with COST Association registered as legal Entity Brussels: 0829090573, supported by the EU framework Programme Horizon 2020, MCTS COST action CA16101 Multi-modal Imaging of Forensic Science Evidence (MULTI-FORESEE).

**Institutional Review Board Statement:** The study was conducted according to the guidelines of the Declaration of Helsinki, and no approval was necessary by the Ethics Committee. Ethical review and approval were waived for this study, as the study did not involve any living animals or humans.

**Informed Consent Statement:** Patient consent was waived due to the fact no patients participated in this study.

**Data Availability Statement:** Data supporting reported results are freely available at: <https://drive.google.com/drive/folders/1UqhTbdDWZwxHamUMh6xxgqx3UDC1wimF> The online location provides full digital photo set and STL segmentations of every from 4-stages of degradation for bone and separately for teeth in that particular segment. Also, digital iTero scan of the mandible and CT segmented with AI is provided in this location.
