Abstract: This article presents, for the first time, the efficacy and curing depth analysis of photo-thermal dual polymerization in metal (Fe) polymer composites for 3D printing of a 3-component (A/B/M) system based on the proposed mechanism of our group, in which the co initiators A and B are Irgacure-369, and charge-transfer complexes (CTC), respectively; and the monomer M is TMPTA filled by Fe. Our formulas show the depth of curing (Z_c) is an increasing function of the light intensity, but a decreasing function of the Fe and photoinitiator concentrations. Z_c is enhanced by the additive [B] which produces extra thermal radical for polymerization under high temperature. The heat (or temperature) increase in the system has two components : (i) due to the light absorption of Fe filler, and (ii) heat released from the exothermic photopolymerization of the monomer. The heat is transported to the additive (or co-initiator) [B] to produce extra radical R' and enhance the monomer conversion function (CF). The CF has two opposite trends in their time profiles: (i) for small Fe concentration (F), it is a time decaying function; and (ii) for large Fe, it is a time increasing profile. This switching feature predicted by our formula is also justified by our measured data. The Fe filler leads to temperature increase, but also limits the light penetration leading to lower CF and Z_c , which could be overcome by the additive initiator [B] in thick polymers. The new finding of optimal Fe for maximal CF and Z_c are explored theoretically.

Keywords: polymerization kinetics; monomer conversion; metal composited; enhancement effects; curing depth; 3 D printing; additive manufacturing.

1. Introduction

To overcome the poor mechanical properties of pure polymers, metal polymer composites (MPCs) combine the functionalities of metals and the advantages of polymers have been proposed [1-7]. However, MPCs are still suffer some problems such as extremely poor metal-polymer compatibility, high metal filler content, and functional singularity [8-10].

Light emitting diodes (LED) photoinitiated polymerization offer many advantages such as its solvent-free formulation, mild conditions (ambient temperature, without monomer purification or stabilizers removal etc.), fast reaction rates, and in line with the green chemistry [11-15]. Copper complex photoredox catalyst photocatalyst have been reported by our group for free radical/cationic hybrid photopolymerization [16,17]. Nevertheless, very few polymeric composite containing metal fillers are prepared by the photopolymerization process due to the poor light penetration depth

which also limits the curing depth. We have recently reported TMPTA as the model monomer, iron powder as filler and Irgacure 369 (Irg 369) as photoinitiator with the aid of two charge-transfer complexes (CTCs) as dual thermal/photochemical initiators using LED at 405 nm [18,19], in which the lack of light penetration was indirectly overcome with the help of CTC in association with heat release during the radical photopolymerization. In the dual thermal/photo polymerization process, we have successfully achieved 10 times more depth of curing than that of photopolymerization alone.

In supporting our recent measured data, Ma et al. [19], this article will present the kinetics, the conversion profiles features and the depth of curing of a 3-component (A/B/M) system based on the proposed mechanism of our group [19]. We will demonstrate that the conversion function (CF) has two opposite trends in their time profiles depending on the amount of Fe. This switching feature predicted by our formula is also justified by our measured data. Analytic formulas for the CF, depth of curing and heat (temperature) profiles will be derived rigorously.

2. Methods and Modeling Systems

2.1. Photochemical Kinetics

In association with the proposed scheme of our group, Ma et al [19], we propose in Fig. 1, a 3-component system (A/B/M) defined by the co initiators [A] and [B] with monomer (M), in which the initiator [A] is excited to its first-excited state A^* , and a triplet excited state T having a quantum yield (q). The triplet state T interacts with [A] to produce radical (R) which couple with M for photopolymerization and release heat (H). Additional heat (H) is produced by the UV light absorption of the filler, iron mixed in the monomer. Heat is also produced by the light absorption of the iron filled in the monomer. The heat is transported to the additive (or co-initiator) [B] to produce extra radical R' . Therefore, the polymerization can be induced by the photo-radical (R) and enhanced by the thermal-radical (R'). A specific measured system related to Fig. 1 was reported by Ma et al [19] for a 3-component system of PI/B/M, where PI is the photoinitiator Irgacure 369, B is a co-initiator of charge-transfer complex (CTC), and the M is the monomer trimethylolpropane triacrylate (TMPTA), which is filled with filler iron (Fe).

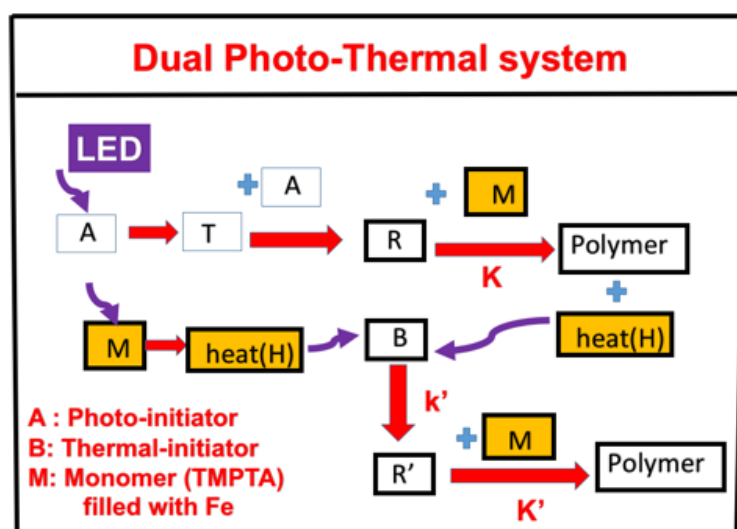

Fig. 1. The schematics of a dual function system, (A/B/H), The heat (H) can be produced by the light absorption of the iron filled in the monomer (M) and the heat released by the photopolymerization, in which R and R' lead to a photo-thermal dual polymerization (see text for more details).

The kinetic equations for our previous systems [20-23] are revised for the new system of Fig. 1 (A/B/H/M) as follows. We will use the short hand notations for the concentrations: [A] for photoinitiator Irgacure 369, [B] for the additive CTC, F for the filler iron (in wt%), R and R' for the photo and thermal radical, respectively.

$$\frac{d[A]}{dt} = -bI[A] + \text{REG} \quad (1)$$

$$\frac{d[B]}{dt} = -k'H[B] \quad (2)$$

$$\frac{dT}{dt} = bI[A] - (K'' + k[A] + k''M)T \quad (3)$$

$$\frac{dR}{dt} = k[A]T - KMR - VR^2 \quad (4)$$

$$\frac{dR'}{dt} = k'H[B] - K'MR' \quad (5)$$

In Eq. (2) and (5), H is the heat (or temperature) in the monomer due to two components : (i) the $aFI(z,t)$ term, due to light absorption of iron filler given by the absorption constant (a), light intensity (I) and iron concentration (F); and (ii) the heat released (the KMR term) from the exothermic photopolymerization of the monomer. Therefore, H is given by a generalized heat diffusion equation

$$\frac{dH(z,t)}{dt} = aFI(z,t) + KMR + c\nabla^2 H - b'H \quad (6)$$

where b' is the heat transport constant, the third term is the thermal conduction term in depth(z). The UV light intensity has the depth (z) dependence due to the absorption of PI, [A], and iron filler (F) given by

$$\frac{dI(z,t)}{dz} = -(b[A] + aF)I(z,t) \quad (7)$$

The monomer (M) conversion rate equation has three components: triplet state (T) direct coupling, and the radicals (R and R') produced by [A] and [B], respectively, given by

$$\frac{dM}{dt} = -(k''T + KR + K'R')M \quad (8)$$

In Eq. (1) the regeneration (REG) term is given by $\text{REG} = k''T + kM$ of the initiator; $b = 83.6a'wq$, where w is the light wavelength (in cm) and q is the triplet state T quantum yield; a' is the mole absorption coefficient, in (1/mM/%) and $I(z,t)$ is the light intensity, in mW/cm². All the rate constants are defined previously [20-21] and they are related by the coupling terms. For examples, k'' is for the couplings of T and [M]; K and K' for the coupling of radicals R and R' with monomer M, respectively. $k'H$ is the production rate of the thermal radical (R') from [B]. Here we have excluded the oxygen inhibition effect [22], and the couplings among R and R', T and [B], which have not yet observed experimentally.

For comprehensive modeling we will use the so-called quasi-steady state assumption [20, 21]. The life time of the singlet and triplet states of photosensitizer, the triplet state (T), and the radicals (R and R'), since they either decay or react with cellular matrix immediately after they are created. Thus, one may set $dT/dt = dR/dt = dR'/dt = 0$, which give the quasi-steady-state solutions: $T = bIg[A]$, $R' = k'H[B]/(K'M)$; and $g = 1/(K'' + k[A] + k''M)$. Steady-state of R is much more complex due to the bimolecular term of VR^2 . We will consider the case of unimolecular, with $V=0$ in Eq. (5) such that $R = (k/K)bIg[A]$, and $KRM = k[A]T$ in Eq. (8).

Under the above quasi-steady-state solutions and for unimolecular case for R, we obtain the simplified equations (with the thermal conduction term ignored) as follows.

$$\frac{d[A]}{dt} = -(bI[A] - \text{REG}) \quad (9)$$

$$\frac{d[B]}{dt} = -k'H[B] \quad (10)$$

$$\frac{dH}{dt} = aFI + k[A]T - b'H \quad (11)$$

The conversion efficacy (CF) defined by $CF = 1 - M(t)/M_0$, with $M(t)$ given by the solution of

$$\frac{dM}{dt} = -(k''TM + k[A]T) - k'H[B] \quad (12)$$

3.. Results and discussions

A full numerical simulation is required for the solutions of Eq. (9) to (12), which will be presented elsewhere. We will focus on comprehensive analysis for special features and the key factors of dual radical enhancement for efficient conversion related to the measured data of Ma et al [19], based on the analytic formulas to be derived as follows.

3.1 Analytic results

In general, Eq. (11) and (12) require numerical simulation. For analytic formulas, we further approximate $g=1/(k[A])$, such that $T=bI/(k[A])$, Eq. (11) and (12) are reduced to

$$\frac{dH}{dt} = [aF + b]I(z, t) - b'H \quad (13)$$

$$\frac{dM}{dt} = -(1 + (k''/k)M/[A])bI(z, t) - k'H[B] \quad (14)$$

Analytic formulas need further assumption of RGE is taken as a mean reduction factor (f'), such that $bI[A]\text{-RGE} = f'bI[A]$ having a value of $f'=0$ to 1.0. The first-order solution of Eq. (9) is given by $[A]=A_0 \exp(-dt)$; with $d=bI(z)$, for $f'=1$, and $I(z, t)$ assumed to be time-independent, that is the increase of $I(z, t)$ due to the depletion of $[A]$ is neglected. For the perfect recycle case, $f=0$, and $[A] = A_0$ is a constant. Using an average of $[A(z, t)]$ over z and t (defined as A'), we obtain $I(z)=I_0 \exp[-Gz]$, with $G=aF + bA'$. The solution of Eq. (13) is given by an integral table

$$H(z, t) = H_0 \exp(-b't) + (d'/b')[1 - \exp(-b't)] \quad (15)$$

where H_0 is the initial value of $H(t=0)$, and $d'=(aF+b)I(z)=(aF+b)I_0 \exp[-Gz]$. We note that $H(t)$ has a transient state value $H_0(1-b't) + d't$, and a steady state value $(aF+b)I(z)/b'$. Moreover, for $z>0$, d' has an optimal value at $F=F^*$, and it is a decreasing function of F , for $F>F^*$. This optimal value is due to the competing term (aF) in $d'=(aF+b)I_0 \exp[-(aF+bA')]$. Therefore, a higher $F>F^*$ and/or A' leads to less light penetration due to the absorption factor $G=aF+bA'$ in $I(z) = I_0 \exp[-Gz]$, and also leads to lower heat released (temperature) in the monomer, $H(t)$.

Using Eq. (15) to solve for Eq. (10), we obtain

$$[B](z, t) = B_0 \exp[-P(t)] \quad (16)$$

where $P(t)=k'[td'/b' + d''Q(t)]$, with $d''=(H_0 - d'/b')$, and $Q(t)=[1 - \exp(-b't)]/b'$.

Using the first-order solution of Eq. (14), with $k'H[B]$ neglected, and for $[A]=A_0 \exp(-dt)$, with $d=bI$, we find the second-order solution (including $k'HB$) of Eq. (14) given by

$$M(t)=M_0 - bI[t + ((k''/k)M_0/A_0)V(t)] - k' B_0 [(d'/b')V'(t) + d''V''(t)] \quad (17)$$

where $V(t)=[1 - \exp(-st)]/s$, with $s=d+bI$; $V'(t)=[1 - \exp(-qt)]/q$, with $q=k'[d'/b' + d'']$; and $V''(t)=[1 - \exp(-q't)]/q'$, with $q'=b'+q'$.

Two special cases are analyzed for Eq. (17) as follows.

(a) For steady-state: from Eq. (16), $V(t)=1/s$, $V'(t)=1/q$, and $V''(t)=1/q'$. $M(t)$ is almost independent of the light intensity, we obtain the conversion efficacy (CF) defined by $CF=1-M(t)/M_0$,

$$CF(z, t) = bI[t + ((k''/k)M_0/(sA_0))] + k' B_0 [(d'/b')/q + d''/q'] \quad (18.a)$$

We note CF is proportional to the light dose (It) that this feature is only for the case of unimolecular termination of the radical R which is proportional to (bI) . For the case of bimolecular, R is proportional to the power of $(bI)^{0.5}$, and the steady-state value of CF is proportional to $(bI)^{-0.5}$ [20].

(b) For transient state, $S(t)=S'(t)=S''(t)=t$, we obtain the CF

$$CF(z,t) = b(I_0 t) [1/M_0 + k''/(kA_0)] + k'tB_0H_0/M_0. \quad (18.b)$$

We note that Eq. (18) has 4 terms proportional to the light dose $E=I(z)t$, and initial concentrations A_0 , and B_0, H_0 and the absorption constants, b . However CF (for $z>0$) is a decreasing function of Fe , since $I(z) = I_0 \exp[-(aF+bA')z]$.

3.2 Depth of Curing (DoC)

As shown by Eq. (7) the light intensity is an exponentially decreasing function of the depth(z) according to a Beer-Lambert law (BLL). However, for the situation of time-dependent intensity $I(z,t)$ due to the depletion of the PI concentration, $A(t)=A_0 \exp(-dt)$, a generalized BLL was developed by Lin [20], such that the solution of Eq. (8) becomes $I(z,t)=I_0 \exp[-Gz]$, in which G is an average of $[A(z,t)]$ over z and t (defined as A'), given by $G=aF + bA'$.

A curing depth (Z_c) is defined by when the conversion efficacy is higher than a critical value, $CF>C^*$. Using $I(z,t)=I_0 \exp[-Gz]$, and Eq. (18) for CF , we obtain

$$Z_c = \ln[(SI_0)/(C^* - S')]/(aF + bA') \quad (19.a)$$

where $S = bt[1/M_0 + k''/(kA_0)]$; and the enhancement factor, $S' = k't(B_0H_0)/M_0$.

We note that Z_c is proportional to the light dose I_0t , but it is a decreasing function of the effective absorption constant $(aF+bA')$, with A' being the z and time -averaged PI concentration $[A]$, given by A' . Eq. (19) show that Z_c is enhanced by the additive $[B]$ via $S' = k't(B_0H_0)/M_0$, which is proportional to $k'B_0H_0$, i.e., the limited light penetration due to Fe is overcome by the additive CTC, or $[B]$. Eq. (19) shows that Z_c is proportional to $\ln(SI_0)$ under the unimolecular case, with neglected VR^2 term in Eq. (4). For the bimolecular dominant case (with $VR^2 \gg KRM$), Eq. (19) is revised to [21]

$$Z_c = 2\ln[SI_0^{0.5}/(C^* - S')]/(aF + bA') \quad (19.b)$$

We note that more detailed discussion and numerical results of Z_c and curing time maybe found in our previous work [20,22].

As shown by Eq.(15), when Fe is too high the DoC is too low to create effective polymerization and it is limited to thin films. For lower Fe of 10% to 30%, the DoC is larger than the sample thickness and sharp edges are produced. Moreover, high Fe leads to strong light absorption and the light dose is smaller than the polymerization threshold at certain sample depth.

3.3 General features and new findings

As shown by Eqs. (9) to (19), the following significant features of the $[A]/[B]/M$ system which was also proposed by Ma et al [23]). Our modeling has explored the follow general features, in which some new findings are not yet explored in our previous experiment of Ma et al {23}, but might be justified in our future works.

(i) As shown by Eq. (6), the heat (or temperature) increase in the system has two components: (a) the $aFI(z,t)$ term, due to light absorption of iron filler given by the absorption constant (a), light intensity (I) and iron concentration (F); and (b) the heat released (the KMR term) from the exothermic photopolymerization of the monomer.

(ii) The solution of heat $H(t)$ given by Eq. (15) has two terms which has opposite trends in their time profiles; the first term is a decaying function, whereas the second term is an increasing profile. This switching feature maybe easily realized by Eq. (13), which has a zero slope when $F=F^*$ and $(aF^*+b)I(z)=b/H$. This new finding will be justified later by our measured data. We note that $H(t)$ has a transient state value $H_0(1-b't) + d't$, and a steady state value $(aF+b)I/b'$. Therefore, for $F>F^*$, higher F and/or A' leads to less light penetration due to the term $G=aF+bA'$ in $I(z) = I_0 \exp[-Gz]$, and lower heat released (temperature) in the monomer. This feature of optimalization is valid only for $z>0$. It does not exist for surface (with $z=0$).

(iii) As shown by Eq. (8) and (12), (14), the monomer conversion has 3 components: (a) from the direct coupling of T and [A], (b) the coupling of photon-radical (R) with M, and (c) coupling of thermal-radical (R') and M; in which R' is an enhancement radical produced from the co-initiator, [B], under a high temperature given by the heat function, H(t). We note that the Fe filler leads to temperature increase, but also limits the light penetration, leading to lower CF and DoC, which could be overcome by the additive initiator [B] for thick samples.

(iv) As shown by Eq. (18) has 4 terms proportional to the light dose $E=It$, and initial concentrations A_0, B_0, H_0 and the absorption constants, a and b and the iron concentration (F), the last term of Eq. (18), $d't=(aF+b)E/b'$. However, the CF at steady-state is independent of the light intensity, i.e., low and high light intensity lead to the same saturated CE, although high intensity has a faster rising profile. Above features are for the case with unimolecular coupling of KRM term in Eq. (4). For the situation of a strong bimolecular termination, we need to include the coupling of VR^2 in Eq. (4), and leading a CF which is proportional to the $(bI)^{0.5}$ (for transient state); and inverse proportional to $(bI)^{-0.5}$ at steady-state, i.e., higher intensity leads to a lower steady-state CF than lower intensity. The enhancement factor is given by $S' = k't(B_0H_0)/M_0$, shown in Eqs. (18) and (19).

(v) In this article, we assume that k' is a rate constant. In general, one should revise it to $k'(H-H^*)$, such that a lower threshold radical temperature (H^*) of [B] leads to a higher conversion rate.

(vi) As show by Eq. (19), the depth of curing (DoC), Z_c , is an increasing function of the light intensity. However, there is an optimal Z_c , based on the parameter of $(aF+b)$, i.e., there is an optimal value of the iron concentration (F) which can be found mathematically by taking the derivative of Z_c over d' , and let it equal 0, which can be also found numerically [20]. This optimal value is due to the competing term in $d'=(aF+b)I_0 \exp[-(aF+A')]$. The enhanced Z_c is given by $S' = k't(B_0H_0)/M_0$. Eq. (19) also defines the minimal enhancement factor (S^*) to reach a sample depth of Z' given by the condition of when $(aF+b)Z'>\ln(SI_0/(C^*-S'))$, or $S'>S^*$, with $S^*=C^*-SI_0 \exp[-(aF+b)Z']$, or $k't(B_0H_0)/M_0>C^*-SI_0 \exp[-(aF+b)Z']$.

(vii) Our modeling also shows that there is an optimal condition for the initiator PI concentration given by $d(CF)/dF=0$, with CF given by Eq. (17), which also requires numerical stimulation [20].

3.3 Theoretical predictions and future directions

Based on our analytic formulas, Eq. (15), we show, in Fig. 2, the surface (at $z=0$) temperature profiles in the monomer in the absence of PI (with $b=0$), with heat produced by light absorption of Fe only. It shows that larger Fe mixed in the monomer leads to higher temperature profiles, for a given light intensity, and the saturation is due to the heat transport term, $b'H$. Fig.3 shows the temperature profiles in the presence of co-initiators, [A] and [B], with $(aF+b)I_0= (0, 0.5, 1.0, 1.2)$ (1/sec), with initial temperature released from monomer conversion $H_0=200$ °C, which decreases due to heat transported to the additive [B], but compensated by the heat produced by light absorption of Fe. It demonstrates the switching feature that higher Fe leads to a reversed temperature profile from a decaying to an increasing profile, at a transition value of about $(aF+b)I_0=1.0$ (1/sec).

Based on our formula, Eq. (19), we also show, in Fig. 5, the DoC (Z_c) as the function of various parameters. Fig 4(A) shows that Z_c is an increasing function of S' , the enhancement factor given by $S' = k't(B_0H_0)/M_0$, for a given curing threshold $C^*=0.4$, and fixed $SI_0=0.7$, $aF+bA'=1.0$. Fig. 5(B) shows that Z_c is a decreasing function of the factor $(aF+bA')$, Fig.5(C) shows that Z_c is an increasing function of SI_0 , which is proportional to the light dose tI_0 , and the coupling constant, b , as shown by Eq. (19).

Fig. 4 shows the optimal feature of the absorption factor, $(aF+b)$, for a maximal heat produced by the light absorption of Fe, based on Eq. (15). The optimal feature exists only for $z>0$, due to the light intensity given by $I(z,t)=I_0 \exp(-Gz)$, with $G=aF + bA'$, which is a strong decreasing function of $(aF+bA')$, for $z>0$. These features are show in Fig.4, for $z=(0, 0.4, 0.5, 0.6)$ cm.

Based on our modeling predictions described above, we propose to conduct the following new measurements, which are not yet explored in Ref. [24].

(i) CF profiles for various initiator concentrations, A_0 and B_0 , to justify our predicted enhancement factor give by S , in Eq. (15) and (19).

- (ii) CF profiles for various light intensity (I_0) to justify the steady-state CF scaling law of $(bI_0)^m$, with $m=1.0$ and -0.5 ;
- (iii) curing depth (Z_c) for various enhanced factor given by $S'=k't(B_0H_0)/M_0$, as shown by Fig. 5.
- (iv) the optimal feature shown by Fig. 4, for various aFI_0 , for a maximal heat produced by the light absorption of Fe.

Besides the enhancement effects discussed in the present article using an additive of CTC, there are many other strategies have been reported by our group, including the use of multi-wavelength light and strategies of reduction the oxygen inhibition [23-27]. A critical review for photopolymerization for 3D bioprinting can be found in Ref. [23].

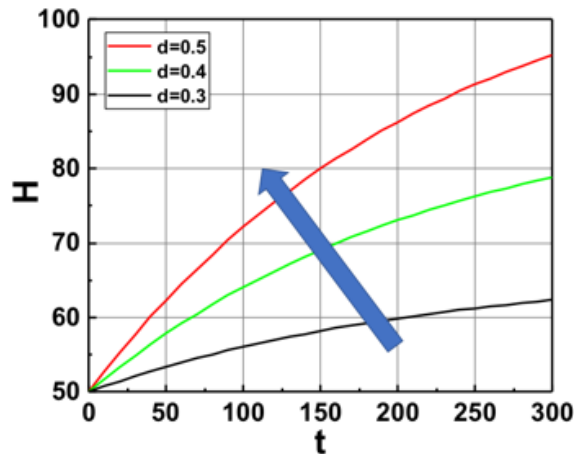

Fig. 2 The calculated surface temperature (at $z=0$) profiles of monomer based on Eq. (15) for various weight concentration of Fe, with $aFI_0 = (0.3, 0.4, 0.5)$ (1/sec) and $b'=0.0045$ (1/s), in the absence of PI (with $b=0$), with heat produced by light absorption of Fe only, with $H_0=50$ °C.

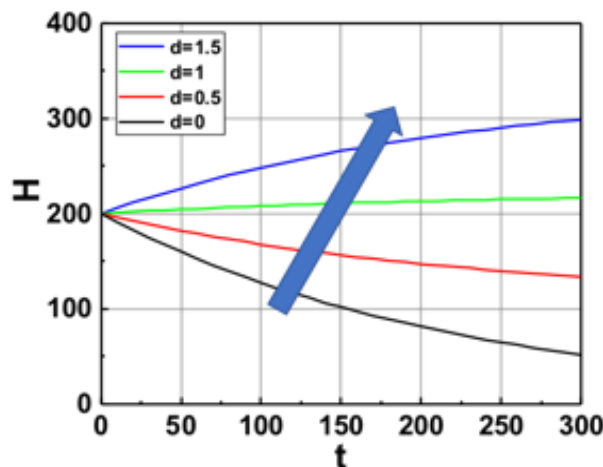

Fig. 3 Same as Fig. 2, but in the presence of co-initiators, [A] and [B]. with $(aF+b)I_0 = (0, 0.5, 1.0, 1.5)$ (1/sec), with initial released heat from monomer conversion $H_0=200$ °C, which decreases due to heat transported to the additive [B], but compensated by the heat produced by light absorption of Fe.

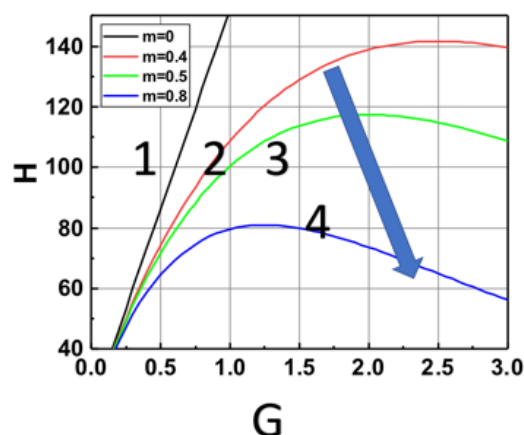

Fig. 4 The calculated temperature of monomer based on Eq. (15) for various absorption $G=aF + bA'$, for $z=(0, 0.4, 0.5, 0.6)$ cm, for curves (1,2,3,4), at $t=200$ sec.

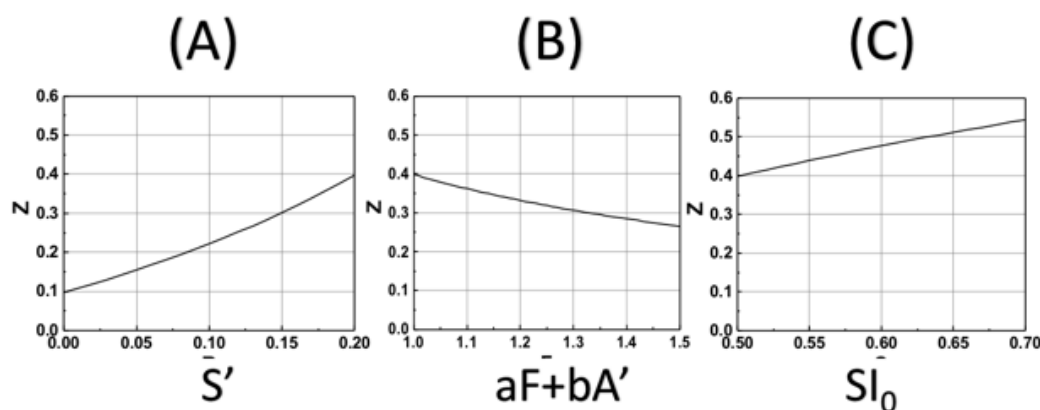

Fig. 5 The calculated DoC (Z_c) based on Eq. (19) for various parameters: (A) for Z_c vs S' with fixed $SI_0=0.7$, $aF+bA'=1.0$ and $C^*=0.4$; (B) for Z_c vs $aF+bA'$, with fixed $SI_0=0.5$ and $S'=0.5$; (C) for Z_c vs $SI_0=0.5$, with fixed $S'=0.2$ and $aF+bA'=1.0$.

3.4 Analysis of measured data

The measured data are shown in Fig. 6 of our group, Ma et al [19], in which a PI Irgacure 369 is exposed to a LED at 405 nm (0.11 W cm^{-2}) for various iron (Fe) concentrations.

Fig. 6 (A) shows the measured conversion profiles of TMPDA for various Fe concentrations. These profiles can be analyzed by our CF shown in Eq. (18), which shows a typical saturation profile defined by $Q'(t)=[1-\exp(-b't)]/b'$ in Eq. (17).

Fig. 6 (B) shows the measured DoC for various Fe concentrations. These profiles can be analyzed by our Z_c shown in Eq. (19), which shows Z_c is an increasing function of the light intensity I_0 , but a decreasing function of the Fe (F) and PI concentration (A'), shown by the term $(aF+bA')$. The DoC is enhanced by the additive [B] via the S function which is proportional to $(bt)[(1/M_0 - A_0) + kB_0/(b'M_0)]$. Our measured data had yielded (10 times) thick composites under the same dose using a LED irradiation at 405 nm.

Fig. 6 (C) shows the temperature profiles in the absence of PI. They are related to the Eq. (13) and (15) with $b=0$, but $b'>0$.

Fig. 6 (D) shows the temperature profiles for various Fe concentrations. These profiles can be analyzed by Eq. (15), which shows that $H(t)$ has a transient state value $H_0(1-b't) + d't$, and a steady state value d'/b' , with $d'=(aF+b)I(z)$, with $I(z) = I_0 \exp[-Gz]$. Therefore, higher F and/or A' leads to less light penetration due to the absorption factor $G=aF+bA'$, and also leads to a lower heat released (temperature) in the monomer, as shown by the measure curves of Fig. 6 (D). Furthermore, the

transient profiles given by two terms having opposite trends in their time profiles: (a) for small $(aF+b)I \ll H_0$, the first term is dominant and given by a decaying function given by $H_0 \exp(-b't)$; (b) for large F with $(aF+b)I(z) \gg H_0$, the second term is dominant and given by an opposite, time increasing profile, given by $(aF+b)I(z)[1 - \exp(-b't)]$. The switching profile from a time decaying one (for small F) to a time growing profile (for large F) are also shown by the measured curves of Fig. 2(D). This is a rather surprising feature predicted by our formula and justified by our measured data in Ma et al [19]. Our formulas also predict the switching value of $F=F^*$, when $(aF^{*++b})I(z)-bH$.

We found that wt10% and wt30% Fe filler resin can achieve perfect three-dimensional structure, as shown in Fig. 7A and B, with great spatial resolution for the photoproducts in the presence of the iron fillers. However, when the content of iron keeps up to 50% wt%, the pattern was not flat and some area under irradiation wasn't be fabricated (Fig. 7C). See more detailed of measurement method in Ref. [19].

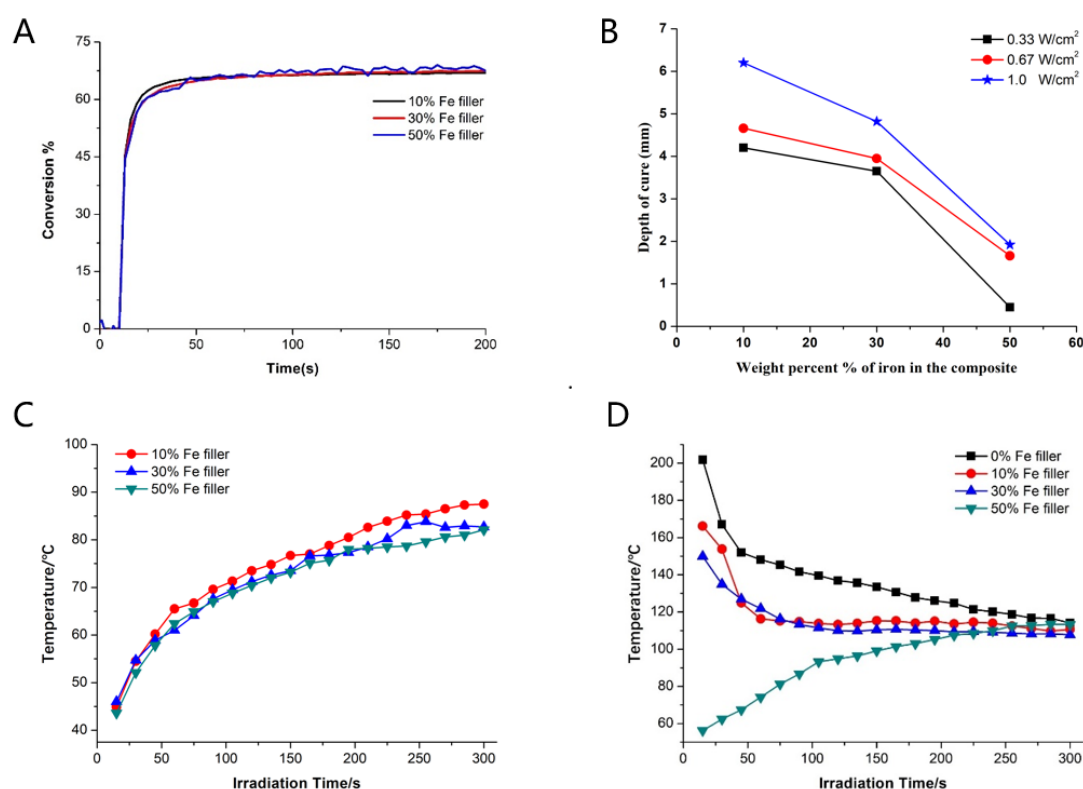

Fig. 6 (A) Measured photopolymerization profiles of TMPTA in laminate (25 μm thickness) initiated by Irgacure 369 upon exposure to LED@405 nm in the presence of Fe filler with different contents (wt%); (B) DoC results for the iron filler-based composites under the irradiation of high power LED@405 nm (0.33 W cm^{-2} ; 0.67 W cm^{-2} ; 1.0 W cm^{-2}); (C) temperature profiles of TMPTA with various wt% Fe in the absence of Irgacure 369; (D) temperature profiles of TMPTA with various wt% Fe in the presence of Irgacure 369 ($2.5 \times 10^{-5} \text{ mol g}^{-1}$ TMPTA). After Ma et al [19].

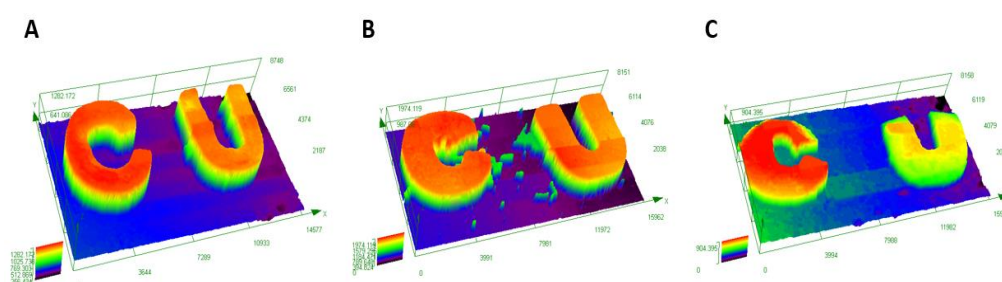

Fig. 7. Optical microscopy of the 3D patterns printed from TMPTA containing: (A) 10% wt%, (B) 30% wt%, and (C) 50% wt% content of iron filler; All printing experiments were performed with 5.5×10^{-5} mol/g CTC(EMIM) in TMPTA. The scale bar is 2000 μm . After Ma et al [19].

4. Conclusions

We have demonstrated theoretically and justified by measured CF profiles of a 3-component (A/B/M) system based on the proposed mechanism of our group, Ma et al [19], in which the co initiators are A, Irgacure 369, and B, charge-transfer complexes (CTC), and the monomer M is TMPDA. Our formula show the depth of curing (Z_c) is an increasing function of the light intensity, but a decreasing function of the Fe and photoinitiator concentration. Z_c is enhanced by the additive [B] which produces extra thermal radical for polymerization under high temperature. The heat (or temperature) increase in the system has two components: due to light absorption of iron filler, and heat released from the exothermic photopolymerization of the monomer. The heat is transported to the additive (or co-initiator) [B] to produce extra radical R' and enhance the monomer conversion function (CF). For small Fe concentration (F), the CF is given by a decaying function; whereas for large F, it is given by a time increasing profile. The switching profile from a time decaying one (for small F) to a time growing profile (for large F) were also shown by the measured curves of Fig. 2(D). This is a rather surprising feature predicted by our formula and justified by our measured data.
