Abstract: The option pricing problem is equivalent with the hedging problem of the option, i.e. what the writer should do in order to hedge the risk that she undertakes selling a contract and moreover what is the probability of profit selling at a specific price. In other words, the writer first designs a way to hedge the risk and then prices the contract according to the amount needed to hedge that risk. The probability of profit is also a useful information for the buyer. The hedging strategy should be practically possible for the writer otherwise has no meaning. In this note we will discuss the option pricing problem and in particular the effect of the volatility on the binomial model which is a way to hedge practically a specific option in contrast to every pricing model that assumes rebuilding of the replicating portfolio continuously in time. In order to use the binomial model we have to modified it accordingly as we have seen in a previous paper. We also point out four open problems regarding the hedging problem.

1. Introduction

An option is a contract between two parties, the writer (seller) of the contract and the buyer. The buyer has the right but not the obligation to exercise the option at some time $T > 0$ or even at any time at the time interval $[0, T]$. The payoff of the option that the buyer will take is an amount $H(S_1, S_2, \dots, S_d)$ where $H: \mathbb{R}_+^d \rightarrow \mathbb{R}_+$ and S_1, \dots, S_d are the underlying assets. Some examples are $P_T = \max\{S_T - K, 0\}$ (call option), $P_T = \max\{K - S_T, 0\}$ (put option), $P_T = \max\{\max_{t \in [0, T]} S(t) - K, 0\}$ (call on maximum), $P_T = \max\{S_1(T), S_2(T), K\}$ and $P_T = \max\{S_1(T) - S_2(T), 0\}$ (spread option) and many others.

For some options (contracts) there is the possibility of bankruptcy for the writer. For example the writer of a spread option may go bankrupt if the price of the asset S_1 reach high levels. The writer can buy a call option written on S_1 in order to eliminate that risk. However this is not the case for the call on maximum option for which the writer can buy a series of call options in order to shrink the possibility of bankruptcy but not to eliminate it.

It is clear that the writer of an option will accept to undertake the risk of selling it only for speculative reasons. So, in what price should the writer sell the option? The option pricing problem is equivalent to the hedging problem. The writer first designs a hedging strategy and then prices the option based on the amount that she need to follow that strategy. The purpose of this hedging strategy is to minimize the probability of bankruptcy and also to increase the probability of profit. Of course the competition will play a decisive role in the final sale price.

Definition 1 (Physical meaning of a price). *We say that the amount Y has a physical (or realistic) meaning for the writer if*

- (i) *with this amount the writer can eliminate or at least shrink the possibility of bankruptcy*
- (ii) *and moreover with this amount has a good chance of profit.*

What do we mean by "has a good chance of profit"? The exact meaning will be given by the writer herself, so in general, a different writer will price a contract differently. At [5] we have given some practical ways of doing this and will refer to them below.

One way to hedge the risk of selling an option is to build a replicating portfolio. We have two main methods to construct replicating portfolios: the first one is in discrete time and the second is in continuous time. The main representative from the first category is the binomial option pricing model, while from the second category is the Black-Scholes model. We will discuss next these two main methods and see their disadvantages.

Let us recall here the binomial option pricing model written on one asset S for the time period $[0, T]$.

Assumption 1. *Let the today price of the asset is S_0 . We suppose that the possible values of the price at the time T are $S_T = uS_0$ with some probability p or $S_T = dS_0$ with probability $1 - p$, for some numbers u, d .*

We call u, d the upward and downward rate of the future price of the asset. There are several choices for the rates in the bibliography, see for example [3], [4] and [9] and the references therein.

For a specific contract, the binomial option pricing model computes the initial value of a replicating portfolio. The basic problem, however, of the binomial model is that the assumption 1 is not realistic, i.e. $\mathbb{P}(S_T = uS_0) = \mathbb{P}(S_T = dS_0) = 0$ in the real world or very small! Therefore the binomial option pricing model does not produce a price with a physical meaning as we define it at definition 1. That is we are almost sure that the writer's guess will not come true so the question is: what happens in this case concerning the value of the replicating portfolio and the payoff?

Now let us recall the Black - Scholes option pricing model, see [2] (see also [1]).

Assumption 2. *If the today price of the asset is S_0 then the price at time T is such that*

$$S_T = S_0 + m \int_0^T S_r dr + \sigma \int_0^T S_r dW_r$$

where $m, \sigma \in \mathbb{R}_+$ are some parameters specified by the writer.

In [1] the author, in fact, proposes the price of a call or a put option to be

$$\mathbb{E}_{\mathbb{P}}(g(S_T))$$

with \mathbb{P} is the real world probability. Here $g(x) = (x - K)^+$ for the call option and $g(x) = (K - x)^+$ for put option. This approach have a clear physical meaning and this price can be considered as a fair price for the put option since the payoff is bounded. On the other hand the Black - Scholes model proposes the price to be

$$\mathbb{E}_{\mathbb{Q}}(g(S_T)|\mathcal{F}_0)$$

where \mathbb{Q} is not the real world probability but an equivalent probability measure to \mathbb{P} . Note that $\mathbb{E}_{\mathbb{Q}}(g(S_T)|\mathcal{F}_0) = V(0, S_0)$ where $V(t, x)$ is the solution of the following famous Black - Scholes partial differential equation

$$\begin{aligned} V_t(t, S) + \frac{\sigma^2 S^2}{2} V_{SS}(t, S) + rSV_S(t, S) - rV(t, S) &= 0 \\ V(T, S) &= g(S) \end{aligned}$$

At the first sight the above price is not intuitive at all. However, if someone go deeper to this theory understands that this price is in fact the initial value of a replicating portfolio and this explains the

proposed price. Therefore, the Black - Scholes model and the binomial model have the same basic pricing principle which is based on the construction of a hedging portfolio.

So the Black - Scholes model prices a contract by the initial value of a replicating portfolio that has to be reconstructed continuously in time. Assumption 2 maybe is not the best for a specific asset but is realistic. However, the problem of the Black - Scholes model is the reconstruction of the replicating portfolio which is not realistic because nobody can reconstruct such a replicating portfolio continuously in time in order to hedge the risk. To be more precise, suppose that at time t the replicating portfolio contain $a(t, S(t))$ assets and $b(t, S(t))$ at a bank account. At the next time that the price of the asset changes to $S(t+h)$ from $S(t)$ the number of the assets should also change instantaneously to $a(t+h, S(t+h))$ which is impossible. Of course every pricing model via replication with reconstruction in continuous time has the same serious problem and therefore does not produce a price with a physical meaning (see definition 1).

In the spirit of [1], for general options with payoff P_T (see Assumption 2.2 of [5] for example), we can define the amount $\mathbb{E}_{\mathbb{P}}(P_T)$ and suggest it to the writer as the possible value of the option, i.e. the average value of the payoff which has an obvious physical meaning for the writer. In [5] we have used for simplicity the Brownian motion to the assumptions concerning the payoff of a contract but is obvious that someone can use any other suitable random variable or stochastic process.

Remark 1 (Choosing a model). *The trickiest part for investors is not the model that have to choose in order to fit the past data of the payoff or the asset price but the impact of recent events (or even potential future events) on the model parameters! To be more precise the main difficulty does not come from a mathematical problem but from the impossibility of predicting the future which cannot be mathematically modeled precisely. After all, for this reason there is always a possibility of profit as well as loss depending on what the investor will bet.* \square

Note that the no arbitrage arguments (see for example [6]) does not give us a specific price for the call and put options but only a relation between them and some bounds for their prices. The situation is worse for more complicated contracts because even if we can prove some bounds for their prices the competition is maybe too low for them in order these bounds come true in the real world.

Therefore, in order to propose a pricing model via replication we should combine the realistic assumption 2 with a replication in discrete time. In [5] we have modified the binomial model in this direction.

2. The Realistic Binomial Model

As we have seen in the previous section, the writer's guess concerning the rates u, d will never come true in the real world or the probability is very low. So what happens when the true upward rate becomes bigger or less than she expected?

In [5] we have show that for the usual call and put options the writer will have a profit if the future upward rate becomes smaller of what the writer predicted or if the downward rate becomes bigger than she expected. Denote the profit of the writer of a call or put option by Π when she is pricing by the binomial model. Let us denote the rates that she used to price the contract by u, d and by u^*, d^* the future rates. Then the profit of these contracts is a function of $u - u^*$ and $d^* - d$, that is $\Pi := \Pi(u - u^*, d^* - d)$, and moreover this function is increasing in both variables.

Let us recall it here for the reader convenience.

Lemma 1. *Let the writer of a put or a call option with strike price K uses the one period binomial model to price it. Then she will choose the rates d, u so as $uS_0 > K$ and $dS_0 < K$.*

Proof. For the call option the writer will prefer to choose d so that $dS_0 < K$ (and of course $uS_0 > K$) where K is the strike price. Indeed, if $dS_0 > K$ then it is easy to see that $a = 1$ and $be^{rT} = -K$. So, the profit Π is as follows

$$\begin{aligned}\Pi &= aS_T + be^{rT} - (S_T - K)^+ \\ &= S_T - K - (S_T - K)^+\end{aligned}$$

If $S_T > K$ then $\Pi = 0$ while if $S_T \leq K$ then $\Pi \leq 0$, that is there is no chance for profit for the writer.

Similarly, for the put option the writer will prefer to choose u so that $uS_0 > K$ (and of course $dS_0 < K$). Indeed, if $uS_0 < K$ then $a = -1$ and $be^{rT} = K$ so the profit is as follows

$$\begin{aligned}\Pi &= aS_T + be^{rT} - (K - S_T)^+ \\ &= K - S_T - (K - S_T)^+\end{aligned}$$

If $S_T < K$ then $\Pi = 0$ while if $S_T \geq K$ then $\Pi \leq 0$, that is there is no chance again for profit for the writer. \square

Theorem 1 (Profit Property for Call and Put Options). *Let the writer has priced a call or a put option with strike price K using the one period binomial model with rates d, u which are such that $uS_0 > K$ and $dS_0 < K$. Then, the writer will have a profit if $\frac{S_T}{S_0} \in (d, u)$ while she will have a loss if $\frac{S_T}{S_0} \notin (d, u)$.*

Proof. We begin with the call option and recall that $a \in (0, 1)$ in this case. The profit is as follows

$$\begin{aligned}\Pi &= aS_T + be^{rT} - (S_T - K)^+ \\ &= a \left(\frac{S_T}{S_0} - u \right) S_0 + auS_0 + be^{rT} - (S_T - K)^+\end{aligned}$$

If $S_T > K$ then we have that $\frac{S_T}{S_0} > d$ and that

$$\begin{aligned}\Pi &= a \left(\frac{S_T}{S_0} - u \right) S_0 + auS_0 + be^{rT} - (uS_0 - K) - \left(\frac{S_T}{S_0} - u \right) S_0 \\ &= \left(\frac{S_T}{S_0} - u \right) S_0 (a - 1)\end{aligned}$$

since $auS_0 + be^{rT} - (uS_0 - K) = 0$. Therefore in the case where $\frac{S_T}{S_0} \in (d, u)$ it holds that $\Pi > 0$ while if $\frac{S_T}{S_0} > u$ it holds that $\Pi < 0$.

If $S_T < K$ then we have that $\frac{S_T}{S_0} < u$ and that

$$\begin{aligned}\Pi &= a \left(\frac{S_T}{S_0} - d \right) S_0 + adS_0 + be^{rT} \\ &= a \left(\frac{S_T}{S_0} - d \right) S_0\end{aligned}$$

since $adS_0 + be^{rT} = 0$. Again, if $\frac{S_T}{S_0} \in (d, u)$ it holds that $\Pi > 0$ while if $\frac{S_T}{S_0} < d$ it holds that $\Pi < 0$.

The same result holds for the put option since $a \in (-1, 0)$ in this case. \square

In [5] we have proposed a way of choosing d, u so as to have

$$\mathbb{P} \left(\frac{S_T}{S_0} \in (d, u) \right) = p$$

for a given probability p under assumption 2. We call this as the realistic binomial model because we assume a realistic assumption for the future prices of the underlying asset and we choose the rates d, u

so as to fix the probability of the event $\{\frac{S_T}{S_0} \in (d, u)\}$. We have already see that this is not enough to have a practically useful pricing model via replication so we should also define a useful property of the replicating portfolio regarding the cases in which the writer has a profit.

Let a contract written on d assets and let the u_i, d_i are the rates guessed by the writer while by u_i^*, d_i^* we denote the future real rates where $i = 1, \dots, d$. Let a replicating portfolio constructed by the (realistic) binomial model, that is let some a_1, \dots, a_d, b such that

$$V_T = a_1 S_1^T + \dots + a_d S_d^T + b \geq P_T$$

assuming for simplicity the risk free rate equal to zero.

Definition 2. We say that a replicating portfolio constructed by the (realistic) binomial model has the profit property for the contract X if the profit for the writer is a function of the $u_i - u_i^*$ and $d_i^* - d_i$ and is increasing in every variable.

That is the profit property is a property of a replicating portfolio that has to be reconstructed in discrete time and not a property of the realistic binomial model.

Figure 1. The replicating portfolios as constructed by the (realistic) binomial model has the profit property for both the call and the put options as we have seen in [5]. If we do not have this information then any guess of d, u is meaningless because the probability to guess right is almost zero in the real world. In addition, using the realistic binomial model, we know also the probability of profit for such a replicating portfolio.

So we have combined the realistic assumption 2 for the price of the asset with the realistic reconstruction of the replicating portfolio in discrete time.

What about the well known arbitrage theorem (see for example [8]) in the binomial model setting? Let us suppose that the writer chooses u, d such as $e^{rT} > u$. In this case the notion of arbitrage has no meaning because the probability of the event $\{u^* > e^{rT}\}$ is strictly positive!

Remark 2 (Completeness). Note that the market is incomplete under assumption 2 when the replicating portfolios has to be reconstructed in discrete time while it is complete when the replicating portfolios can be reconstructed continuously in time. However, the continuous reconstruction is not realistic so we conclude that the market is incomplete in the real world assuming 2. The best we can do in this case is to built a replicating portfolio with as high as possible probability to hedge the option. The situation is different if the underlying asset can take finite many values (due to floating point arithmetic for example) or even the quantity

$U = \frac{S_T}{S_0} \in (m_T, M_T)$ for some constants m_T, M_T . In this case we can design a super - hedging strategy without risk. The competition however will drive prices down in a way that the writer of the option has to undertake some risk in order to be more competitive. Therefore the writer should have a practical way to measure that risk as we have proposed by estimating the probability of profit. \square

3. A generalization of the safe price

In this section we will describe a generalization of the safe price notion by combining it with the notion of static replication. Let an option written on d assets with payoff P_T at time T . The problem can be stated as follows: given some $p \in (0, 1)$ and $\sigma > 0$, construct a portfolio with price process V_t by buying a_i number of asset S_i , with $i = 1, \dots, k$ at time 0 and by putting the amount b at a bank account in the following way,

$$\min_{a_i, b \in \mathbb{R}_+, i=1, \dots, k} V_0 = \min_{a_i, b \in \mathbb{R}_+, i=1, \dots, k} \left(\sum_{i=1}^k a_i S_i(0) + b \right)$$

such that $\mathbb{E}(P_T) \leq \mathbb{E}(V_T)$
or/and $\mathbb{P}(P_T \leq V_T) \geq p$
or/and $\text{Var}(V_T) \leq \sigma$

or any combination of the above. This point of view has a clear physical meaning for the writer and is in fact a generalization of the safe price that we have proposed before because one can choose $a_i = 0$ at the above construction. Here $k \neq d$ in general because a very important advantage of the (generalized) safe price is that we can build a replicating portfolio as above by buying assets which are, in general, different from the underlying assets! This is very useful in the case where the underlying assets can not be traded at the market.

Of course we can build a portfolio by only one asset but a diversified portfolio is more stable. An interesting problem is the following.

Problem 1. *How should the writer choose among n assets those k (k is not known in advance) to create the best possible portfolio? Can we standardize a specific mathematical methodology based on past data?*

One way of course is to build a portfolio that will contain all the n assets and then simply try to choose appropriately the corresponding a_i , i.e. the weight of each asset.

After the construction of this replicating portfolio the writer can rebuilt it accordingly as soon as she has new information from the market.

4. Examples

Note that the model parameters are dependent also on the number of the particular N past years which have used to get the corresponding data. That is, an investor can use any N past years, not necessarily consecutive, in order to estimate the parameters of the model.

Assumption 3. *We assume that all investors think rationally and according to their own benefit. We also assume that their decisions are based only on past data of N years and not on future expectations. If the competition is strong we assume that the writers will try to find the lower price for the contract but with a physical meaning for them.*

Assumption 3 is obviously not that realistic, as most investors rely on their intuition about future market movement, so the reality is even more complicated. Anyway, the calculations we propose here using the historical data are certainly a good first estimate to which one can then add her/his intuition about the future evolution of the phenomenon. For example, a recent event has not left its

mark on historical data, yet it is going to affect future ones. An investor should take this into account by increasing or decreasing the model parameters appropriately which has been calculated based on historical data.

4.1. Prices of the call and put options

Let us suppose that a writer want to sell a put and a call option on an underlying asset that follows the following sde

$$S_T = 40 + 0.01 \int_0^T S_r dr + 0.4 \int_0^T S_r dW_r$$

where $T = 50$ days and the strike price is $K = 41$.

Let us recall here how the writer will compute the safe price for the put option as this was proposed in [5]. For a given probability p one has to find Y such that

$$\mathbb{P}(K - S_T \leq Y) = p$$

Under the assumption 2 about the price of the underlying asset is an easy problem to compute the safe price Y .

The price of the put option via replication (via the realistic binomial model) is about 2.8 with probability of profit 0.57 while the price without replication is 2.4 with the same probability of profit. Note that in order to construct the replicating portfolio the writer has to borrow some assets therefore under assumption 3 the writer will choose to sell without replication, i.e. at the price 2.4 or higher.

If she sell the put option at the price 2.4 then the price of the call option has to be 1.4 for the put - call parity to hold, assuming that the risk free rate is zero. Speaking about put - call parity, we can argue that taking for granted that different organizations can apply a different interest rate we find that the put - call parity is relative. At this price the probability of profit for the writer is about 0.677 for the call option without construction of a replicating portfolio. If she sell at this price the call option constructing a replicating portfolio via the realistic binomial model then the probability of profit is 0.49.

Let us suppose that the writer sell the put option at the price $Y = 3.1$. Then the probability of profit without replication is about 0.62. But in this case the writer can construct a replicating portfolio without borrowing assets i.e. with $a = 0.05$ and $b = 1$ assuming that $u = 1$ and $d = 0.95$. In this case the writer will have a (possible unbounded!) profit if $\frac{S_T}{S_0} \geq 0.95$ and the probability of this event is about 0.52.

The Black - Scholes model price is about 2.91 (constructing a replicating portfolio) while $\mathbb{E}_{\mathbb{P}}((K - S_T)^+) = 2.89$ under assumption 2. Here

$$\mathbb{E}_{\mathbb{P}}((K - S_T)^+) = \frac{1}{\sqrt{2\pi T}} \int_{-\infty}^M (K - S_0 e^{(m - \sigma^2/2)T + \sigma x}) e^{-x^2/(2T)} dx$$

with $M = (\sigma^2/2 - m)\frac{T}{\sigma} + \frac{\ln K - \ln S_0}{\sigma}$. In the Black - Scholes setting one should borrow assets, assuming that can indeed rebuilt the portfolio continuously in time, while the physical meaning of the mean value of the payoff is clear without replication.

Suppose now that the underlying asset can not be traded at the market. The writer choose another asset which follows the following stochastic differential equation

$$\hat{S}_t = 2 + \int_0^t 0.02 \hat{S}_s ds + \int_0^t 0.3 \hat{S}_s d\hat{W}_s, \quad t \in [0, T]$$

where \hat{W}_t is a Brownian motion independent (in general) of W_t . The writer decide to construct a portfolio containing the asset \hat{S} which can be traded at the market. One way to choose such an asset is

to choose between those having a high drift parameter and small diffusion parameter (i.e. volatility). The portfolio will contain $a \in \mathbb{R}_+$ number of the asset \hat{S} and $b \in \mathbb{R}_+$ at the bank account. The writer, in order to price the contract, choose to solve the following minimization problem

$$\min_{a,b \in \mathbb{R}_+} (a\hat{S}_0 + b) \\ \mathbb{E}(P_T) = \mathbb{E}(V_T)$$

where $V_T = a\hat{S}_T + b$ and therefore $\mathbb{E}(V_T) = 2ae^{0.02T} + b$. Recall that $\mathbb{E}(P_T) = 2.89$ so from the equality $\mathbb{E}(P_T) = \mathbb{E}(V_T)$ we deduce that $b = \max\{2.89 - 2ae^{0.02T}, 0\}$. That is we have to minimize the quantity

$$2a + \max\{2.89 - 2ae^{0.02T}, 0\}$$

for $a \in \mathbb{R}_+$. It follows that the minimum is for $a = \frac{2.89}{2e^{0.02 \cdot 50/360}} = 2.005$ and $b = 0$ and consequently the suggested price is $2.005 \cdot 2 = 2.87$ recalling that we assumed that the interest rate is zero.

Recalling that the price $Y = 1.4$ is the value which is such that $\mathbb{P}(P_T \leq Y) = 0.5$, the writer can construct a portfolio with $\mathbb{P}(V_T \geq Y) = 0.5$ where $V_T = a\hat{S}_T + b$. That is the probability $\mathbb{P}(P_T \leq Y \leq V_T) = \mathbb{P}(V_T \geq Y)\mathbb{P}(P_T \leq Y)$. We can work of course directly on the probability $\mathbb{P}(P_T \leq V_T)$ but with a different result. It follows that the minimum portfolio is that with $a = \frac{Y}{\hat{S}_0} e^{(\hat{\sigma}^2/2 - \hat{m})T}$ and $b = 0$. Here $\hat{\sigma}$ and \hat{m} are the parameters of \hat{S}_t . If the asset has small volatility, say $\hat{\sigma} = 0.001$ and high drift term, say $\hat{m} = 0.01$, then the value $a\hat{S}_0 + b = 1.39$ can be considered as a price for this contract with a clear physical meaning.

If the competition is strong the writers will try to find the lower price for the contract but with a physical meaning for them. Assuming that the competition is strong, the most likely price for the put option is about 1.4 for which both the buyer and the writer have the same probability of profit (without replication), i.e. 0.5, while for both of them the possible profit is bounded. That is the notion of the fair price exists only if both the buyer and the seller have bounded possible profits and does not come necessarily by a replicating portfolio! The price of the call option then has to be 0.4 in order the put - call parity holds. The probability of profit is about 0.617 for this price, that is far enough from the probability 0.5.

It will be very interesting if we can find other, different from the above, realistic ways to price these options.

Consider now the case of a put option in which the Black - Scholes price equal X_1 , the safe price equal X_2 and the average value of the payoff equal X_3 with $X_3, X_2 > X_1$. If the writer sell the option at the price X_1 she should construct the replicating portfolio in order to have a meaning for her but this is not possible in practice. Selling the option either at the price X_2 or X_3 then the physical meaning is clear and therefore the competition will force the price of this contract to be $\min\{X_2, X_3\}$.

Problem 2. What is the probability of profit for a call option using the n period realistic binomial model?

A partial answer is the following theorem. By q we denote the probability $q = \{\frac{S_{n+1}}{S_n} > 1\}$ which we have computed in [5].

Theorem 2. Let a call option with strike price K . Suppose that the writer has priced it by using the n - period realistic binomial model under assumption 2 with

$$u = e^{\sigma z_p \sqrt{\frac{T}{n}} + (m - \sigma^2/2)\frac{T}{n}}, \quad d = e^{-\sigma z_p \sqrt{\frac{T}{n}} + (m - \sigma^2/2)\frac{T}{n}}$$

Here z_p is such that $\frac{1}{\sqrt{2\pi\frac{T}{n}}} \int_{-z_p\frac{T}{n}}^{z_p\frac{T}{n}} e^{-\frac{t^2}{2\frac{T}{n}}} dt = p$ with p chosen by the writer and is such that $u > 1$ and $d < 1$.

Then the probability of profit at the last step $\mathbb{P}(\Pi \geq 0) \rightarrow 0$ as $n \rightarrow \infty$ assuming that the writer construct the replicating portfolio as she design it at first by placing or withdrawing corresponding amounts of money.

Proof. Let's assume that the writer constructs the replicated portfolio as she originally designed it by placing or withdrawing corresponding amounts of money. This is because the asset price will almost never receive the appraised values.

The profit at time T is

$$\Pi = a_{n-1}US_0 + b_{n-1} - H(US_0)$$

where $H(x) = (x - K)^+$ and a_{n-1}, b_{n-1} are such that $a_{n-1}uS_{n-1} + b_{n-1} = H(uS_{n-1})$ and $a_{n-1}dS_{n-1} + b_{n-1} = H(dS_{n-1})$. Finally $U = e^{\sigma W_T + (m - \sigma^2/2)T}$ is the real value of the asset at time T after some upward and downward jumps. From now on we will denote by a, b the a_{n-1} and b_{n-1} and by S_{n-1} the estimated value of the asset after the same upward and downward jumps.

Suppose that $dS_{n-1} < US_0 < K$. Then the profit is

$$\begin{aligned} \Pi &= aUS_0 + b - H(US_0) \\ &= a(US_0 - dS_{n-1}) + H(dS_{n-1}) - H(US_0) \\ &= (US_0 - dS_{n-1}) \left(a - \frac{H(US_0) - H(dS_{n-1})}{US_0 - dS_{n-1}} \right) \end{aligned}$$

and it follows that $\Pi \geq 0$. If $US_0 < dS_{n-1} < K$ then $\Pi \leq 0$ and if $US_0 < K < dS_{n-1}$ then $\Pi \leq 0$ because $a = 1$ and $\frac{H(US_0) - H(dS_{n-1})}{US_0 - dS_{n-1}} \leq 1$. Similarly, if $K < US_0$, it follows that $\Pi \geq 0$ if $US_0 \leq uS_{n-1}$ and $\Pi \leq 0$ if $US_0 \geq uS_{n-1}$.

Therefore the profit is no-negative in the case where $dS_{n-1} \leq US_0 \leq uS_{n-1}$ and non positive otherwise.

The probability of profit is then

$$\begin{aligned} \mathbb{P}(dS_{n-1} \leq US_0 \leq uS_{n-1}) &= \\ \sum_{k=0}^{n-1} q^k (1-q)^{n-1-k} \mathbb{P}(u^k d^{n-1-k}(dS_0) \leq US_0 \leq u^k d^{n-1-k}(uS_0)) \end{aligned}$$

But

$$\begin{aligned} &\mathbb{P}(u^k d^{n-1-k}(dS_0) \leq US_0 \leq u^k d^{n-1-k}(uS_0)) \\ &= \mathbb{P}\left(e^{\sigma z_p \sqrt{\frac{T}{n}}(2k-n) + (m - \sigma^2/2)T} \leq e^{\sigma W_T + (m - \sigma^2/2)T} \leq e^{\sigma z_p \sqrt{\frac{T}{n}}(2k+2-n) + (m - \sigma^2/2)T}\right) \\ &= \mathbb{P}\left(\sigma z_p \sqrt{\frac{T}{n}}(2k-n) \leq \sigma W_T \leq \sigma z_p \sqrt{\frac{T}{n}}(2k+2-n)\right) \\ &= \frac{1}{\sqrt{2\pi T}} \int_{\sigma z_p \sqrt{\frac{T}{n}}(2k-n)}^{\sigma z_p \sqrt{\frac{T}{n}}(2k+2-n)} e^{-t^2/(2T)} dt \\ &\leq \frac{2\sigma z_p}{\sqrt{2\pi n}} \end{aligned}$$

Therefore

$$\mathbb{P}(dS_{n-1} \leq US_0 \leq uS_{n-1}) \leq \frac{2\sigma z_p}{\sqrt{2\pi n}} \sum_{k=0}^{n-1} q^k (1-q)^{n-1-k} = \frac{2\sigma z_p}{(1-q)\sqrt{2\pi n}}$$

Therefore, the probability of profit at the last step is getting smaller as $n \rightarrow \infty$ and of course that means that the probability of loss is getting bigger. \square

Problem 3. At time k , knowing the actual path of the asset's price until that time, what the writer can do concerning the hedging strategy in order to increase the profit and the probability of profit? What about other types of options written on one asset, for example path dependent options?

Remark 3. Intuitively speaking, the realistic binomial model can be used for one period without troubles while for n periods there are open questions concerning the hedging strategy and how should be modified by the writer given the actual path of the asset's price. Theorem 2 together with problem 3 can be considered as a recommendation for static hedging only and in particular for only one time. The situation for more complex options seems to be worse. \square

Example 1. Suppose that the underlying asset today price is $S_0 = 1$ and the strike price is $K = 1$. Suppose that the writer prices a call option using the two period realistic binomial model choosing $u = 1.2$ and $d = 0.8$. It follows that the initial price of the replicating portfolio is $V_0 = 0.11$.

Suppose now that the first jump of the asset is upward but with $u^* = 1.4$. Then, the replicating portfolio has the price $V_1^{u^*} = a_0 u^* S_0 + b_0 = 0.33$. At time $n = 1$ the writer should reconstruct the replicating portfolio and chooses to stay at the a_1^u, b_1^u as these have computed at first. To do so, the writer has to put the amount $0.4033 - 0.33$, which is such that $a_1^u u^* S_0 + b_1^u = 0.4033$. Supposing that the next jump is upward with $u = 1.2$ we have that the writer profit is

$$a_1^u u^* S_0 + b_1^u - \max(u^* S_0 - K, 0) + 0.33 - 0.4033 = -0.0933$$

Is there another reconstruction which will drive the writer to a less loss or even to a positive profit?

At the time $n = 1$ new information from the market has arrived so the writer can use these information to make a better guess of the future. At time $n = 1$ the value of the replicating portfolio is 0.33 and the writer decides to construct the portfolio (a, b) with $a = 2$ and $b = -2.47$ using this amount of money. Suppose that at the time $n = 2$ the asset goes upward with $u = 1.3$, that is the value of the asset at time $n = 2$ is $S_2^{uu} = 1 \times 1.4 \times 1.3 = 1.82$ while the value of the portfolio is $2 \times 1.4 \times 1.3 - 2.47 = 1.17$. The payoff in this case is $1.4 \times 1.3 - 1 = 1.82 - 1 = 0.82$. Therefore the writer make a profit in this case. If the writer deems it appropriate, she can reconstruct the portfolio more often or less frequently than she originally planned.

In short, it may be preferable (in a multi-period binomial model) for the seller to reconstruct the portfolio not as originally designed but using new information as well as making new guesses. \square

Summing up, the well known binomial option pricing model has no meaning because the writer's guess will not come true in the real world and in addition the writer does not know anything about a possible profit and what is the probability of profit. On the other hand, concerning the realistic binomial model, given that the corresponding replicating portfolio has the profit property, the writer knows what is the probability of profit and in which cases will have a profit, at least for the one period model. Pricing by the Black - Scholes model the problem is that the writer can not built the replicating portfolio in order to hedge the risk and therefore nobody will price a contract in this way. Therefore the only practically useful way to construct a replicating portfolio is by the realistic binomial model assuming that this portfolio has the profit property.

4.2. An option written on two underlying assets

Let two assets S_1, S_2 that follows the following sdes

$$\begin{aligned} S_1(T) &= 0.98 + 0.001 \int_0^T S_1(r)dr + 0.5 \int_0^T S_1(r)dW_r \\ S_2(T) &= 0.99 - 0.02 \int_0^T S_2(r)dr + 0.6 \int_0^T S_2(r)dW_r \end{aligned}$$

where $T = 50$ days. Let $K = 0.99$ and consider the option that pays $P_T = \max\{S_1, S_2, K\}$ at the time T . The writer of the option computes a replicating portfolio via the realistic binomial model with probability of profit $p = 0.7$ and finds that she should buy $a_1 = 0.47$ shares of the S_1 asset, $a_2 = 0.49$ shares of the S_2 asset and $b = 0.23$ at the bank account assuming zero risk free rate. To be more precise the probability $p = 0.7$ is not the probability of profit but the probability of the event $\{\frac{S_i^T}{S_i^0} \in (d_i, u_i)\}$. The probability of profit in this case is not so easy to compute as in the call and put options. The initial value of this portfolio is $V_0 = 1.18$. It is easy to prove that this replicating portfolio has the profit property. In fact any replicating portfolio with $a_i \in [0, 1]$ has the profit property concerning this type of contract. That is we can find the minimum replicating portfolio for $a_i \in [0, 1]$ therefore this portfolio will have the profit property. The writer, if she wants to be more competitive, she will try to find the replicating portfolio with the profit property having the minimum initial value. At this example the notion of the fair value does not have any sense because the possible profit of the buyer is unbounded while the possible profit for the writer is bounded.

The writer computes also the safe price under the same hypotheses as above and finds that this price is $Y = 1.09$ with the same probability p but without replication. Let us recall here how to compute the safe price under the above assumptions as we have proposed in [5]. For a given probability p we find the prices S_1^Y and S_2^Y so that

$$\begin{aligned} \mathbb{P}(S_1^T \leq S_1^Y) &= p \\ \mathbb{P}(S_2^T \leq S_2^Y) &= p \end{aligned}$$

Then the safe price is $Y = \max\{S_1^Y, S_2^Y, K\}$.

The writer has to buy some call options in order to eliminate the risk of bankruptcy. At the first case, i.e. with the construction of the replicating portfolio, should buy $(1 - a_1)$ calls with underlying asset S_1 for some strike price K_1 and $(1 - a_2)$ calls with underlying asset S_2 for some strike price K_2 . At the second case she should buy one call per asset.

The final price will be computed after the estimation of the transactions costs for the replication and the cost of the call options, i.e. in the first case the price will be $Y = 1.18 + (1 - a_1)C(S_1, K_1) + (1 - a_2)C(S_2, K_2) + T$ where $C(\cdot, \cdot)$ are the call options and T the transactions costs. At the second case the final price will be $U = 1.09 + C(S_1, K_1) + C(S_2, K_2) + T$.

As we have seen in [5] there is also another way to compute a price for some given probability of profit for the writer. The writer can assume that $P_T = \max\{X_T, K\}$ for a stochastic process X_t suitably chosen by her. In fact the same assumption can be done by the buyer in order to estimate the probability of profit for her, however, the way that the two parties estimates the probability of profit are in general different from each other.

Note that the writer's profit is always bounded while the buyer's possible profit in this case is unbounded. After the decision of the writer about the price (say U) of this option the buyer can compute also the probability of profit for her buying at this price. This probability is more likely to be under $1/2$ but this is acceptable by the buyer because the profit is unbounded from above. Recall that the call options will pay this extra difference.

Problem 4. Does the (realistic) binomial model can produce a replicating portfolio with the profit property for any known contract? Let a replicating portfolio $(a_1^*, a_2^*, \dots, a_d^*, b^*)$ such that

$$V_0 = a_1^* S_1 + a_2^* S_2 + \dots + a_d^* S_d b^* = \min_{a_1, a_2, \dots, a_d, b \in \mathbb{R}} (a_1 S_1 + a_2 S_2 + \dots + a_d S_d + b)$$

and the minimum is taken over all the replicating portfolios. The question is: does this portfolio has the profit property for a specific contract? If yes, what is the probability of profit for the writer?

4.3. A spread option

In this subsection we will study a spread option with payoff $P_T = \max\{S_1 - S_2, 0\}$. We will compute a replicating portfolio by using the realistic binomial model and this portfolio will have the profit property. Therefore the writer will know in which cases she will have a profit. Moreover, we will compute the safe price, i.e. a price without a replicating portfolio. The final price will be decided by the writer after the computation of the call options in order to eliminate the risk of bankruptcy and of course the transaction costs. On the other hand, the buyer has the ability to estimate the profit probability for her buying at this price.

Let two assets S_1, S_2 that follows the following sdes

$$\begin{aligned} S_1(T) &= 0.98 + 0.001 \int_0^T S_1(r) dr + 0.5 \int_0^T S_1(r) dW_r \\ S_2(T) &= 0.99 - 0.02 \int_0^T S_2(r) dr + 0.6 \int_0^T S_2(r) dW_r \end{aligned}$$

where $T = 50$ days. The writer finds a replicating portfolio with $a_1 = 1.0$, $a_2 = -0.06$ and $b = -0.714$. This portfolio clearly has the profit property using the realistic binomial model with $p = 0.7$. The initial value of this portfolio is $V_0 = 0.19$. We compute also the safe price with probability $p = 0.7$ and the price is $Y = 0.19$.

The writer computes also another replicating portfolio with $a_1 = 0.09$, $a_2 = 0.07$ and $b = 0.058$ with initial value $V_0 = 0.22$ assuming $u_2 = 1.0$ and $d_2 = 0.95$. The advantage of this replicating portfolio is that the writer will have a profit if the price of $S_2(T)$ becomes bigger than $d_2 S_2(0)$ and that profit is unbounded from above on the event $\{\frac{S_1^T}{S_1^0} \in (d_1, u_1)\}$.

The final price using the above hedging strategies will come by adding the call options the writer needs and also the transaction costs.

In [7] the author computes the price of such an option using the Black-Scholes model. Unfortunately, the writer need to know the hedging strategy in order to sell this option at this price but the replicating portfolio proposed by the Black-Scholes model should be reconstructed continuously in time and that is impossible in practice. A price without a practical hedging strategy has no meaning for the writer. On the contrary all the above hedging strategies that we have proposed can be applied in practice.

5. Conclusion

We gave the concept of a price with a physical (or realistic) meaning and gave ways to produce such prices. It will be very interesting if we can find other, different from the above, realistic ways to price an option! Unfortunately, the binomial option pricing model and the Black - Scholes model do not produce prices with some physical meaning!

In [5] we have classified the options into two main classes. At the first one belong all the options with unbounded payoffs (like the call options) and at the second one belong the options with bounded payoffs (like the put options). The first class can be divided into two subcategories. At the first belong the options with unbounded payoffs but in which we can bound the payoff buying some call options (like in a spread option) and at the second belong the options with unbounded payoff in which we can

not bound it buying call options (like in a call on maximum option). This classification is important because the notion of the fair price has a meaning only at the class of options with bounded payoff and this price does not come necessarily by a replicating portfolio as we have seen at the section 4.1.

We have also recalled the realistic binomial option pricing model as we had proposed it in [5] and we have point out four open problems. We have given some examples of option pricing using the realistic binomial model and the notion of the safe price. We compare them and give the advantages and their disadvantages in every situation so as the writer can decide how to hedge the option and consequently how to price the option. The notion of the safe price can be used also by the buyer in order to estimate the probability of profit. The Black - Scholes model and all the models that assumes replication continuously in time is not practical since no one can construct such a portfolio in practice. In the hypothetical case that one could construct such a portfolio it is not certain that it would be preferred by writers over the safe or acceptable price as for example we have seen comparing the realistic binomial price with that of the safe price at the section 4.1.

In the case where someone can find a super - hedging strategy which hedge the option without any risk then the same maybe can be done by the buyer of this option. Moreover, if we assume that there is some competition, there will be someone else which will sell this option for a lower price undertaking some risk.

Summing up, in order the writer to price an option she first have to design a hedging strategy. For example, for a spread option she should buy some call options concerning the asset S_1 in order to bound the possible payoff. She estimate the amount of money that she need for building a replicating portfolio with the one period realistic binomial method. If this replicating portfolio assumes borrowing assets she should also buy call options for each such an asset! Next she estimate the safe price given a probability of profit and finally the average value of the payoff. All the above hedging strategies have a clear physical meaning and moreover they are applicable in practice. The writer need to know the smallest price, but with a physical meaning, for the contract in order to be competitive. The competition, if any, will drive the price of this option to the minimum assuming 3. The buyer has also a way to estimate the probability of profit buying at a specific price, assuming that she need this contract for speculation, by using the safe price notion. For example a writer of a spread option will buy a call option of the asset S_1 for security reasons and not for speculation. Finally, one way to eliminate the risk of bankruptcy selling a call option is by owning one stock per call option.

Assuming the d assets follows the following stochastic differential equation

$$S_i(t) = S_i(0) + \int_0^t f_i(s, S_i(s))ds + \int_0^t g_i(s, S_i(s))dW_s, \quad i = 1, \dots, d$$

we can estimate by means of the Monte Carlo method the expectations

$$\mathbb{E}_{\mathbb{P}}(H(S_1, \dots, S_d)) \quad \text{and} \quad \mathbb{E}_{\mathbb{Q}}(H(S_1, \dots, S_d))$$

where \mathbb{P} is the real world probability and \mathbb{Q} is an equivalent probability to \mathbb{P} so that the stochastic processes S_i are martingales under \mathbb{Q} . Here f_i, g_i are suitable functions chosen for each asset and H is the payoff function of the contract written on d assets. The physical meaning of the first expectation is clear for both the writer and the buyer. On the other hand the physical meaning of the second is clear only if the writer construct the corresponding replicating portfolio. If she don't construct the replicating portfolio then, in fact, she sell at the fair price with appropriately chosen probability p . That is, if the price Y is such that $\mathbb{P}(P_T \leq Y) = 1/2$ with $Y > \mathbb{E}_{\mathbb{Q}}(H(S_1, \dots, S_d))$ and the writer sell at the price $\mathbb{E}_{\mathbb{Q}}(H(S_1, \dots, S_d))$, i.e. with probability of profit less than $1/2$, then she should construct the replicating portfolio in order to hedge the risk which is impossible in practice. If $Y < \mathbb{E}_{\mathbb{Q}}(H(S_1, \dots, S_d))$ and the competition is high then there will be someone that will sell this contract at the price Y .

Every investor needs to know the future beliefs of other investors as well. This can be done by computing the implied probability of profit (fixing the parameters m, σ) using the above models, i.e. first compute the implied z_p and then p . The implied probability of profit is a criterion of how other investors see the future market concerning the underlying asset and is equivalent with the implied volatility using the Black - Scholes model.

As we have seen, the concept of fair price is not well defined because of the different perspective on the future of the writer and the buyer. However, the notion of the unfair price for the writer or for the buyer can be well understood. Consider for example a put option with strike price K . In this case, any price $Y \geq K$ is an unfair price for the buyer because the payoff will be less than K . Consider now an option with payoff $P_T = \max\{S_1(T), S_2(T), K\}$. Any price $Y \leq K$ is an unfair price for the writer because the payoff will be more than K . Therefore we can have the following definition of the unfair price.

Definition 3. Any price Y that drives either the writer or the buyer to certain loss is called unfair.

Consider now the case of a spread option with payoff $P_T = \max\{S_1(T) - S_2(T), 0\}$ and consider the price $Y = C(S_1, K) + K$ where $C(S_1, K)$ is a call option written on S_1 with strike price K . This price will drive the writer to certain profit without risk (arbitrage) but there is also the possibility for profit also for the buyer. So this price is not an unfair price for the buyer according to the above definition. However, if the competition is strong there will be another writer which will sell this contract for less money undertaking some risk.
