Abstract: *Background and Objectives:* The practice of physical activity is an effective non-pharmacological strategy for preventing and treating chronic diseases. A large body of evidence has contributed to establishing a positive correlation between a physically active lifestyle and health benefits, including enhanced vaccination responses, lower numbers of senescent T-cells, increased T-cell proliferative capacity, lower levels of inflammatory cytokines, and improved neutrophil and macrophage function. While females are generally thought to exert more robust immune responses than males in response to a variety of challenges, and both male and female sex hormones have been suggested as mediators of immune function, research on this topic has not always been designed with a sex-specific lens. *Materials and Methods:* We summarized the available experimental and clinical evidence linking exercise and immune function in male and female subjects, with an emphasis on sex differences and sex-specific mechanisms. *Results:* Overall, the available evidence indicates that moderate exercise and physical activity improves immune function in both sexes, whereas prolonged and high-intensity exercise temporarily impairs immune responses at a higher degree in females. *Conclusions:* Combined, the available literature suggests that moderate exercise and activity may enhance immune function, regardless of sex, whereas prolonged and high-intensity exercise temporarily impairs immune responses with effects that are more predominant in females than males.

Keywords: moderate exercise; vigorous exercise; upper respiratory infection; immunity

1. Introduction

More than 100 years ago, Larrabee (1902) observed a marked leukocytosis after violent exercise, including many polymorphonuclear neutrophils [1]. Since then, research on exercise-induced effects on the immune system has advanced tremendously. The practice of physical activity is an efficient free-drug strategy for preventing and treating several chronic diseases. In addition, a significant body of scientific evidence has contributed to establishing a positive correlation between a physically active lifestyle and health benefits [2], although not all studies have considered sex as a biological variable.

Regular physical activity and exercise are associated with numerous physical and mental health benefits in both men and women. Population studies consistently show that all-cause mortality is delayed by regularly engaging in physical activity [3,4]. Both middle-aged and older adult patients who engage in physical activity display reduced risk of chronic metabolic and cardiorespiratory diseases, enhanced vaccination responses, and longer leukocyte telomere lengths [5,6]. The practice of regular exercise results in increased natural killer cell cytotoxic activity, lymphocyte proliferation, and granulocytes counts [7,8], and has been shown to lower numbers of exhausted/senescent T-cells, elevate circulatory anti-inflammatory markers, and increase neutrophil phagocytic activity [9–13]. Similarly, exercise has been associated with improvements in mitochondrial function and activation of inflammasome-related signaling pathways [14,15]. In this regard, multiple studies have reported effects of different type of exercise on immune cells (Table 1).

Together, this evidence indicates that regular exercise practice is capable of modulating the immune system's function and delaying the onset of immunosenescence [16].

Immune system function is regulated by many factors in males and females. Due to the presence of hormone receptors on immune cells, sex hormones are one of the major factors that regulate the immune system. Generally speaking, females have more robust immune responses than males [17]. In addition, studies suggest that B-cell, T-cell, and other immune cell's function are affected by sex hormones [18-21]. Furthermore, sex hormones markedly modulate T-cell mediated delayed-type hypersensitivity reactions [22]. Female sex hormones such as estrogen, human chorionic gonadotropin, and progesterone can also affect the activation of dendritic cells and subsequent development of T-cells [23-26]. Estrogen influences not only the development but also various functions of T cells, in particular, CD4⁺ T-cells, including activation, cytokine production, differentiation, and regulatory functions, as well as B cells activation to produce antibodies [27]. Moreover, female sex hormones can also down-regulate specific cellular immune responses to prevent an immune attack on the fetus during pregnancy. In contrast, dominant male sex hormones including testosterone play a critical role in inducing type 1 T-helper cell function, which are critical players in cellular immune responses [28]. Despite this evidence, very few studies have attempted to investigate sex differences in exercise-induced changes in immunity or identify sex-specific immune mechanisms. Therefore, this review aims to provide updated and concise information to understand exercise-induced immune responses and provide insights into the role of sex hormones on their regulation.

2. Materials and Methods

2.1. Literature search

2.1.1. Databases and key terms searched

We performed a literature search on PubMed and Google scholar databases to identify eligible papers. We used the following search terms and logic: exercise OR physical activity OR physical exercise AND exercise-induced immune response AND immune response OR sex differences AND sex hormones OR male OR female. All articles were recovered and selected on the basis of the presence/absence of the search criteria.

2.1.2. Inclusion criteria

The search was limited to papers written in English. No limit of year of publication was set, and the final search is updated to March 2022. Articles were selected if they assessed the effects of moderate-intensity exercise (30- to 45-min/day) or vigorous exercise (endurance-trained athletes) on the immune system through the incidence of infection, study population 18-65 years old, both sexes. The incidence of infection was assessed by self-reporting (using health logs) or physician reporting. Health symptoms were defined as symptoms of illness that the athletes had experienced in the four weeks before the measures. An illness was defined as any physical complaint unrelated to an injury incurred during the same period.

2.1.3. Search process and study selection

All articles were recovered and selected based on the presence/absence of the search criteria. Articles were de-duplicated using the built-in mechanisms of university library services and further completed manually. Articles were assessed by their titles and abstracts for inclusion. Final selections were determined after a complete reading of articles.

2.1.4. Data Extraction and Analysis

The following information was extracted from the studies: the first author of the study, the year of publication, the study design or details of the intervention, data on the sample size, and critical outcomes. In addition, articles were categorized and organized in tables according to response to moderate-intensity or vigorous exercise.

Table 1. Studies investigating the effects of exercise on immune cells

Author, year [Reference #]	Study goal	Key findings
Kraemer, 1996 [14]	Examine the impact of heavy-resistance exercise-induced elevations of plasma cortisol on circulating leukocyte counts.	Significant acute increases in total leukocyte counts (but no differential counts) occur in response to heavy-resistance exercise that does not significantly elevate plasma cortisol.
Potteiger, 2001 [15]	Examine white blood cell counts (WBC), immunoglobulin (IgA, IgG, IgM) levels, and T-cell proliferation following acute resistance training.	WBCs were significantly elevated in subjects 1.5 and 3 hours post exercise compared with pre- and immediately post-exercise. T-cell proliferation was significantly decreased at 3 hours post-exercise
Dohi, 2001 [16]	Examine the influence of physical strength on lymphocyte proliferation after an acute bout of heavy resistance exercise	Squat exercise was associated with a decrease in lymphocyte responsiveness in the high strength but not in the low strength
Miles, 2003 [17]	Examine whether the immune response to resistance exercise was associated with changes in workload or anaerobic exercise intensity	Exercise induced increases in NK, CD4+, CD8+ and B lymphocyte concentrations.
Ramel, 2003 [18]	Examine the acute effects of submaximal resistance exercise on immunological and hormonal parameters	Total leukocytes, neutrophils, lymphocytes, and monocytes increased during exercise. T-helper cells returned to resting values after exercise, NK and T-suppressor cells decreased below resting values. The CD4/CD8 ratio decreased during exercise but increased during recovery. Resistance-trained participants tended to have lower T-helper cell counts before, during and immediately after exercise and a lower CD4/CD8 ratio during recovery than the non-resistance-trained.
Simonson, 2004 [19]	Examine the effects of a single bout of resistance exercise on immune cell numbers.	Resistance exercise induced leukocytosis was due to an increase in circulating LY (natural killer cells increased most, CD4+/CD8+ ratio unchanged) and monocytes (MO). The transient, inconsequential immune cell population responses to resistance exercise are similar to those during aerobic activity
Natale, 2003 [20]	Examine the effects of three different exercise protocols on blood leukocyte count during and following exercise	The peak aerobic and prolonged submaximal exercise induced similar alterations in cell counts. Both resistance and peak aerobic exercise resulted in a significantly longer-lasting decrease in the CD4+/CD8+ ratio than the submaximal exercise bout.
Ramel, 2004 [21]	Examine noradrenaline concentrations, neutrophil counts, plasma antioxidants, and lipid oxidation products before and after acute resistance exercise.	Neutrophils, noradrenaline, fat soluble antioxidants, and lipid oxidation products increased after exercise. Neutrophil counts were related to higher concentrations of conjugated dienes.

Mayhew, 2005 [22]	Examine the effect of varying rest intervals on leukocyte levels during heavy resistance exercise	Greater lymphocytosis and monocytosis following exercise. Serum creatine kinase (CK) activity was increased and correlated to lymphocytosis.
Peake, 2006 [23]	Examined changes in markers of muscle damage and systemic inflammation after submaximal and maximal lengthening muscle contractions of the elbow flexors	Total leukocyte and neutrophil numbers, and serum TNF α 1 receptor were elevated after both trials. Serum IL-6 was elevated 3h after submaximal contractions. Plasma myoglobin concentration and creatine kinase activity increased after both trials but were not significantly different between trials.
Ghanbari-Niaki, 2010 [24]	Examined effects of circuit resistance exercise (CRE) on peripheral blood lymphocyte (PBL) AgRP mRNA expression and its concentrations in lymphocytes and plasma	CRE increased AgRP mRNA lymphocyte expression at all intensities. A higher and significant increase was found in the resistance exercise group. The CRE-induced lymphocyte AgRP expression was accompanied by elevations in plasma AgRP, glucose and GH levels as well as higher WBCs, lymphocytes and neutrophil counts. Lymphocyte AgRP and GH concentrations were significantly reduced
Mooren, 2012 [25]	Examined the influence of a long-distance exercise on neutrophil apoptosis	After both marathon run and intensive laboratory exercise tests, neutrophil apoptosis was delayed. Neutrophils mitochondrial membrane potential and death receptor/ligand expression were not affected by exercise. Apoptosis delay was accompanied by enhanced intracellular calcium transients and decreased glutathione levels.
Ihalainen, 2014 [27]	Examine the acute immune response (circulating levels of leukocytes, cytokines and adipocytokines) to maximal resistance and hypertrophic resistance exercise bouts.	Leukocytes (WBC) significantly increased immediately after exercise. Monocyte chemoattractant protein-1 (MCP-1) decreased and interleukin-1 receptor antagonist (IL-1ra) increased after exercise.
Jamurtas, 2018 [29]	Examine the effects of HIIT on hematological profile and redox status compared with those following traditional continuous aerobic exercise (CET)	WBC increased after both exercise protocols immediately post-exercise. Both HIIT and CET increased uric acid after exercise. There were no significant changes for TBARS and catalase following either exercise protocol.

3. Results

3.1. Search results

The search yielded a total of 984 studies (Figure 1). Of these, 132 studies were found to be duplicates. Of the remaining 852 studies, 759 were discarded as irrelevant due to irrelevant study design or setting, not explicitly defined sample size and/or interventions, and language. The full text of the remaining 93 articles were reviewed, and those that did not comply with the inclusion criteria were discarded. The final selection included 32 articles that met the selection criteria. These were subsequently divided into articles

studying moderate intensity exercise (10 articles, Table 2) vs. vigorous exercise (23 articles, Table 3).

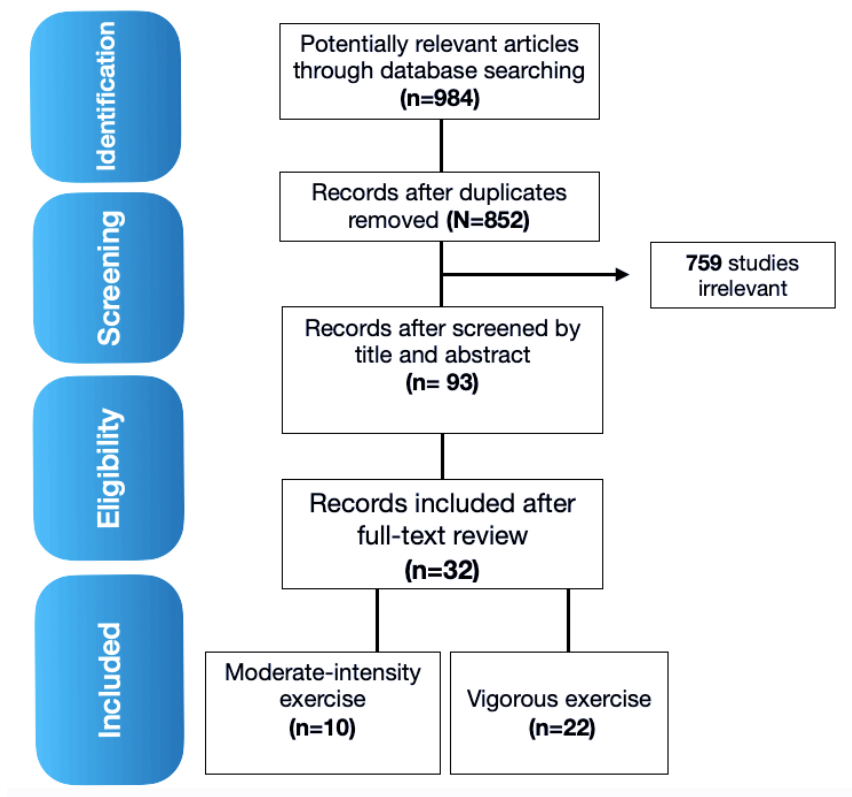

Figure 1. Literature search results and selection of studies for review.

3.2. Effects of moderate physical activity intensity on immune responses in female and male subjects

The literature review identified 10 publications linking moderate-intensity exercise with immune response and upper respiratory tract infection outcomes (Figure 1). The moderate-intensity exercise studies consisted of brisk walking, stretching, jogging or mild aerobic exercise, and the main results, study design, participant information, and study goals are summarized in Table 2.

Our search identified 4 studies including only female participants [29-32], 6 papers that included both males and female subjects [33-38], and no studies including only males. Overall, enrollment of subjects ranged from 32 to 1509 for the selected studies. The combined total of participants from all studies was 5,284 (including 3,442 females and 1,842 males), and the proportion of female participants ranged from 0.93% (N=32) to 23% (N=791). In all studies enrolling only females, moderate physical activity was associated with reductions in upper respiratory tract infections. Interestingly, all four studies included female subjects who were sedentary, overweight, or obese, although one study compared the effect in highly conditioned females and found a reduced effect in this group versus the sedentary group [30].

In studies enrolling participants from both sexes, both male female responses to moderate-intensity physical activity were characterized by strong reductions in upper respiratory tract infections, as well as fewer symptomatic days compared to sedentary subjects. Unfortunately, comparisons between male and female effects were not tested or reported in all studies, except for only one study that indicated that the effect on upper respiratory tract infection was stronger in males than females [33].

Table 2. Articles establishing a relationship between moderate exercise and immune responses

Author, year, country [Reference #]	Study goal	Exercise protocol [Exercise type]	N subjects [Sex]	Key findings
Nieman, 1990, USA [29]	Randomized controlled trial to investigate the relationship between improvement in cardiorespiratory fitness, changes in natural killer (NK) cell number and activity, and acute upper respiratory tract infection (URTI) symptomatology.	A randomly controlled 15-wk exercise training (ET) study (five 45-min sessions/wk, brisk walking at 60% heart rate reserve). Conducted using 2 (exercise and non-exercise groups) × 3 (baseline, 6-, and 15-wk testing sessions). [brisk walking]	36 mildly obese sedentary women (aged 34.4 ± 1.1 years)	The ET group was found to have significantly fewer URTI symptom days/incident than the nonexercised group. Moderate ET was associated with elevated NK cell activity after six but not 15 weeks, and reduced URTI symptomatology in comparison to a randomized, sedentary control group.
Nieman, 1993, USA [30]	Randomized controlled trial to investigate the relationship between cardiorespiratory exercise, immune function, and URTI in elderly women.	Sedentary women randomized to a 12-week moderate intensity (30- to 40-min/day × 5 days/week) walking program or stretching (45 min/day × 5 days/week) in fall season. [brisk walking or stretching]	32 sedentary women (aged 73.4 ± 1.2 years); 12 highly conditioned women (aged 72.5 ± 1.8 years)	URTI incidence 8% in highly conditioned, 21% in walkers, and 50% in controls.
Nieman, 1998, USA [31]	Randomized controlled trial to investigate the effect of ET and/or moderate energy restriction on innate and adaptive immunity, NK cell activity, and mitogen-stimulated lymphocyte proliferation.	12-week (five 45-min walking sessions/wk at 60-75% maximum heart rate) and/or moderate energy restriction (4.19-5.44 MJ or 1,200-1,300 kcal × d(-1)) randomized to one of four groups: control, exercise, diet, exercise + diet. [brisk walking]	N = 91 obese women, aged 45.6 ± 1.1 yr., body mass index 33.1 ± 0.6 kg × m(-2)	Days with symptoms of URTI were reduced in subjects in the exercise group, relative to subjects in the non-exercise groups. Energy restriction and weight loss increased mitogen-stimulated lymphocyte proliferation but had no effect on NK cell activity.
Chubak, 2006, USA [32]	Randomized controlled trial to investigate the effect of a moderate-intensity, year-long exercise program on the risk of colds and other URTI in postmenopausal women.	Subjects randomized to 12 months of moderate intensity exercise (45 min/day × 5 days/week) or stretching control (45 min/day × 1 day/week) [brisk walking or stretching]	115 overweight and obese, sedentary, postmenopausal women (aged 60.7 ± 6.9 years)	URTI incidence was 30% in exercise vs. 48% in controls.

Barrett, 2012, USA [34]	Randomized controlled trial to investigate potential preventive effects of meditation or exercise on incidence, duration, and severity of acute respiratory infection (ARI) illness	Randomized to 1 of 3 study groups: 8-week training in mindfulness meditation, matched 8-week training in moderate-intensity sustained exercise, or observational control. [brisk walking or jogging]	149 (82% female, 94% white, mean age 59.3 ± 6.6 years)	Both global severity and total days of illness (duration) displayed lower trends the exercise group.
Barrett, 2018, USA [35]	Randomized controlled trial to investigate preventive effects of meditation and exercise on ARI illness.	Randomized to 1) 8-week behavioral training in mindfulness-based stress reduction (MBSR); 2) matched 8-week training in moderate intensity sustained exercise; or 3) observational waitlist control. [brisk walking or jogging]	390 male and female (76% female) (mean age 49.6 ± 11.6 years)	There were 112 ARI episodes and 1045 days of ARI illness, compared to 120 episodes and 1010 illness days in the moderate intensity sustained exercise group, and 134 episodes with 1210 days of ARI illness for controls.
Fondell, 2011, Sweden [36]	Epidemiologic study to investigate differences in URTI risk between physically inactive and moderately active adults. Population-based prospective cohort study with baseline questionnaire on physical activity; illness symptoms assessed every 3 weeks for a follow-up period of 4 months.	Three 24-h physical activity recalls per evaluation were obtained and averaged to quantify total moderate-vigorous activity (≥ 3.0 MET) [Several]	1509 (725 male, 784 female) aged 20-60 yr.	High levels of physical activity were associated with an 18% reduced risk of self-reporting URTI compared with low levels of physical activity.
Matthews, 2002, USA [33]	Epidemiologic study (observational) to investigate differences in URTI risk between physically inactive and moderately active adults.	Reported URTI events at 90-d intervals over 12-month of follow-up (5 evaluations) were measured. Three 24hr physical activity recalls per evaluation were obtained and averaged to quantify total moderate-vigorous activity (≥ 3.0 metabolic equivalent, MET) [Several]	547 healthy adults (49% female) aged 20-70 yr.	Male and female subjects reported mean and (SD) of 1.2 (1.4) and 1.2 (1.2) URTI events per year, respectively. This effect was stronger in males although at similar expenditure levels, risk was reduced by about 20% in both sexes.

Zhou, 2018, China [37]	Epidemiologic study (cross-sectional) to investigate associations between the frequency of leisure-time exercise, cigarette smoking status, and frequency of the common cold in a cold area. Participants retrospectively reported frequency of illness and physical activity over the past year	[Any type of moderate-intensity exercise]	1413 male and female adults (aged 38.9 +/- 9.04 years) 44.4% of them were male	A high frequency of leisure-time exercise (≥3 days/week) was associated with a 26% reduced risk of having at least one episode of the common cold compared with a low frequency group (< 4 days/month).
Nieman, 2011, USA [38]	Epidemiologic study to investigate URTI symptoms and severity in a heterogeneous group of community adults with various physical activity and fitness levels.	Assessment over 12 weeks during the winter and fall seasons while monitoring URTI symptoms and severity using the Wisconsin Upper Respiratory Symptom Survey and reported frequency of aerobic activity. [Aerobic activity (mild)]	1002 adults (ages 18-85 years, 60% female, 40% male)	The number of days with URTI during the 12-week period was significantly reduced by 43% in subjects reporting ≥ 5 days/week aerobic exercise compared to those who were largely sedentary (≤ 1 day/week), and by 46% when comparing subjects in the high versus low fitness. URTI severity and symptomatology were also reduced in the physical fitness group.

ARI: acute respiratory illness; ET: exercise training; MBSR: mindfulness-based stress reduction; MET: metabolic equivalent; NK: natural killer cell; SD: standard deviation; URI: upper respiratory tract infection; USA: United States of America

3.3. Effects of vigorous physical activity intensity on immune responses in females and males

Our literature review identified 22 publications linking vigorous exercise and immune-related outcomes (Table 3) [39-60]. Across all studies, vigorous exercise consisted of long distance running, endurance training, swimming, triathlon, track and field, athletics, cross-country skiing, and both winter and summer Olympic sports. Of the 22 studies selected, 5 did not report the sex of the participants enrolled [39-43], whereas 17 enrolled both male and female subjects [44-60]. Studies ranged from 20 to 11,274 total participants, and the proportion of female participants ranged from 0.12% (N=23) to 26% (N=5,089).

In general, participants engaging in vigorous exercise displayed an increased incidence of illness compared to controls. For instance, marathon runners had increased odds for infectious episodes during heavy training or following a marathon race. Female sex

was identified as a risk factor, as illness incidence was higher in female athletes in nine studies comparing both sexes [49,52-59].

Table 3. Relationship between vigorous exercise and immune responses in studies enrolling male and female subjects

Author, year, country [Reference #]	Study goal	Exercise protocol [Exercise type]	N subjects [Sex]	Key findings
Peters, 1983, South Africa [39]	Prospective study of the incidence of symptoms of upper respiratory tract infections (URTI) in 150 randomly selected runners taking part of the 1982 Two Oceans Marathon in Cape Town, and compared incidence in individually matched controls who did not run.	Participants reported 2-week recall of illness symptoms after 56-km race [Ultramarathon]	41 ultramarathon runners and 124 controls (aged 18-65 years) [No sex reported]	Illness incidence was 2-times higher in runners (after race) vs. controls.
Nieman, 1993, USA [45]	Epidemiologic study of Los Angeles Marathon applicants to investigate the relationship between self-reported infectious episodes and training.	Participants were asked to report illness symptoms 2 months before and 1 week after March 42.2-km race. [Marathon]	2311 marathon runners (aged 36.9 + 0.2 years) [male: 1941 and female: 370]	Runners experienced increased odds for infectious episodes during heavy training or following a marathon race.
Raysmith, 2016, multiple countries [43]	Retrospective cohort to investigate the impact of training modification on achieving performance goals and illness.	Participants reported illness symptoms during 6 months across five international competition seasons. [Track and Field]	33 international track and field athletes. [No sex reported]	Illness incidence was 23%; one-half of illnesses occurred 2 months before competition.
Heath, 1991, USA [46]	Prospective cohort study. To investigate illness patterns in a cohort of 530 male and female runners who completed a monthly log for 12 months.	Participants reported training log and illness symptoms every month for 1 year. [Running]	530 runners (average age 39.4 years) [male: 447 and female: 83]	Participants running > 485 miles/year (780 km/year) displayed an increased risk of illness. The average number of events per person per year

				was 1.2, and slightly higher in females than males (1.2 for males vs. 1.3 for females).
König, 2000, Germany [40]	Epidemiological study to investigate the association between incidence of illness and exercise, stress and sleep deprivation.	Participants retrospectively reported illness episodes over the past 12 months. [Athletics]	852 German athletes (aged 23.6 + 9.5 years) [No sex reported]	Illness incidence was 2 times higher in participants conducting endurance sports.
Alonso, 2012, Korea [50]	Epidemiological study to investigate the incidence and characteristics of newly incurred injuries and illnesses the 13th International Association of Athletics Federations World Championships in Athletics 2011 in Daegu, Korea.	Medical staff reported illness symptoms during competition event (<4 weeks) [Athletics]	1,851 registered athletes (1,063 males and 964 females).	No differences in illness and time-loss illness incidence were reported between male and female athletes.
Timpka, 2017, China [59]	Cohort study to investigate pre-participation predictors of injury and illness during the 15th International Association of Athletics Federations World Athletics Championships in Beijing (22–30 August 2015).	Athletes answered pre-participation health questionnaire including individual pre-participation information (personal characteristics and health status during the month preceding the championship). [Athletics]	307 athletes (Female 135 and male 172)	No sex difference found in athletes reporting an illness symptom.
Alonso, 2010, Germany [51]	Epidemiological study to investigate the frequency and characteristics of sports injuries and illnesses incurred during the	Medical staff reported illness symptoms during competition event (<4 weeks) [Athletics]	2,378 athletes (1,301 males and 1,077 females)	A total of 382 injury and illness reports were returned. More illnesses were reported for female

	12 th International Association of Athletics Federations World Championships in Athletics 2009 in Berlin, Germany.			than for male athletes.
Gleeson, 2013, UK [44]	Prospective cohort to investigate the effect of training load on URTI incidence in men and women engaged in endurance-based physical activity during the winter.	Participants followed for 4 months in winter; reported weekly illness symptoms and training. Exercised 3-6 h/week (low), 7-10 h/week (medium) or ≥ 11 h/week (high). [Endurance training]	75 endurance trained university students (aged 18-35 years) [male and female number not reported]	The high and medium intensity groups reported higher rates of URTI episodes than the low intensity group.
Rama, 2013, Portugal [41]	Prospective cohort study to investigate the occurrence of episodes of upper respiratory symptoms (URS), over a winter swimming season.	Participants followed for 7 months in winter; reported daily illness symptoms. [Swimming]	19 elite swimmers vs. 11 nonathlete controls (aged 17.6 ± 1.0 years) [No sex reported]	67% of URS episodes occurred during high volume training in swimmers vs. no illness in control at same time points.
Hellard, 2015, France [42]	Prospective cohort study to investigate the relationship between sport training and the risk of common illnesses: URTI and pulmonary infections, muscular affections, and all-type pathologies in highly trained swimmers.	Participants followed for 4 years; monitored weekly for illness. [Swimming]	28 elite swimmers (aged 16-30 years) [No sex reported]	Illness increased 1.08 times for every 10% increase in resistance training and 1.10 times for every 10% increase in high-load training.
Prien, 2017, Russia [60]	Comparative study to investigate the frequency and characteristics of injuries/illnesses in the 4 weeks prior to, and during the Fédération	Athletes answered a retrospective questionnaire, and medical staff reported injuries/illnesses prospectively. [Swimming]	2413 athletes who competed at the FINA World Championships 2015 in one of the six aquatic disciplines. Both	Around a quarter (26.1%) of athletes reported health complaints in the 4 weeks prior to the championships.

	Internationale de Natation (FINA) World Championships in 2015.		female (n=1262) and male athletes (n=1151) participated; age ranged from 10-40 years with an average of 22.1 years (SD=4.5)	
Spence, 2007, Australia [47]	Prospective cohort to investigate the incidence, pathogenic etiology, and symptomatology of acute URTI during a 5-month training and competition period.	Participants followed for 5 months in summer/autumn; reported daily illness symptoms. [Triathlon and cycling]	17 elite male and female triathletes and cyclists (age 18–34 yr.), 30 male and female recreationally competitive triathletes and cyclists (age 19–34 yr.), and 18 male and female untrained sedentary controls who did less than 60 min walk (age 19–29 yr.)	Elite athletes had higher rates of illness than recreationally competitive athletes and sedentary controls.
Svendsen, 2015, multiple countries [48]	Prospective cohort study to investigate whether participating in a cross-country skiing stage race (Tour de Ski) affects subsequent illness incidence, training, and race performance.	Participants followed for 8 years; reported illness symptoms daily for 10 days after the Tour de Ski race. [Cross-country skiing]	42 male and female elite cross-country skiers (aged 24 + 4 years)	Illness incidence was 3 times higher in skiers who raced the Tour de Ski vs. non-competing skiers.
Drew, 2018, Brazil [49]	Retrospective Cohort. To investigate the prevalence of illness symptoms, poor sleep quality, poor mental health symptoms, low energy availability and stress-recovery state in an Olympic cohort late	3 months before competition, participants reported illness symptoms during a 1-month time period. [Summer Olympic sports]	132 elite athletes preparing for the Olympics (male, n=47, age 25.8±4.1 years; female, n=85, age 24.3±3.9 years)	Illness symptoms were found in 100% athletes. Risk factors were female sex , low energy availability, and a combination of anxiety and stress-recovery states.

in the 3 months prior
to the Summer Olympic Games.

Mountjoy, 2015, Spain [52]	Epidemiological study to investigate injuries among athletes of aquatic disciplines in the 4 weeks prior to and during the 2013 FINA World Championships.	Medical staff reported illness symptoms during competition event (<4 weeks) [Water sports]	1,110 (500 males and 610 females) Mean age: 22.5 (4.35)	Significantly more females than males reported physical complaint prior to the Championships.
Mountjoy, 2010, Italy [53]	Epidemiological study to investigate the frequency and characteristics of injuries and illnesses occurring during the 13th FINA World Championships 2009	Medical staff reported illness symptoms during competition event (<4 weeks) [Water sports]	2,592 athletes (1,293 females and 1,299 males)	Female athletes had a higher risk of injury than male athletes.
Engebretsen, 2010, Canada [58]	Epidemiological study to investigate the frequencies and characteristics of injuries and illnesses during the XXI Winter Olympic Games in Vancouver (2010)	Medical staff reported illness symptoms during the competition event (<4 weeks) [Winter Olympic sports]	2,567 athletes (1,045 females and 1,522 males)	There was a significantly higher proportion of illness in female athletes compared to male athletes.
Soligard, 2015, Russia [55]	Epidemiological study to investigate injuries and illnesses that occurred during the XXII Olympic Winter Games, held in Sochi in 2014	Medical staff reported illness symptoms during competition event (<4 weeks) [Winter Olympic sports]	2,780 athletes (1,121 females and 1,659 males)	Female athletes were at significantly higher risk of contracting an illness than male athletes.

Palmer-Green, 2015, Russia [56]	Observational prospective cohort study to investigate the prevalence, severity, nature, and causes of athlete injuries and illnesses in the Great Britain Olympic Team during the Sochi 2014 Winter Olympic Games	Medical staff reported illness symptoms during competition event (<4 weeks) [Winter Olympic sports]	56 Athletes (33 males and 23 females) members of the Great Britain Olympic Team (13 sports represented).	There were more illnesses sustained by female athletes compared to male athletes.
Engelbrecht, 2013, UK [57]	Epidemiological study to investigate injuries and illnesses that occurred during the Games of the XXX Olympiad, held in London in 2012	Medical staff reported illness symptoms during the competition event (<4 weeks) [Summer Olympic sports]	10,568 athletes (4,676 females and 5,892 males)	Overall, female athletes suffered higher rates of illnesses than males.
Soligard, 2017, Brazil [54]	Epidemiological study to investigate the recorded daily incidence of athlete injuries and illnesses through the reporting of all National Olympic Committee medical teams, and in the polyclinic and medical venues in Rio de Janeiro 2016.	Medical staff reported illness symptoms during competition event (<4 weeks) [Summer Olympic sports]	11,274 athletes (5,089 female, 6,185 male) participating in the Games of the XXXI Olympiad, hosted in Rio de Janeiro.	Women were at significantly higher risk of contracting an illness than men.

4. Discussion

An extensive volume of peer-reviewed studies in the field of exercise immunology has established links between immune function and exercise [61-64]. High levels of physical activity have sometimes been associated with a decrease in circulating sex hormones in pre-and-postmenopausal women, and alterations in susceptibility to infection and disease [65,66]. Hence, it is evident that biological sex plays an important role as an essential modulator of the immune response. Sex hormones including estrogens can act as enhancers of humoral immunity, and androgens and progesterone (and glucocorticoids) can act as natural immunosuppressors [67]. Equally important is to remark that sex steroids—estrogens, progesterone, and testosterone—differ between sex and within different reproductive stages. In this context, several aspects of the immune response have been reported to display marked sex differences under both exercising and non-exercising conditions [68-73].

Both innate and adaptive immune system key cellular players bear receptors for sex hormones and respond to hormonal cues, suggesting that the effects of exercise on the immune system may also be sex-dependent [19,74,75]. Similarly, the female reproductive cycle can affect inflammatory gene expression changes triggered by exercise in a variety of conditions [76]. In the current study, we sought to identify sex differences in the effects of different exercise modalities on immune responses and associated outcomes, by reviewing the available literature. Overall, we confirmed that multiple studies conducted in the field are not designed or powered to test for sex as a biological variable, nor attempted to evaluate the contributions of sex hormones to measured outcomes. However, our literature search identified many effects of exercise on immune function that appear to correlate with the intensity of the bouts of exercise and modulated by sex.

When reviewing the available work relating moderate exercise modalities to immune function (determined by either incidence of respiratory tract infection, duration of infection or illness, and natural killer cell activity) we noticed that in most cases, individuals who sparkled in moderate-intensity exercise had significantly fewer upper respiratory tract infections (URTI), and fewer days with symptoms relative to sedentary individuals, regardless of sex. While most studies did not account for sex in the data reporting and analysis, one study reported that the URTI effect was slightly higher in male than female subjects [33]. In addition, moderate-intensity exercise was associated with improved immune cell function in previously non-sedentary individuals. Together, the available literature supports the notion that moderate exercise is beneficial to prevent infection and improve immunity in both male and female individuals.

In contrast, when reviewing the literature on the effects of vigorous exercise on immune function and infection incidence, we repetitively found that different forms of intense and vigorous exercise were reported to exert a negative effect on the immune system's phenotypic makeup and functional capacity. In most cases, it was found that both URTIs and symptomatic days were higher in individuals involved in vigorous exercise, as shown in Table 3. Interestingly, studies incorporating both male and female individuals reported that females displayed higher incidence of illness in the majority of studies, indicating that female sex represents an additional risk factor for the negative effect of intense exercise. Despite these findings, we found that most studies were not designed to detect sex-specific effects or disaggregated all data by sex. Thus, it is important to emphasize that future work should follow the Sex and Gender Equity in Research (SAGER) guidelines in reporting findings [77].

Over the past few decades, a number of studies have indicated that, after a prolonged heavy endurance exercise, several immune system components display a suppressed function for several hours [62,78-81]. This down-regulation of immunity after intense exercise has been described as a protective response to limit inflammation following periods of heavy and prolonged training. While in most studies, the overall cytokine response to exercise has not been found to be markedly different between the sexes in non-exercising conditions [82,83], extensive research has compared innate and adaptive immune responses to exercise between sexes, and found that females of reproductive age have a more active immune system than age-matched males in non-exercising conditions [72,73,84-86]. For example, Nieman *et al.* found no difference in serum IL-10, IL-1ra, IL-6, and IL-8 between male and female subjects either immediately or 1.5 hours after completing a marathon [87]. However, it is important to remark that the female cyclic phase must be considered when investigating female responses in exercise and immunity.

Regarding the roles of female reproductive cycles in these effects, Northoff *et al.* found a sex and menstrual phase difference in mRNA inflammatory gene expression in response to a 60 min run at 93% of the individual's anaerobic threshold. In this context, women in the luteal phase demonstrated higher pro-inflammatory markers than women in the follicular phase or men immediately after exercise. Compelling, post-exercise IL-6

mRNA was down-regulated in the luteal phase while up-regulated in the follicular phase after exercise [76] (Figure 2). Similarly, studies including women taking different types of oral contraceptives have reported cycle-specific exercise-induced changes [83], and premenopausal women have shown menstrual function dysfunction and delay in the onset of menarche with regular, vigorous-intensity exercise [88-90]. Taken together, the available literature indicates that the intensity and duration of exercise, fitness level, and circulating sex hormone levels can all affect the immune system's response to exercise. This body of work suggests a modulatory crosstalk of female sex hormones and exercise-induced physiological responses. However, many of these studies have significant limitations because sex differences and the role of sex hormones was not elaborated on or investigated.

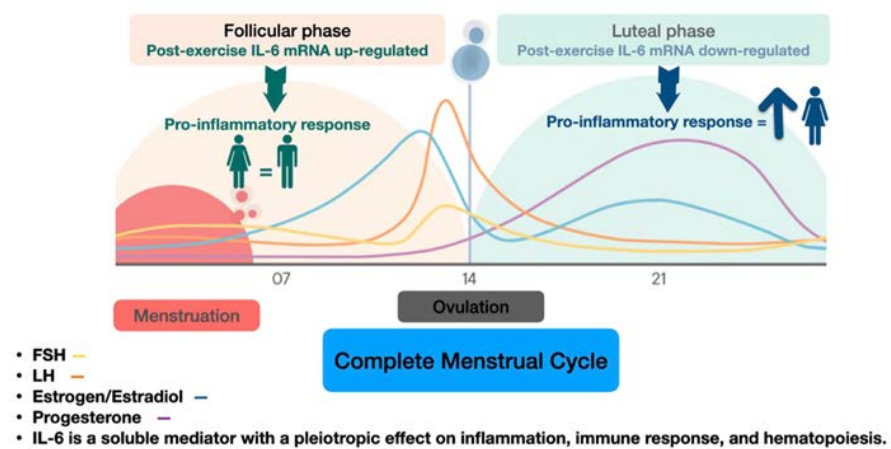

Figure 2. Variation of IL-6 mRNA gene expression throughout the female menstrual cycle and hormonal variations in response to exercise, and comparison of the response with males. Physiological fluctuation of hormone levels in the follicular and luteal phases are shown. Modified from [76].

Athletes, which are often considered healthier than the average population, are in fact more prone to infection due to alterations in the immune system that occur during and after periods of heavy training. Our literature review not only confirms this, but also indicates that female sex represents a risk factor in multiple exercise modalities and populations. Hence, medical personnel, coaches, and athletes must be aware of the increased risk of illness during vigorous exercise, particularly in females. That said, while the current study provides a comprehensive assessment of the relationship between exercise and immunity, it has several limitations. First, while the reports reviewed were conducted in different countries, most of the studies investigating moderate exercise effects on immune function were conducted in the United States, whereas studies investigating vigorous exercise were conducted in multiple countries. Second, our study focuses on studies addressing effects on upper respiratory infections in professional athletes, which may limit its generalizability to other populations. Finally, information about body mass index, medication use, and other medical conditions of participants was not consistently available in the studies consulted, limiting our ability to collectively assess their impact on the effects reported in males and females.

Overall, the body of literature summarized in the current study suggests that promoting training programs with increasing low- to moderate-intensity training volumes and ensuring sufficient rest and recovery may help maintain immune health and decrease the incidence of infection. More research must be done to fully elucidate the contributions

of sex-specific factors to these outcomes, as well as the mechanisms underlying sex-specific immune response to exercise.

5. Conclusion

Combined, the available literature suggests that moderate exercise and activity may enhance immune function, regardless of sex, whereas prolonged and high-intensity exercise temporarily impairs immune responses with effects that are more predominant in female than male subject.
