Rise and Fall of Caribbean Mangroves

Valentí Rull

Botanic Institute of Barcelona, Spanish Research Council (CSIC), Barcelona, Spain; vrull@csic.es

Abstract: Tropical mangroves, one of the most important blue-carbon ecosystems, are among the world's most threatened ecosystems and are in danger of disappearing within the next century, which may have a significant impact on coastal ecology and biodiversity, and also on the global capacity of climate change mitigation. The Caribbean region is one of the main mangrove hotspots on Earth. This paper is a thorough updated synthesis on the origin, evolutionary turnover, diversification and historical decline of the Caribbean mangroves, in relation to tectonic, climatic, eustatic and anthropogenic shifts. Neotropical mangroves originated in the Caribbean during the Middle Eocene, after the emergence of the first known mangrove-forming tree (*Pelliciera*). The abrupt cooling and sea-level fall of the Eocene-Oligocene transition (EOT) would have facilitated the replacement of the primeval mangroves by others dominated by *Rhizophora*. This was a major evolutionary disruption and gave rise to the modern Neotropical mangrove forests, still dominated by *Rhizophora*, with *Pelliciera* restricted to a relictual equatorial patch. The other extant mangrove-forming trees (*Avicennia*, *Pelliciera*) appeared in the Mio-Pliocene and the main diversification burst occurred in the Plio-Pleistocene, when 80% of extant genera emerged, with no extinctions documented. Pleistocene climatic and eustatic glacial cycles promoted recurrent spatial and compositional reorganizations. Natural drivers were the most influential until the Middle Holocene, when Amerindian cultures settled the whole Caribbean region and began to modify mangrove communities for agriculture and other activities using fire. During the last decades, deforestation has accelerated and the Caribbean mangrove cover has been reduced by >30%. A variety of conservation actions have been undertaken, but paleoecological and evolutionary knowledge remains to be fully incorporated into mangrove preservation. It is hoped that contributions like the present will help raising awareness on the importance of past records for conservation purposes.

Keywords: Caribbean; mangroves; evolution; paleoecology; climate; sea level; anthropization; conservation

Introduction

Mangroves form a distal continental fringe along the tropical/subtropical coasts (Figure 1), which marks the extent of normal tides. Mangrove forests protect coasts and other coastal ecosystems (corals, seagrasses, salt marshes) from erosion and develop a complex physical structure that favors habitat and niche diversification, which allows many terrestrial and aquatic species to thrive, thus enhancing biodiversity and ecological complexity (Laegdsgaard & Johnson 2001, Saenger 2002, Nagelkerken et al., 2008). Mangroves not only provide ecological and cultural services (fisheries, cultivation, aquaculture, timber, fuel, aesthetics, ecotourism) but also contribute to the mitigation of global warming. These communities, along with seagrasses and salt marshes, are among the most important blue-carbon ecosystems – i.e., marine ecosystems that sequester and immobilize carbon, thus removing it from the global cycle – acting as efficient carbon sinks and contributing to the alleviation of atmospheric CO₂ increase (Nellemann et al., 2009, Mcleod et al., 2011, Fest et al. 2022). Presently, mangrove forests are among the world's most threatened ecosystems (Worthington et al. 2020). According to the latest estimates, the global mangrove extent was reduced by ~25% in only three decades (1980-2010) due to natural and anthropogenic deforestation (Bunting et al. 2022). If these rates are maintained, these ecosystems will be severely reduced during this century and could disappear from the face of the Earth within the next century (Duke et al. 2017).

The Neotropical Caribbean region is one of the main mangrove hotspots (Duke, 2017), and the most relevant threats are urbanization, damming, agriculture, forestry, tourism, fisheries, salt

production and shrimp farming (Lacerda et al., 2019). A significant amount of basic ecological information is still needed to properly address the conservation and restoration of Caribbean mangroves. Part of this information may be retrieved from paleoecological and evolutionary records, which provide a natural laboratory where to study the responses of Neotropical ecosystems to long-term natural and anthropogenic drivers of ecological change (Vegas-Vilarr bia et al., 2011). In the last couple of years, the paleoecological and evolutionary study of Caribbean mangroves has experienced a significant burst with the compilation of a nearly exhaustive database of ~140 sites encompassing the whole history of these communities from their origin, ~50 million years ago (Ma), to their anthropization during the last millennia. The detailed analysis of this dataset has provided new clues on the origin, evolution and biogeography of Caribbean mangroves that challenge classical views and have been published in a collection of recent papers, sorted chronologically (Rull, 2022a, b, c, 2023a, b). A synthetic update of this new information is still unavailable and is the main target of this paper, which highlights the most relevant findings for understanding the shaping of these ecosystems and for informing their conservation.

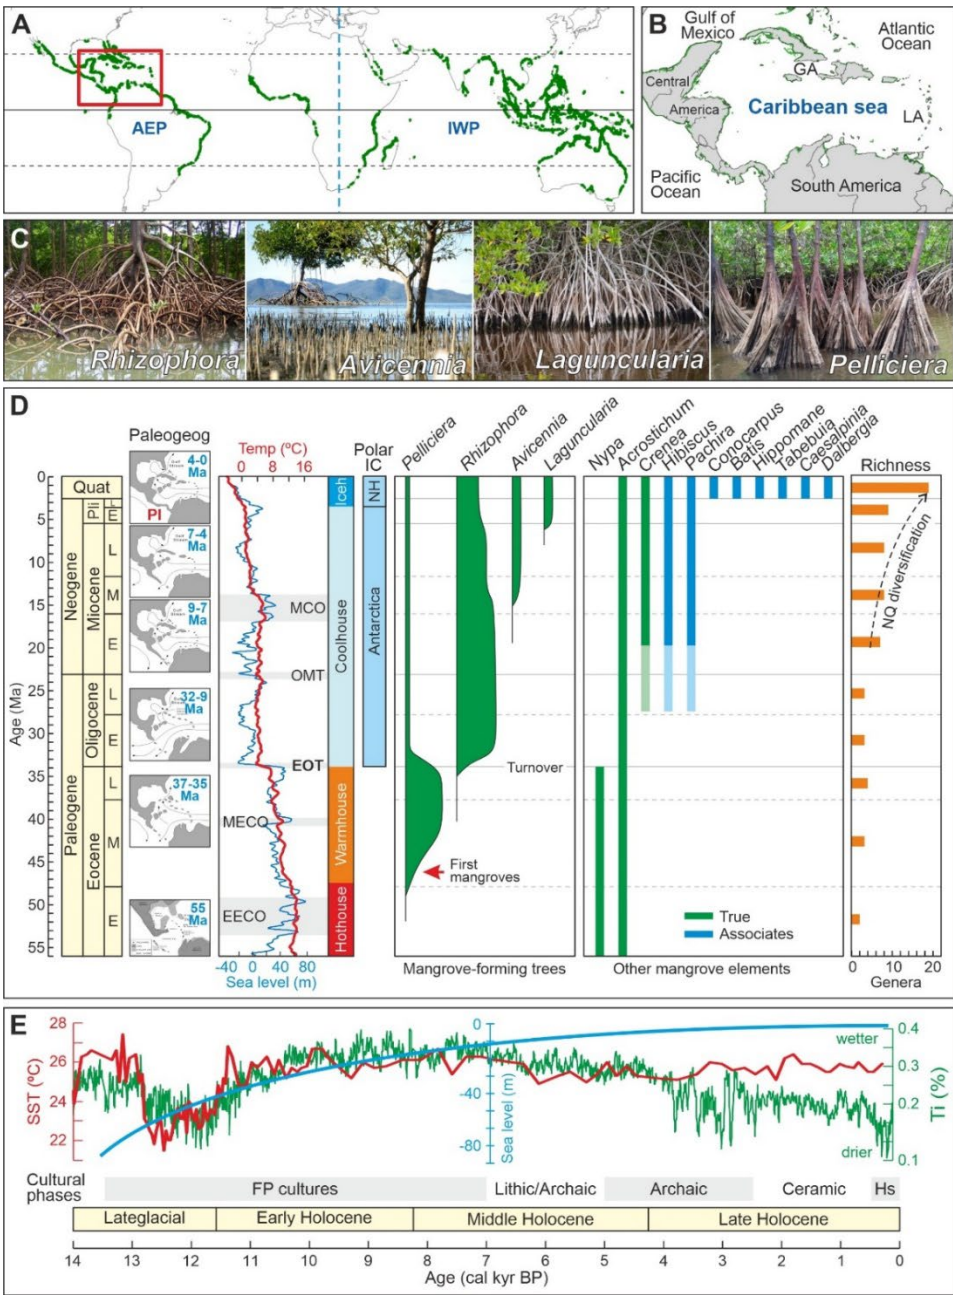

Figure 1. Present patterns and past trends of Caribbean mangroves. (A) Present worldwide mangrove distribution (green patches) (Spalding et al., 2010) and the two main biogeographical regions (AEP,

Atlantic-East Pacific; IWP, Indo-West Pacific). The location of the Caribbean region is indicated by a red box. (B) The Caribbean region, as considered in this study (GA, Greater Antilles; LA, Lesser Antilles). (C) The main genera of mangrove-forming trees (Rull, 2022a, b). (D) Paleogene and Neogene evolution of Caribbean mangroves (Rull, 2022a, c, 2023a) in relation to paleogeographic (Iturralde-Vinent, 2006), paleoclimatic (Westerhold et al., 2020) and paleoeustatic (Miller et al., 2020) shifts. Chronology: Quat, Quaternary; Pli, Pliocene; E, Early, M. Middle; L, Late. Paleogeography: PI, Panama Isthmus. Paleoclimates: EECO, Early Eocene Climatic Optimum; MECO, Middle Eocene Climatic Optimum; EOT, Eocene–Oligocene Transition; OMT, Oligocene/Miocene Transition; MCO, Miocene Climatic Optimum; Iceh, Icehouse; NQ, Neogene-Quaternary. Polar Ice Caps (IC): NH, Northern Hemisphere. Richness: NQ, Neogene-Quaternary. (E) Holocene paleoclimatic (Haug et al., 2002, Lea et al., 2003), paleoeustatic (Khan et al., 2017) and cultural trends and events (Rull, 2022b). SST, Sea Surface Temperature; Ti, Titanium concentration as a moisture proxy.

Extant Mangroves

The extant Caribbean mangroves are characterized by three main tree genera, known as mangrove-forming trees: *Rhizophora* (Rhizophoraceae), *Avicennia* (Acanthaceae) and *Laguncularia* (Combretaceae) (Figure 1). The first is the most abundant and widespread and is represented by two species (*R. mangle*, *R. racemosa*), whereas the second has three Caribbean species (*A. germinans*, *A. bicolor*, *A. shaueriana*) and the third is monospecific (*L. racemosa*). These trees are known as major true-mangrove elements, as they are restricted to mangrove ecosystems, play a major structural role and are able to develop pure stands, possess special morphological adaptations to tidal environments and bear physiological mechanisms of salt exclusion (Tomlinson, 2016). Minor true-mangrove elements share the same features but occupy peripheral habitats, rarely form pure stands and are not major structural elements; they are the tree *Pelliciera rhizophorae* (Tetrameristaceae), the herb *Crenea patentinervis* (Lythraceae) and the ferns *Acrostichum aureum* and *A. danaefolium* (Pteridaceae). Other 25 species are known as mangrove associates, as they are characteristic of these communities but are not restricted to them and lack the adaptations that characterize true-mangrove elements (Tomlinson, 2016). Some important mangrove associates are *Conocarpus erectus* (Combretaceae), *Mora oleifera* and *Muelleria moniliformis* (Fabaceae), *Pavonia paludicola* and *P. rhizophorae* (Malvaceae), and *Tabebuia palustris* (Bignoniaceae) (Duke, 2017).

The Neotropical mangrove forests show a characteristic sea-inland zonal pattern with no herbaceous understory, characterized by the sequence *Rhizophora-Avicennia-Laguncularia* in the more saline zone dominated by normal tides, *Acrostichum* and *Conocarpus* in the brackish back-mangrove swamps and elevated areas under the influence of spring tides, and *Mauritia* and other palms in the more inland freshwater swamps, which mark the transition to the interior savannas and rainforests. Mangrove zonation is influenced by a diversity of biotic and abiotic factors, notably geomorphology, inundation frequency/intensity, salinity, propagule sorting and competition (Tomlinson, 2016). Biogeographically, Caribbean mangroves belong to the Atlantic-East Pacific (AEP) region (Figure 1), which is significantly less diverse (17 typical mangrove species belonging to 11 genera and 9 families) than the Indo-West Pacific region, with 54 species (24 genera and 17 families) characteristic of mangroves (Duke, 2017). Among mangrove-forming trees, the genera *Rhizophora* and *Avicennia* occur in both the AEP and IWP but are represented by different species, whereas *Laguncularia* and *Pelliciera* occur only in the AEP, with the second restricted to a relictual patch around the Central American Panama Isthmus (Duke, 2020).

Eocene Origin

According to the classical and more accepted view, the Neotropical mangroves would have originated by regional differentiation from a hypothetical Late Cretaceous (>65 Ma) pantropical mangrove belt along the coasts of the Tethys Sea after the formation of the African barrier by continental drift (Figure 1). This idea was based on qualitative evidence, usually the presence of pollen and other fossils from assumed mangrove elements, notably *Spinizonocolpites* (the fossil representative of the palm *Nypa*, characteristic of the IWP mangroves) and *Deltoidospora* (the fossil

representative of *Acrostichum*) (Srivastava & Prasad, 2018). However, a recent analysis of the quantitative palynological evidence has shown that Neotropical mangroves, as ecosystems, likely originated much later, between 50 and 40 Ma (Lutetian, Middle Eocene) (Rull, 2022a). Rather than the evolutionary descendants of a former hypothetical pantropical belt, the Caribbean mangroves signified an evolutionary innovation that emerged de novo, thanks to the evolutionary appearance of *Pelliciera*, the oldest known mangrove-forming tree, represented in the fossil record by the pollen morphospecies *Lanagiopollis crassa* (also *Psilatricolporites crassus*). This tree dominated the Eocene mangrove communities, with *Nypa* in the understory, *Acrostichum* in the back-mangrove belt and *Mauritia* (represented by the fossil pollen *Mauritiidites franciscoi*) in the inland freshwater swamps. The communities quickly dispersed across the region and were distributed across the Caribbean area by the Middle/Late Eocene. According to the updated Caribbean database, evidence for mangrove communities before the Middle Eocene is lacking, and the scattered individual appearances of fossil pollen from nonmangrove-forming elements, such as the palm *Nypa* or the fern *Acrostichum*, are insufficient to support the occurrence of mangrove forests (Rull, 2022a).

Oligocene Revolution

The newly assembled Caribbean database also allowed the identification of a major evolutionary shift that occurred in the Eocene/Oligocene transition, hereafter EOT (~34 Ma), characterized by the replacement of ancient *Pelliciera* mangroves by modern-like *Rhizophora* mangroves (Figure 1). *Rhizophora* (represented by the fossil pollen *Zonocostites ramonae*) was absent from the Neotropics during the Eocene (Graham, 1995) and reached the Caribbean region in the EOT, likely by trans-Atlantic dispersal from the IWP, where it originated (Takayama et al., 2021). Quantitative pollen records showed that the dominance shifted abruptly from *Pelliciera* to *Rhizophora* in the EOT, coinciding with global cooling and sea-level fall, along with an intense biotic turnover, although not as catastrophic as the Big Five mass extinctions, characterized by enhanced Eocene extinction and Oligocene radiation rates (Coxall & Pearson, 2007, Hutchinson et al., 2021). Noteworthy, *Nypa* disappeared from the EAP region during the EOT (Figure 1). This major community turnover did not signify the disappearance of *Pelliciera*, which remained a minor component of the new *Rhizophora* mangroves since the Oligocene and expanded its range to the whole Neotropics in the Miocene, always as a subordinate component represented by small and diffuse populations (Rull, 2023b). It has been suggested that the continuity and further expansion of *Pelliciera*, a stenothermic taxon with low dispersal power, was facilitated by the protection offered by *Rhizophora*, a more eurythermic and vagile element, whose canopy would have created a microhabitat for the first to endure the new less favorable environments created by the EOT global disruption, as occurs today (Dangremond et al., 2015). After the Miocene, *Pelliciera* underwent a significant reduction in its range to an area similar to the Middle Eocene equatorial distribution, which led to its present-day residual distribution (Rull, 2023b).

Neogene Diversification

The main diversification trend of Caribbean mangroves occurred in the Neogene (Mio-Pliocene), when the remaining true mangrove elements (*Crenea*, *Avicennia*, *Laguncularia*) and most of the associated taxa (>20 genera) emerged (Rull, 2023a), thus conforming the present-day richness patterns (Figure 1). This represented a diversity increase of almost 80% with respect to the Paleogene (Eocene–Oligocene), when only half of the present-day true-mangrove elements (*Rhizophora*, *Pelliciera*, *Acrostichum*) were present. No extinctions have been recorded since the Miocene in Caribbean mangroves at the genus level (Graham, 1995). The potential influence of climatic and sea-level fluctuations on the Neogene-Quaternary diversification trend (NQDT) remains unclear.

The Enigmatic Pleistocene

A significant gap exists in the Caribbean mangrove record for most of the Pleistocene (the last 2.6 Ma), the oldest records dating from ~130,000 years before present (yr BP), which corresponds to

the Eemian Interglacial or the Marine Isotopic Stage (MIS) 5e, occurred just before the Last Glaciation (Weichselian). This has been attributed to the lack of full Pleistocene records for the Caribbean region, and the need for developing extensive coring campaigns, especially in marine environments, has been emphasized (Rull, 2022b). In the Caribbean, the Eemian interstadial was characterized by sea-surface temperatures (SST) a few degrees above the present ones and sea levels at least 3 m (maximum estimates of 20 m) higher than today. During the Last Glacial Maximum (LGM), which occurred ~21,000 yr BP, SSTs were 2-4 °C lower than today, and sea levels were up to 120 m below their present position (Schmidt et al., 2006, Hearnthy et al., 2007). The extrapolation of these trends to former Pleistocene glacial-interglacial cycles suggests that full Pleistocene records should be sought in deep (>120 m) marine environments beyond the present continental shelf, where the Caribbean coasts were located during glacial maxima. Otherwise, glacial records would be lost due to coastal erosion. The available records suggest that all extant mangrove elements (true and associate) were already present at the beginning of the Pleistocene, and this period was characterized by spatial and community reorganization driven by climatic and eustatic fluctuations (Rull, 2022b), but more studies are needed to test this hypothesis.

Holocene Warming, Sea-Level Rise and Anthropization

A new external environmental driver, anthropogenic pressure, was added in the Holocene. Although Paleoindian settlements as old as ~13,000 yr BP (Lateglacial) are known for the southern Caribbean coasts (Bryan et al., 1978), the first significant disturbances on mangrove ecosystems did not occur until the Middle Holocene (~6000 yr BP), when Mesoamerican Maya societies cleared these forests using fire, mainly for maize and squash cultivation (Neff et al., 2006, López-Angarita et al., 2016). The Greater and Lesser Antilles (Figure 1) were colonized by humans between approximately 6000 and 2000 yr BP (Napolitano et al., 2019), and therefore, mangrove disturbance was posterior. Superimposed on the growing Holocene human influence were the maintained temperature and sea level increases and the nondirectional moisture variability (Figure 1), along with the corresponding feedbacks and synergies among these drivers (Rull, 2020b). Rising sea levels were a major influence on mangrove communities, which responded in different ways, according to the particular features of each locality. The balance between sediment input from the continent and sea-level rise seems to have been crucial for mangrove dynamics. When this balance was biased toward continental terrigenous input, coastal progradation overcame sea-level rising and favored seaward mangrove migration of mangrove communities. Conversely, when sea-level rise was dominant, landward migration was favored. Regional moisture declines and increases in drought frequency/intensity were especially important during the Late Holocene, causing significant mangrove reductions by salinity stress caused by increasing evaporation and reduced freshwater input from the continent (Rull, 2022b). Human disturbance has grown during the last millennia, as shown in paleoecological records documenting increased mangrove deforestation for wood extraction, fisheries, coconut plantations and rice crops (González et al., 2010, Urrego et al., 2019).

Historical Decline

In recent decades, the Caribbean mangrove extent has been drastically reduced by natural and anthropogenic deforestation. According to the most updated data, the total mangrove cover of this region dropped from ~21,000 km² in 1980 (FAO, 2007) to ~14,000 km² in 2010 (Bunting et al., 2022). This represents a one-third reduction in three decades, at an average rate of >2300 km² per decade. If these deforestation rates were maintained, the Caribbean mangroves would totally disappear within the next 90 years (Rull, 2022b). Warming and aridification driven by ongoing anthropogenic climate change, along with the associated acceleration of sea-level rise, can aggravate the situation and exacerbate mangrove loss in the Caribbean and the Neotropics, in general (Ellison & Farnsworth, 1996, Godoy & Lacerda, 2015). This has fostered the development of a number of conservation and restoration initiatives to palliate the decline of Neotropical mangrove forests (Lacerda et al., 2019).

Discussion

In conservation discussions, it is often said that what evolution has taken millions of years to develop might be lost in centuries. In the case of Caribbean mangroves, this assessment may be quantified, as these ecosystems originated ~50 million years ago and, if current loss rates are maintained, they may disappear in less than a century. Given the importance of mangroves for terrestrial and marine biodiversity and ecology, as well as for climate change mitigation, the conservation of Caribbean mangroves is a priority and may benefit from paleoecological and evolutionary studies such as those summarized in this paper. These studies have shown the influence of environmental drivers such as paleogeographical shifts, climate changes, sea-level fluctuations and anthropogenic pressure on the biodiversity, biogeography, ecology and evolution of Caribbean mangroves. The lessons learned from these studies may be useful to inform conservation and restoration actions, as they provide evidence-based past analogs that can be incorporated into predictive models aimed at forecasting the responses of these communities to future environmental changes. The availability of a newly assembled and updated database encompassing virtually all the paleoecological and evolutionary studies developed to date on Caribbean mangroves provides an advantage with respect to other mangrove-bearing tropical/subtropical areas that should not be neglected. It is hoped that contributions such as the present will help raise awareness of the importance of past records for conservation and restoration purposes.
